Ethanol produces hypoglycemia by inhibiting gluconeogenesis, and this inhibition is aggravated by malnutrition (low glycogen stores) in individuals with chronic alcoholism. Individuals with hepatic failure (e.g., viral hepatitis, ingestions of toxins) have impaired gluconeogenesis or glycogen storage, which may result in hypoglycemia. Decreased hepatic glucose production requires dysfunction of more than 80% of the liver. Deficiencies of (1) growth hormone (especially with coexistent ACTH deficiency), (2) glucocorticoids, (3) thyroid hormone, or (4) glucagon may also produce hypoglycemia. Although a deficiency of glucocorticoids (e.g., Addison disease) is most consistently associated with hypoglycemia, most glucocorticoid-deficient adults are not hypoglycemic. Hormonal deficiency causes hypoglycemia in children more frequently than in adults.

Demonstration of a low plasma glucose concentration in the presence of a high plasma insulin value is highly suggestive of an insulin-producing pancreatic islet cell tumor. Because healthy people exhibit a wide range of insulin concentrations, absolute hyperinsulinemia occurs in less than 50% of individuals with insulinomas. Serum insulin concentrations inappropriately high for concurrent plasma glucose values denote autonomous insulin secretion. Provocative tests (glucagon, tolbutamide, or calcium) or suppression tests (infusion

of insulin and measurement of C-peptide), although strongly recommended in the past, generally are not necessary.

Nonpancreatic neoplasms that cause hypoglycemia are rare, but, when present, they often are extremely large mesenchymal neoplasms. No single mechanism explains the hypoglycemia in all cases, but secretion of a precursor of insulin-like growth factor (IGF)-2 is the most commonly encountered finding. Glucose utilization is increased, especially in muscle, presumably reflecting activity of the hormone.

Hypoglycemia caused by septicemia should be relatively easy to diagnose. The mechanism is not well defined, but depleted glycogen stores, impaired gluconeogenesis, and increased peripheral use of glucose may all be contributing factors. Glucose tolerance is commonly depressed in individuals with renal disease, and hypoglycemia may occur in those with end-stage renal failure.

Some of the conditions that produce fasting hypoglycemia are readily apparent, but others require a lengthy diagnostic work-up. Once fasting hypoglycemia is demonstrated, specific tests should be performed to establish the underlying cause. The **oral glucose tolerance test (OGTT)** is not an appropriate study for evaluation of a patient suspected of having hypoglycemia.

Postprandial Hypoglycemia

Drugs, antibodies to insulin or the insulin receptor, inborn errors (e.g., fructose-1,6-diphosphatase deficiency), and reactive hypoglycemia (also referred to as *f*unctional hypoglycemia) produce hypoglycemia in the postprandial (fed) state. It has been proposed that for individuals with vague symptoms after food ingestion, the preferred terminology should be idiopathic reactive hypoglycemia or **idiopathic postprandial syndrome**.

At the Third International Symposium on Hypoglycemia, reactive hypoglycemia was defined as a "clinical disorder in which the patient has postprandial symptoms suggesting hypoglycemia that occur in everyday life and are accompanied by a blood glucose concentration less than 45 to 50 mg/dL (2.48-2.75 mmol/L) as determined by a specific glucose measurement on arterialized venous or capillary blood, respectively." Patients complain of autonomic symptoms that occur approximately 1 to 3 hours after eating and seem to obtain relief, lasting 30 to 45 minutes, by food intake. These symptoms are rarely due to low blood glucose concentrations. A 5- or 6-hour glucose tolerance test had been the standard procedure to establish the presence of postprandial hypoglycemia, but that has been discredited. Consequently, an OGTT should not be used in the diagnosis of reactive hypoglycemia.

Postprandial hypoglycemia is infrequent, and demonstration of hypoglycemia during spontaneously occurring symptomatic episodes is necessary to establish the diagnosis. If this is not possible, a 5-hour meal tolerance test (which simulates the composition of a normal diet) or a "hyperglucidic" (high glucose) breakfast test has been proposed.

The diagnosis of hypoglycemia has also been used to explain a wide variety of disorders that appear unrelated to blood glucose abnormalities. These nonspecific symptoms include (1) fatigue, (2) muscle spasms, (3) palpitations, (4) numbness, (5) tingling, (6) pain, (7) sweating, (8) mental dullness, (9) sleepiness, (10) weakness, and (11) fainting. Behavioral abnormalities, poor school performance, and delinquency have been incorrectly attributed to low blood glucose concentrations. A diagnosis of hypoglycemia should not be made unless a patient meets the criteria of **Whipple's triad** of low blood glucose concentration. They are (1) symptoms known or likely to be caused by hypoglycemia, (2) low glucose measured when symptoms occur, and (3) relief of symptoms when glucose is increased to normal. Demonstration of normal plasma glucose concentration when the patient exhibits symptoms excludes the possibility of a hypoglycemic disorder.

Hypoglycemia in Diabetes Mellitus[9]

Hypoglycemia occurs frequently in individuals with type 1 or type 2 diabetes.[1] Patients using insulin experience approximately one to two episodes of symptomatic hypoglycemia per week, and severe hypoglycemia that requires assistance from others or is associated with loss of consciousness affects about 10% of this population per year. In patients practicing intensive insulin therapy (e.g., multiple injections, continuous subcutaneous insulin infusion), these figures are increased twofold to sixfold. The chief adverse event associated with intensive therapy in the **Diabetes Control and Complications Trial (DCCT)** was a threefold increase in the incidence of severe hypoglycemia.[5] Similarly, hypoglycemia occurs in patients with type 2 diabetes (caused by oral hypoglycemic agents or insulin) but is less frequent than in type 1 diabetes.[10] Pathophysiological mechanisms that contribute to hypoglycemia in patients with diabetes are (1) defective glucose counterregulation (ability to increase glucose, counter to the effect of insulin) and (2) unawareness of hypoglycemia.

Defective Glucose Counterregulation

Counterregulatory responses become impaired in patients with type 1 diabetes, increasing the risk of hypoglycemia. The secretion of glucagon in response to hypoglycemia is impaired by an unknown mechanism early in the course of type 1 diabetes. The secretory response of epinephrine to hypoglycemia becomes deficient later in the course of the disease. These defects are selective because other stimuli continue to elicit glucagon and epinephrine secretion. Glucose counterregulation does not appear to be notably defective in patients with type 2 diabetes.

Unawareness of Hypoglycemia

Up to 50% of patients with long-standing (longer than 30 years) type 1 diabetes do not experience neurogenic warning symptoms and are prone to more severe hypoglycemia. The mechanism is thought to be associated with a decreased epinephrine response to hypoglycemia. Intensively treated patients with type 1 diabetes require lower plasma glucose concentrations to elicit symptoms of hypoglycemia. Some authors have claimed that therapeutic use of human insulin rather than other insulins results in an increased incidence of unawareness of hypoglycemia, but analysis of 45 studies revealed no significant differences in hypoglycemic episodes among insulin species.

Lactate and Pyruvate

Lactic acid, an intermediary in carbohydrate metabolism, is predominantly derived from (1) white skeletal muscle, (2) brain, (3) skin, (4) renal medulla, and (5) erythrocytes. The blood lactate concentration depends on the rate of production in these tissues and the rate of metabolism in the liver and kidneys. The liver uses approximately 65% (75 g/d) of the total basal lactate produced, predominantly in gluconeogenesis. The **Cori cycle** is the conversion of glucose to **lactate** in the periphery and reconversion of lactate to glucose in the liver. Extrahepatic removal of lactate occurs by oxidation in red skeletal muscle and the renal cortex. A moderate increase in lactate production results in increased hepatic lactate clearance, but uptake by the liver is saturable when concentrations exceed 2 mmol/L. During strenuous exercise, for example, lactate concentrations may increase significantly, from an average concentration of about 0.9 to more than 20 mmol/L within 10 seconds. No concentration of lactate is uniformly accepted for the diagnosis of lactic acidosis, but lactate concentrations exceeding 5 mmol/L with pH less than 7.25 indicate significant lactic acidosis.

Lactic Acidosis[7]

Lactic acidosis occurs in two clinical settings: (1) type A (hypoxic), associated with decreased tissue oxygenation, such as shock, hypovolemia, and left ventricular failure; and (2) type B (metabolic), associated with (1) diseases such as (e.g., diabetes mellitus, neoplasia, liver disease), (2) drugs/toxins (e.g., ethanol, methanol, salicylates), or (3) inborn errors of metabolism. Lactic acidosis is not uncommon and occurs in approximately 1% of those admitted to the hospital. It has a mortality rate greater than 60%, which approaches 100% if hypotension also is present. Type A is much more common.

An uncommon but often undiagnosed cause of lactic acidosis is d-lactic acidosis. Absorption and accumulation of d-lactate from abnormal intestinal bacteria may cause systemic acidosis. This condition occurs after jejunoileal bypass surgery and manifests as altered mental status (from mild drowsiness to coma) with increased blood concentrations of d-lactate. Virtually all the commonly used laboratory assays for lactate use l-lactate dehydrogenase, which does not detect d-lactate. d-Lactate is also measured by gas-liquid chromatography or, enzymatically, with a specific d-lactate dehydrogenase.

Lactate in cerebrospinal fluid normally parallels blood concentrations. With biochemical alterations in the CNS, however, CSF lactate values change independently of blood values. Increased CSF concentrations are noted in individuals with (1) cerebrovascular accidents, (2) intracranial hemorrhage, (3) bacterial meningitis, (4) epilepsy, and (5) other CNS disorders.

Inborn Errors of Carbohydrate Metabolism

Deficiency or absence of an enzyme that participates in carbohydrate metabolism may result in accumulation of monosaccharides, which are measured in the urine. Techniques used to separate and identify these sugars include (1) fermentation, (2) optical rotation, (3) osazone formation with phenylhydrazine, (4) specific chemical tests, and (5) paper or thin-layer chromatography. The availability of glucose oxidase test strips, specific for glucose, has greatly simplified the differentiation of glucose from other reducing substances. For practical purposes, the only urinary sugars of clinical interest are glucose and galactose. Urine from infants and children should be tested by both the glucose oxidase and copper reduction tests to identify individuals with inborn errors of metabolism.

Glycogen Storage Disease

Glycogen, although present in most tissues, is stored predominantly in the liver and skeletal muscle. During fasting, liver glycogen is converted to glucose to provide energy for the whole body. In contrast, skeletal muscle lacks glucose-6-phosphatase, and muscle glycogen is used locally for energy. **Glycogen storage disease** is a generic name encompassing at least 10 rare inherited disorders of glycogen storage in tissues.[3] The different forms of glycogen storage disease are categorized by numerical type in the chronological sequence in which these defects were identified. Each form is due to a deficiency of a specific enzyme in glycogen metabolism, producing a quantitative or a qualitative defect of glycogen storage.

Because both the liver and skeletal muscle have the highest rates of glycogen metabolism, these structures are most affected. The liver forms (types I, III, IV, and VI) are marked by hepatomegaly (due to increased liver glycogen stores) and hypoglycemia (caused by inability to convert glycogen to glucose). Hypoglycemia is manifested by (1) autonomic clinical symptoms (sweating, shakiness, and a light-headed feeling), (2) growth retardation, and (3) laboratory findings of decreased insulin and increased glucagon concentrations in the blood. The muscle forms (types II, IIIa, V, and VII), in contrast, have mild symptoms that usually appear in young adulthood during strenuous exercise owing to the inability to provide energy for muscle contraction. Other muscle disorders may exhibit similar symptoms but are readily differentiated through evaluation of glycogen stores. The specific diagnosis of each type is made directly by demonstrating the enzyme defect in tissue.

Analytical Methodology

Analytical methods for measuring (1) glucose, (2) ketone bodies, (3) lactate, (4) pyruvate, (5) insulin, and (6) proinsulin are discussed in this section.

Measurement of Glucose in Body Fluids

Several methods are used to measure glucose in (1) blood, (2) serum, (3) plasma, and (4) urine. Current surveys conducted by the College of American Pathologists (CAP) demonstrate that all methods exhibit a coefficient of variation (CV) among laboratories that is less than or equal to 2.6% for glucose values on lyophilized serum.

Specimen Collection and Storage

In individuals with a normal hematocrit, fasting whole-blood glucose concentration is approximately 10% to 12% lower than plasma glucose. Although the glucose concentrations in the water phase of red blood cells and plasma are similar

(the erythrocyte plasma membrane is freely permeable to glucose), the water content of plasma (93%) is approximately 11% greater than that of whole blood at a normal hematocrit. In most clinical laboratories, plasma or serum is used for most glucose determinations. However, methods for self-monitoring of glucose typically use whole-blood samples but may measure the glucose concentration in the plasma phase. During fasting, capillary blood glucose concentration is only 2 to 5 mg/dL higher than that of venous blood. After a glucose load, however, capillary blood glucose concentrations are 20 to 70 mg/dL (1.11 -3.89 mmol/L) (mean, ≈30 mg/dL/1.67 mmol/L; equivalent to 20% to 25%) higher than the concentrations in concurrently drawn venous blood samples.

Glycolysis decreases serum glucose by approximately 5% to 7% in 1 hour (5 to 10 mg/dL) in normal uncentrifuged coagulated blood at room temperature. The rate of in vitro glycolysis is higher in the presence of leukocytosis or bacterial contamination. In separated, nonhemolyzed sterile serum, the glucose concentration is generally stable as long as 8 hours at 25 °C and up to 72 hours at 4 °C; variable stability is observed with longer storage periods. Plasma, removed from the cells after moderate centrifugation, contains leukocytes that also metabolize glucose—although cell-free sterile plasma has no glycolytic activity.

Sodium fluoride or, less commonly, sodium iodoacetate, is used to inhibit glycolysis.[2] Fluoride ions prevent glycolysis by inhibiting enolase, an enzyme that requires Mg^{2+}. Inhibition is due to the formation of an ionic complex consisting of Mg^{2+}, inorganic phosphate, and fluoride ions; this complex interferes with the interaction of enzyme and substrate. Fluoride is also a weak anticoagulant because it binds calcium; however, clotting may occur after several hours, and it is therefore advisable to use a combined fluoride-oxalate mixture, such as 2 mg of potassium oxalate ($K_2C_2O_4$) and 2 mg of NaF/mL of blood, to prevent late clotting. Other anticoagulants such as (1) ethylenediaminetetraacetic acid, (2) citrate, or (3) heparin have also been used. Fluoride ions in high concentration inhibit the activity of urease and certain other enzymes; consequently the specimens may be unsuitable for determination of urea in procedures that require urease and for direct assay of some serum enzymes. $K_2C_2O_4$ causes loss of cell water, thereby diluting the plasma. Samples collected in these tubes therefore should not be used for measurement of other analytes.

Although fluoride has been widely used to inhibit glycolysis, the rate of decline in the first 1 to 2 hours after sample collection is not altered, and glycolysis may continue at a slower rate for up to 4 hours. Acidification of blood using citrate buffer inhibits in vitro glycolysis more effectively than fluoride.

To minimize glycolysis, the cells should be removed within minutes. Alternatively, the tube should be placed in an ice-water slurry and the cells separated within 30 minutes. Neither of these approaches is practical in routine analysis. It may not be necessary in routine analysis to use a fluoride-containing tube if plasma is separated from cells or if glucose is measured within 30 minutes of blood collection. However, inhibitors of glycolysis are necessary in patients with greatly increased leukocyte counts because differences of up to 65 mg/dL (3.60 mmol/L) have been observed between glucose values with and without glycolytic inhibitors after 1 to 2 hours of contact with the blood cells.

CSF may be contaminated with bacteria or other cells and should be analyzed immediately for glucose. If a delay in measurement is unavoidable, the sample should be centrifuged and stored at 4 °C or −20 °C.

In 24-hour collections of urine, glucose may be preserved by adding 5 mL of glacial acetic acid to the container before starting the collection. The final pH of the urine is usually between 4 and 5, which inhibits bacterial activity. Other preservatives that have been proposed include 5 g of sodium benzoate per 24-hour specimen, or chlorhexidine and 0.1% sodium nitrate with 0.01% benzethonium chloride. These may be inadequate, and urine should be stored at 4 °C during collection. Urine samples may lose as much as 40% of their glucose after 24 hours at room temperature.

Measurement of Glucose in Blood

Hexokinase or glucose oxidase is widely used in assays to measure the concentration of glucose in body fluids.

Hexokinase Methods

Hexokinase (HK) methods are based on a coupled enzyme assay that uses HK and glucose-6-phosphate dehydrogenase (G-6-PD):

$$\text{Glucose} + \text{ATP} \xrightarrow{\text{Hexokinase}} \text{Glucose-6-phosphate} + \text{ADP}$$

$$\text{Glucose-6-phosphate} \xrightarrow{\text{G-6-PD}} \text{6-Phosphogluconate}$$

$$\text{NADP}^{\oplus} \quad (\text{or NAD}^{\oplus}) \qquad \text{NADPH} + \text{H}^{\oplus} \quad (\text{or NADH})$$

As indicated, glucose is first phosphorylated by ATP in the presence of HK and Mg^{2+}. The glucose-6-phosphate formed is oxidized by G6PD to 6-phosphogluconate in the presence of $NADP^+$ or NAD^+. The amount of reduced NADP (NADPH) or NADH produced is directly proportional to the amount of glucose in the sample and is measured by the increase in absorbance at 340 nm. $NADP^+$ is the cofactor when G6PD derived from yeast is used in the assay; NAD^+ is the cofactor when bacterial (Leuconostoc mesenteroides) G6PD is used. A reference method based on this principle has been developed and validated. In the reference method, serum or plasma is deproteinated by the addition of solutions of barium hydroxide and zinc sulfate. The clear supernatant is mixed with a reagent containing ATP, NAD^+, hexokinase, and G6PD, incubated at 25 °C until the reaction is complete and NADH is measured. Calibrators and blanks are carried through the entire procedure, including the deproteination step.

Although highly accurate and precise, the reference method is too exacting and time-consuming for routine use in a clinical laboratory. An alternative approach is to apply the reaction directly to serum or plasma and use a

specimen blank to correct for interfering substances that absorb at 340 nm.

Serum or plasma may be used. NaF, with an anticoagulant such as (1) EDTA, (2) heparin, (3) oxalate, or (4) citrate, may be used. Hemolyzed specimens containing more than 0.5 g of hemoglobin/dL are unsatisfactory because phosphate esters and enzymes released from red blood cells interfere with the assay. Other sources of interference include drugs, bilirubin, and lipemia (triglycerides of 500 mg/dL or greater causing a positive interference).

Absorbances of sample or calibrator reaction mixtures are measured after the reactions have continued to completion (equilibrium reaction, "end-point" method) or at a fixed time after initiation of the reaction (fixed-time kinetics). In the equilibrium methods for glucose concentrations may be calculated directly, based on the molar absorptivity of NADPH or NADH, but inclusion of a set of calibrators is recommended to detect possible deterioration of enzymes, ATP, $NADP^+$, or NAD^+—all of which are unstable. Reagents may also contain substances that react with the coenzymes. The presence of these substances is evaluated by measurement of the increase in absorbance observed in a reagent blank. The highest calibrator provides a check on the linearity of the response and the adequacy of the enzyme reagent. The procedures typically show a linear relation between absorbance and glucose concentrations of 0 to 500 mg/dL (27.75 mmol/L). Serum or plasma samples with glucose concentrations that exceed 500 mg/dL (27.75 mmol/L) should be diluted (usually with isotonic saline) and re-assayed.

Also available are hexokinase procedures in which indicator reactions produce colored products, enabling absorbance measurements in the visible range. An oxidation reduction system containing phenazine methosulfate and a substituted tetrazolium compound, 2-(p-iodophenyl)-3-p-nitrophenyl-5-phenyltetrazolium chloride (INT), is reacted with NADPH formed in the reaction. The reduced INT is colored, with maximal absorbance at 520 nm.

Glucose Oxidase Methods

Glucose oxidase catalyzes the oxidation of glucose to gluconic acid and hydrogen peroxide:

$$\text{Glucose} + H_2O + O_2 \xrightarrow{\textit{Glucose Oxidase}} \text{Gluconic acid} + 2\,H_2O_2$$

Addition of the enzyme peroxidase and a chromogenic oxygen acceptor, such as o-dianisidine, results in the formation of a colored compound that is measured:

$$\textit{o}\text{-Dianisidine} + H_2O_2 \xrightarrow{\textit{Peroxidase}} \text{Oxidized } \textit{o}\text{-Dianisidine} + H_2O \ \text{(Colored)}$$

Glucose oxidase is highly specific for β-d-glucose. Because 36% and 64% of glucose in solution are in the α- and β-forms, respectively, complete reaction requires mutarotation of the α-form to the β-form. Some commercial preparations of glucose oxidase contain an enzyme, mutarotase, that accelerates this reaction. Otherwise, extended incubation time allows spontaneous conversion.

The second step, involving peroxidase, is much less specific than the glucose oxidase reaction. Various substances, such as (1) uric acid, (2) ascorbic acid, (3) bilirubin, (4) hemoglobin, (5) tetracycline, and (6) glutathione, inhibit the reaction (presumably by competing with the chromogen for H_2O_2), producing lower values. Some glucose oxidase preparations contain catalase as a contaminant that decomposes peroxide and decreases the intensity of the final color obtained. Calibrators and unknowns should be simultaneously analyzed under conditions in which the rate of oxidation is proportional to the glucose concentration.

Glucose oxidase methods are suitable for measurement of glucose in CSF. Urine, however, contains high concentrations of substances (such as uric acid) that interfere with the peroxidase reaction, producing falsely low results. The glucose oxidase method therefore should not be used for urine. A method in which the urine is first pretreated with an ion exchange resin to remove interfering substances has been described.[8]

Some instruments use a polarographic oxygen electrode that measures the rate of oxygen consumption after the sample is added to a solution containing glucose oxidase. Because this measurement involves only the glucose oxidase reaction, interferences encountered in the peroxidase step are eliminated. To prevent formation of oxygen from H_2O_2 by catalase present in some preparations of glucose oxidase, H_2O_2 is removed by two additional reactions:

$$H_2O_2 + C_2H_5OH \xrightarrow{\textit{Catalase}} CH_3CHO + 2\,H_2O$$

$$H_2O_2 + 2H^+ + 2I^- \xrightarrow{\textit{Molybdate}} I_2 + 2\,H_2O$$

The latter reaction is effective even when catalase activity has diminished on storage of reagents. The procedure has been applied directly to (1) urine, (2) serum, (3) plasma, or (4) CSF. However, this approach should not be used for determination of glucose in whole blood because blood cells consume oxygen.

In dry, multilayer, slide automated systems, glucose is measured by a glucose oxidase procedure. A 10-μL sample of (1) serum, (2) plasma, (3) urine, or (4) CSF is placed on a porous film on top of the layer containing the reagents. Glucose diffuses through the film and reacts with the reagents to produce a colored end product or dye. The intensity of this dye is measured through a lower transparent film by reflectance spectrophotometry. Advantages include (1) small sample size, (2) no liquid reagents, and (3) improved stability on storage.

Glucose Dehydrogenase Method

The enzyme glucose dehydrogenase (β-d-glucose: NAD oxidoreductase, EC 1.1.1.47) catalyzes the oxidation of glucose to gluconolactone with concomitant reduction of NAD^+ to NADH. Mutarotase is added to shorten the time necessary to reach equilibrium. The amount of NADH generated is proportional to the glucose concentration. The reaction appears to be (1) highly specific for glucose, (2) shows no interference from common anticoagulants and substances normally found in serum, and (3) provides results in close agreement

with hexokinase procedures. The glucose dehydrogenase procedure is not widely used in the United States, except in a glucose meter.

Measurement of Glucose in Urine

A method for the examination of urine for glucose is rapid, inexpensive, and noninvasive and has been used to screen large numbers of samples.[8] Monitoring of urine glucose lacks sensitivity and specificity and provides no information about blood glucose concentrations below the renal threshold (usually 180 mg/dL/9.99 mmol/L). Older screening tests detect all sugars that reduce copper and produce a chromagen. Unfortunately, these tests also react with reducing substances other than glucose. Qualitative, quantitative, and semi-quantitative methods are widely available for measuring glucose in urine and have essentially replaced the nonspecific tests in adults. Note that a reducing sugar method other than an enzymatic method for glucose must be used when neonates or infants are screened for inborn errors of metabolism that result in the appearance of reducing sugars other than glucose (e.g., galactose, fructose) in the urine.

Qualitative Method for Measurement of Total Reducing Substances

Benedict qualitative reagent contains cupric ion complexed to citrate in alkaline solution. Reducing substances convert cupric to cuprous ions, forming yellow cuprous hydroxide or red cuprous oxide. A convenient adaptation of the procedure is marketed in tablet form (Bayer Corporation CLINITEST Reagent Tablets).

Semi-quantitative Measurement of Glucose in Urine

Paper test strips are commercially available from several manufacturers. All use the glucose-specific enzyme glucose oxidase in a chromogenic assay. Dyes used include o-tolidine and. Tetramethylbenzidine (TMB) with the intensity of the color developed proportional to the concentration of glucose in the urine sample. A typical cutoff is a glucose concentration of 100 mg/dL (5.55 mmol/L) with an upper limit of detection of 250 mg/dL/13.8 mmol/L).

When using these strips, false positive results may be produced by contamination of urine with H_2O_2 or a strong oxidizing agent, such as hypochlorite (bleach). False negative results may occur with large quantities of reducing substances, such as (1) ketones, (2) ascorbic acid, and (3) salicylates. For routine examinations, a negative result by the strip test is usually interpreted to mean that the urine specimen is negative for glucose.

Other strip tests have been designed for the semi-quantitative estimation of both glucose and ketone bodies.

Quantitative Methods for Determination of Glucose in Urine

Applications of various procedures for quantitative determination of glucose in urine were previously discussed in the section on the determination of glucose in body fuids. Hexokinase or glucose dehydrogenase procedures are recommended for greatest accuracy and specificity. Glucose oxidase procedures that depend only on the consumption of oxygen or the production of H_2O_2 are also reliable. Glucose oxidase procedures that include the H_2O_2-peroxidase reaction are not used for urine.

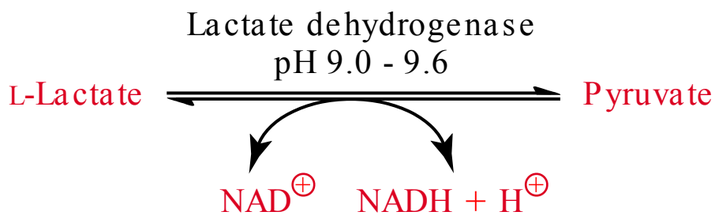
Reference Intervals

Although glucose is assayed by several different analytical procedures, reference intervals do not vary significantly among methods. The following values are representative of glucose assays:

Sample Reference Intervals for Fasting Glucose

Plasma/Serum	
Adults	74 to 100 mg/dL (4.1 to 5.5 mmol/L)
Children	60 to 100 mg/dL (3.5 to 5.5 mmol/L)
Premature neonates	20 to 60 mg/dL (1.1 to 3.3 mmol/L)
Term neonates	30 to 60 mg/dL (1.7 to 3.3 mmol/L)
Whole blood	65 to 95 mg/dL (3.6 to 5.3 mmol/L)
CSF	40 to 70 mg/dL (60% of plasma value) (2.2 to 3.9 mmol/L)
Urine	
24 hour	1 to 15 mg/dL (0.1 to 0.8 mmol/L)

No sex difference exists. Plasma glucose concentrations increase with age—fasting glucose concentrations increase approximately 2 mg/dL (0.11 mmol/L) per decade; postprandial concentrations increase by 4 mg/dL (0.22 mmol/L) per decade; and concentrations after a glucose challenge increase by 8 to 13 mg/dL (0.44- 0.72) per decade.



CSF glucose concentrations should be approximately 60% of the plasma concentrations and must always be compared with concurrently measured plasma glucose for adequate clinical interpretation.

Lactate and Pyruvate

Measurement of pyruvate is useful in the evaluation of patients with inborn errors of metabolism who have increased serum lactate concentrations. A lactate-to-pyruvate ratio of less than 25 suggests a defect in gluconeogenesis, whereas an increased ratio (<35) indicates reduced intracellular conditions found in hypoxia. Inborn errors associated with an increased lactate-to-pyruvate ratio include pyruvate carboxylase deficiency and defects in oxidative phosphorylation. Pyruvate is also measured in clinical studies evaluating reperfusion after myocardial ischemia.

Determination of Lactate in Whole Blood

Lactate is oxidized to pyruvate by lactate dehydrogenase in the presence of NAD^+. The NADH formed in this reaction is measured spectrophotometrically at 340 nm and serves as a measure of the lactate concentration:

The equilibrium of the reaction typically lies far to the left. However, by buffering the pH between 9.0 and 9.6, adding an excess of NAD^+, and trapping the reaction product pyruvate with hydrazine, the equilibrium is shifted to the right. Pyruvate can also be removed through reaction with l-glutamate in the presence of alanine aminotransferase.

Because of its high specificity and simplicity, the enzymatic method is the method of choice for the measurement of lactate, although other methods such as gas chromatography have been used.

Specimen Collection and Storage

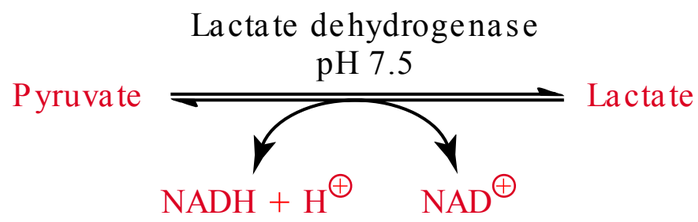
Careful techniques are necessary to prevent changes in lactate concentration while blood is drawn and afterward. Patients should be fasting and at complete rest for at least 2 hours to allow lactate concentrations to reach steady state.

Venous specimens should be obtained without the use of a tourniquet or immediately after the tourniquet has been applied. Alternatively, the tourniquet should be removed after the puncture has been performed, and the blood should be allowed to flow for several minutes before the sample is withdrawn. Arterial blood sampling, which prevents these potential pitfalls, may also be used. Patients should avoid exercise of the hand or arm immediately before and during the procedure.

Both venous and arterial blood may be collected in heparinized syringes and immediately delivered into a premeasured amount of chilled protein precipitant, such as (1) trichloroacetic, (2) metaphosphoric, or (3) perchloric acid. The clear supernatant, after centrifugation, is stable at 4 °C for as long as 8 days. Meticulous attention to sample preparation is required. If blood is not preserved as directed, lactate rapidly increases in blood as a result of glycolysis. Increases may be as great as 20% within 3 minutes and 70% within 30 minutes at 25 °C. Specimens collected as described in this section are also suitable for determination of pyruvate.

If plasma is required as specimen, blood should be collected in a tube containing 10 mg of NaF and 2 mg of $K_2C_2O_4$ per milliliter of blood. Ideally, the specimen should be immediately cooled and the cells separated within 15 minutes, but reasonable stability of volunteers' lactate is seen at room temperature for 30 minutes in whole blood with NaF. Once the plasma is separated from the cells, lactate is stable.

Reference Intervals



The reference intervals for lactate are:

	Lactate	
Specimen	mmol/L	mg/dL
Venous Blood		
At rest	0.5 to 1.3	5 to 12
In hospital	0.9 to 1.7	8 to 15
Arterial Blood		
At rest	0.36 to 0.75	3 to 7
In hospital	0.36 to 1.25	3 to 11

Individuals in the hospital exhibit a wider range of values. Lactic acidosis occurs with blood lactate concentrations exceeding 5 mmol/L (45 mg/dL). Severe exercise dramatically increases lactate concentrations, and even movement of leg muscles by individuals at bed rest may result in significant increases. Plasma values are about 7% higher than those in whole blood, although differences depend on the procedure used. CSF values are usually similar to blood concentrations but may change independently in CNS disorders. Normal 24-hour urine output of lactate is 5.5 to 22 mmol/d.

Determination of Pyruvate in Whole Blood

The reaction involved in the determination of pyruvate is essentially the reverse of the reaction used in the lactate procedure:

At about pH 7.5, the equilibrium constant strongly favors the reaction to the right. The method is very specific, and (1) 2-oxoglutarate, (2) oxaloacetate, (3) acetoacetate, and (4) β-hydroxybutyrate do not interfere as with photometric methods. Pyruvate is extremely unstable in blood, more so than lactate; immediate use of a chilled protein precipitant is recommended.

Fasting venous blood, drawn when the individual is at rest, has a pyruvate concentration of 0.03 to 0.10 mmol/L (0.3-0.9 mg/dL). Arterial blood contains 0.02 to 0.08 mmol/L (0.2-0.7 mg/dL). Values for CSF are 0.06 to 0.19 mmol/L (0.5-1.7 mg/dL). Urine output of pyruvate is 1 mmol/d or less. Few clinical indications warrant the measurement of blood or urine pyruvate concentrations.

Glucagon

Extremely high concentrations of glucagon are present in individuals with a **glucagonoma**, which are tumors of the α-cells of the pancreas. Individuals with this type of tumor frequently experience (1) weight loss, (2) necrolytic migratory erythema, (3) diabetes mellitus, (4) stomatitis, and (5) diarrhea. Most tumors have metastasized at the time of diagnosis. Low glucagon concentrations are associated with chronic pancreatitis and long-term sulfonylurea therapy.

A standard preparation, WHO Glucagon International Standard (69/194), is available to manufacturers of reagent sets (kits) for use in assigning values to calibrators.

Fasting plasma concentrations of glucagon vary from 20 to 52 pmol/L (70 to 180 ng/L). Values up to 500 times the upper reference limit may be found in individuals with autonomously secreting α-cell neoplasms.

Review Questions

1. The formation of glucose from noncarbohydrate sources occurs mostly in the liver and is referred to as:
   a. gluconeogenesis.
   b. glycogenesis.
   c. glycolysis.
   d. glycogenolysis.
2. Which of the following hormones decreases blood glucose?
   a. Epinephrine
   b. Glucagon
   c. Cortisol
   d. Insulin
3. Which anticoagulant is considered the best for serum glucose analysis because it inhibits glycolysis?
   a. Sodium oxalate
   b. EDTA
   c. Sodium fluoride
   d. Heparin
4. An example of a disaccharide is:
   a. glucose.
   b. starch.
   c. lactose.
   d. fructose.
5. The conversion of glucose into its storage form is referred to as:
   a. glycogenesis.
   b. glycolysis.
   c. glycogenolysis.
   d. glyconeogenesis.
6. Which of the following statements concerning carbohydrates is incorrect?
   a. Individuals diagnosed with type 1 diabetes mellitus can display hypoglycemic symptoms because of the impairment of glucagon secretion.
   b. Ethanol produces hypoglycemia by inhibiting gluconeogenesis.
   c. Monosaccharides are formed from the breakdown of starches and disaccharides within the small intestine.
   d. The brain functions normally with a low concentration of plasma glucose (<20 to 30 mg/dL).
7. The formation of 6-phosphogluconate with concomitant production of NADH is the final step in which of the following coupled-enzyme assays for glucose?
   a. Hexokinase method
   b. Glucose oxidase method
   c. Glucose dehydrogenase method
   d. Polarographic method
8. The typical cause of an inborn error of carbohydrate metabolism is:
   a. lack of insulin production.
   b. glucagonoma.
   c. absence of an enzyme involved in carbohydrate metabolism.
   d. chronic alcoholism with hepatic failure.
9. The most widely used cutoff blood glucose concentration that indicates hypoglycemia is:
   a. 100 mg/dL.
   b. 75 mg/dL.
   c. 50 mg/dL.
   d. 25 mg/dL.
10. Deficiency of a specific enzyme involved in glycogen metabolism will produce some type of:
    a. glycogen storage disease.
    b. lactic acidosis.
    c. insulin deficiency.
    d. glycolysis.

CHAPTER

23

Lipids, Lipoproteins, Apolipoproteins, and Other Cardiac Risk Factors*

Alan T. Remaley, M.D., Ph.D., Nader Rifai, Ph.D., and G. Russell Warnick, M.S., M.B.A.

Objectives

1. Define the following terms:

Apolipoprotein	Lipid	Type V hyperlipoproteinemia	Familial defective apolipoprotein B-100
Atherosclerosis	Lipoprotein	Dysbetalipoproteinemia	Hypoalphalipoproteinemia
Cholesterol	Lipoprotein lipase		disorders
Cholesterol ester	Phospholipid	Familial hypercholesterolemia	
Emulsification	Prostaglandin		
Fatty acid	Sphingolipid		
Glycerol	Triglyceride		
Ketone bodies			

2. List and describe the six classes of lipids based on chemical structure and function.
3. Discuss the metabolism of cholesterol, fatty acids, and triglycerides, including biochemical structure, synthesis, esterification, absorption, and catabolism.
4. Compare and contrast the six lipoprotein classes on the basis of their characteristics, functions, and clinical significance; list the apolipoproteins that are carried by these lipoproteins and their functions.
5. Describe the exogenous, endogenous, intracellular-cholesterol transport, and reverse-cholesterol transport pathways of lipoprotein metabolism, including the following:

Function	Enzymes involved
Lipoproteins and apolipoproteins involved	Cells/cellular components and organs involved

6. State the effects that the following disorders have on lipid metabolism, lipoproteins, apolipoproteins, and laboratory lipid values, and state the genetic defect, if any:

Uncontrolled diabetes mellitus	Familial combined hyperlipidemia
Lipoprotein lipase deficiency	Familial hypertriglyceridemia

7. List five major risk factors for coronary heart disease; describe how lipoprotein disorders are managed in adults and children, including therapeutic lifestyle changes and use of pharmacological agents.
8. List five specific causes of secondary hyperlipidemia/dyslipoproteinemia, including examples of exogenous, endocrine, storage, and renal disorders.
9. Diagram the typical enzymatic procedures used in the laboratory to measure cholesterol and triglyceride; state specimen requirements and describe current assays used to assess the following analytes:

HDL	Apolipoprotein A-I and B-100
LDL	Lipoprotein(a)

10. State the uses for and the calculation of the Friedewald formula; calculate LDL cholesterol using this formula when given appropriate information.
11. Describe high-sensitivity CRP and state its usefulness in predicting coronary heart disease events; state the laboratory technique used to detect hsCRP.
12. Analyze and solve case studies related to disorders of lipids and lipoproteins.

*The authors gratefully acknowledge the contributions by Drs. John Albers and Paul Bachorik, on which portions of this chapter are based. Additional portions have been adapted from Rifai N, Kwiterovich PO Jr. Disorders of lipid and lipoprotein metabolism in children and adolescents. In: Soldin SJ, Rifai N, Hick JMB, eds. Biochemical basis of pediatric diseases, 3rd edition. Washington, DC: AACC Press, 1998.

Key Words and Definitions

Acylglycerol (glycerol ester) A three-carbon alcohol that contains a hydroxyl group on each of its carbons and is classified by the number of fatty acyl groups present; triglycerides are the predominant form of glycerol ester in plasma.

Apolipoproteins The major protein components of lipoproteins.

Atherosclerosis A pathogenic process that is the underlying cause of the common cardiovascular disorders of (1) myocardial infarction, (2) cerebrovascular disease, and (3) peripheral vascular disease.

Cholesterol A steroid alcohol with 27 carbon atoms that are arranged in a tetracyclical sterane ring system, with a C-H side chain and a polar hydroxyl group on its A-ring, making it an amphipathic molecule.

Coronary heart disease A narrowing of the small blood vessels that supply blood and oxygen to the heart.

Fatty acid Any straight-chain monocarboxylic acid with an alkyl chain generally classed as saturated fatty acids with no double bonds; monounsaturated fatty acids with one double bond; and polyunsaturated fatty acids—those with multiple double bonds.

Lipids A class of compounds that are soluble in organic solvents but are nearly insoluble in water and that contain nonpolar carbon-hydrogen bonds.

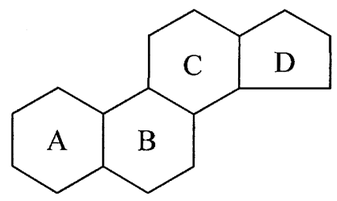
Lipoproteins Spherical particles involved in the transport of lipids with nonpolar neutral lipids (triglycerides and cholesterol esters) in their core and more polar amphipathic lipids (phospholipids and free cholesterol) at their surface.

Lipoprotein(a) A lipoprotein structurally similar to low-density lipoprotein but containing a carbohydrate-rich protein and that carries only a relatively small fraction of total cholesterol; it is considered particularly pro-atherogenic.

Phospholipid A polar amphipathic lipid located on the surface of a lipoprotein; phospholipids are also found at the aqueous interface of biological membranes.

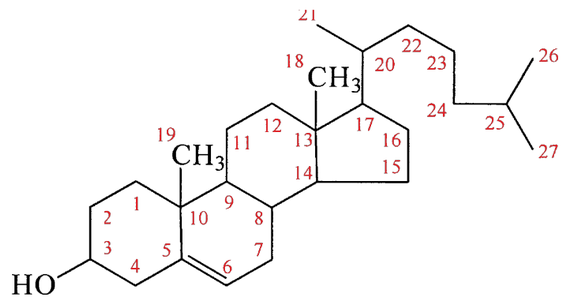
Prostaglandin Any of a group of compounds derived from unsaturated 20-carbon fatty acids (primarily arachidonic acid) via the cyclo-oxygenase pathway; these compounds are involved in a number of physiological processes.

Triglyceride A glycerol ester consisting of three molecules of fatty acid esterified to glycerol and constituting 95% of tissue storage fat.



Lipids have important roles in virtually all aspects of life, including (1) serving as hormones, (2) serving as an energy source, (3) assisting digestion, and (4) acting as structural components in cell membranes. In addition, lipids and **lipoproteins**, the particles that transport lipids in the blood, are intimately involved in the development of **atherosclerosis**—a common disorder that occurs when fat, cholesterol, and other substances build up in the walls of arteries and form hard structures called plaques. It is a pathogenic process that is the underlying cause of the common cardiovascular disorders of (1) myocardial infarction, (2) cerebrovascular disease, and (3) peripheral vascular disease. In this chapter, the basic biochemistry, clinical significance, and laboratory analysis of each of the major lipid and lipoprotein classes and other cardiovascular risk factors are discussed.

Basic Lipids [1,12]



The term lipid applies to a class of compounds that are soluble in organic solvents but nearly insoluble in water. Lipids primarily contain nonpolar carbon-hydrogen (C-H) bonds and often yield fatty acids and/or complex alcohols after hydrolysis. Some lipids also contain charged or polar groups, which makes these lipids amphipathic with affinity for both water and organic solvents, such as lipids like phospholipids, which are found at the aqueous interface of biological membranes. **Phospholipids** are a class of lipids that are a major component of all cell membranes, as they can form lipid bilayers. Most phospholipids contain a diglyceride, a phosphate group, and a simple organic molecule such as choline; one exception to this rule is sphingomyelin, which is derived from sphingosine instead of glycerol. Overall, lipids are broadly subdivided into six groups on the basis of their chemical structure, namely, (1) cholesterol, (2) **fatty acids,** (3) **acylglycerols,** (4) sphingolipids, (5) **prostaglandins,** and (6) terpenes.

Cholesterol

Cholesterol is found almost exclusively in animals and is a key membrane component of all cells. It is a steroid alcohol with 27 carbon atoms that are arranged in a tetracyclical sterane ring system, with a C-H sidechain (Figure 23-1). Although it is relatively hydrophobic, cholesterol does contain a polar hydroxyl (OH) group on its A-ring (see Figure 23-1), thus

Perhydrocyclopentanophenanthrene (sterane) skeleton

Cholesterol

Figure 23-1 Structure of cholesterol.

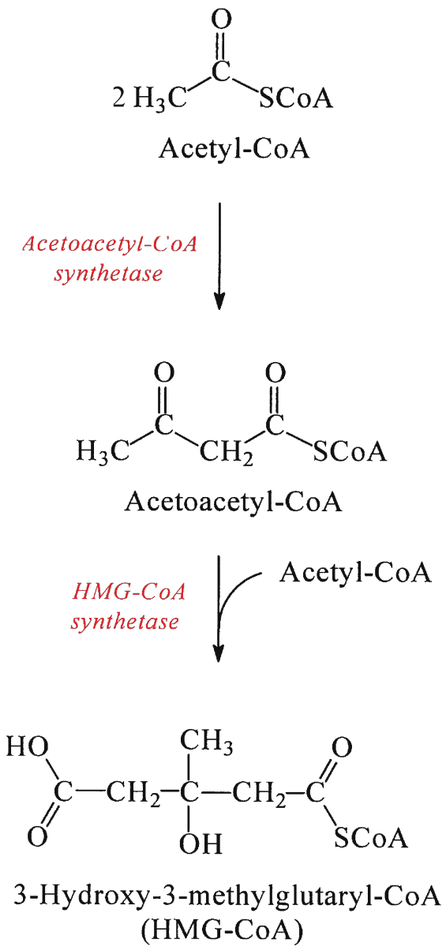


Figure 23-2 Cholesterol biosynthesis (stage 1).

making it amphipathic (i.e., possessing both hydrophilic and lipophilic properties) and accounting for its ability to insert into cell membranes.

Cholesterol Absorption

The average Western diet contains approximately 300 to 450 mg of cholesterol per day, which is derived mostly from animal and dairy products, but only 30% to 60% of it is absorbed. Any dietary esterified cholesterol that contains a fatty acid attached to the hydroxyl group on the A-ring is rapidly hydrolyzed in the intestine to free cholesterol and fatty acids by cholesterol esterases secreted from the pancreas and the small intestine.

Before it is absorbed, cholesterol is first solubilized through a process called emulsification, which involves the formation of mixed micelles that contain (1) unesterified cholesterol, (2) fatty acids, (3) monoglycerides, (4) phospholipids, and (5) conjugated bile acids. Bile acids, by acting as detergents, are the most critical factor in micelle formation. Increased amounts of fat favor the absorption of cholesterol by the formation of

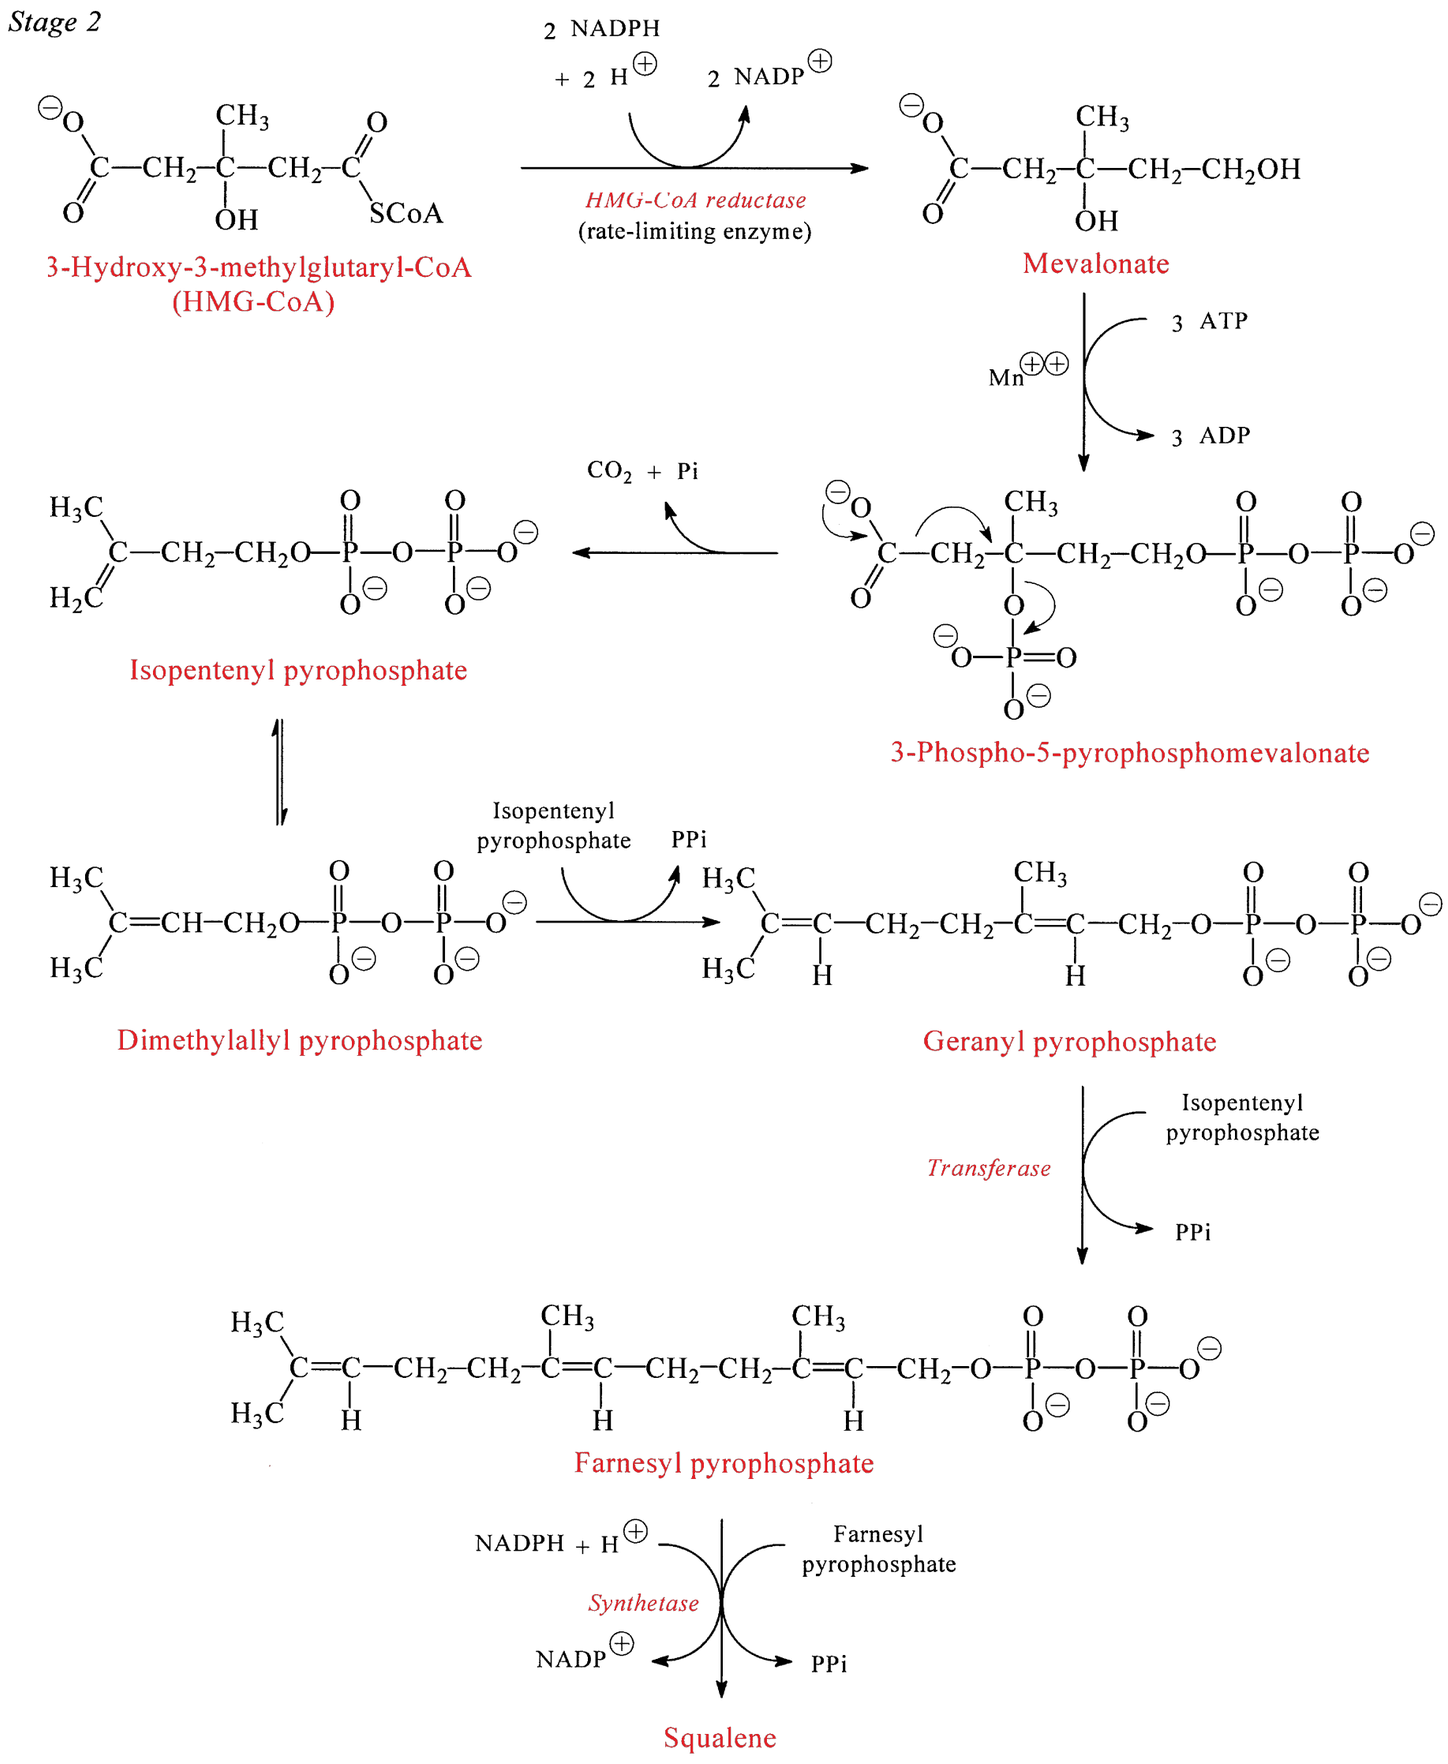

Figure 23-3 Cholesterol biosynthesis (stage 2).

more micelles. Most cholesterol absorption occurs in the middle jejunum and the terminal ileum of the small intestine and is mediated by the enterocyte protein, NPC1L1 (Niemann-Pick C1-like 1), which is the target for the drug ezetimibe, which blocks cholesterol absorption. Once cholesterol enters the intestinal mucosal cell, it is packaged with **triglycerides,** phospholipids, and a large protein called **apolipoprotein (apo)** B-48 into large lipoprotein particles called chylomicrons. Chylomicrons are secreted into the lymph and eventually enter the circulation, where they deliver the absorbed dietary lipid to the liver and peripheral tissues.

Cholesterol Synthesis

Cholesterol is synthesized by all cells in the body, but particularly by the liver and the intestine. Cholesterol biosynthesis occurs in three stages. In the first stage (Figure 23-2), acetyl-coenzyme A (CoA), a key metabolic intermediate, forms the six-carbon thioester 3-hydroxy-3-methyl-glutaryl (HMG)-CoA. In the second stage (Figure 23-3), HMG-CoA is reduced to mevalonate and then is decarboxylated to a series of five-carbon isoprene units. T ese isoprene units are condensed to form first a 10-carbon (geranyl pyrophosphate) and then a 15-carbon intermediate (farnesyl pyrophosphate). Two of these C_{15} molecules then combine to produce the final product of the second stage, squalene, a 30-carbon acyclic hydrocarbon. T e second stage is important because it contains the step involving the microsomal enzyme HMG-CoA reductase, which is the rate-limiting enzyme in cholesterol biosynthesis; it is inhibited by statins, the most effective class of current cholesterol-lowering drugs. T e third stage (Figure 23-4) occurs in the endoplasmic reticulum, with many of the intermediate products bound to a specific carrier protein. In a series of oxidation-decarboxylation reactions, a number of sidechains are removed from the tetracyclical sterane ring structure to form the 27-carbon molecule of cholesterol.

Cholesterol Esterif cation

Cholesterol is esterified to a fatty acid to form a cholesteryl ester by two different enzymes. In cells, excess cholesterol is esterified by acylcholesterol acyltransferase (ACAT) (Figure 23-5), which helps reduce the cytotoxicity of excess free cholesterol. Once esterified, cholesteryl esters are stored in intracellular lipid drops. Cholesteryl esters also are formed in the circulation by the action of a plasma enzyme called lecithin cholesterol acyltransferase (LCAT), which is bound to lipoproteins, particularly high-density lipoproteins (HDL). T e reaction involves the transfer of a fatty acid from the second carbon position of phosphatidylcholine (lecithin) to cholesterol (see Figure 23-5). Cholesteryl esters account for about 70% of the total cholesterol in plasma. Once cholesterol is esterified, it loses its free hydroxyl group and becomes much more hydrophobic, moving from the surface of lipoprotein particles to the hydrophobic core.

Cholesterol Catabolism

Except for specialized endocrine cells that use cholesterol for the synthesis of steroid hormones, most peripheral cells have limited ability to further catabolize cholesterol. Cholesteryl esters are hydrolyzed to free cholesterol by various lipases in all cells, but thereafter, cholesterol has to be returned to the liver to undergo any further catabolism. Approximately one-third of the daily production of

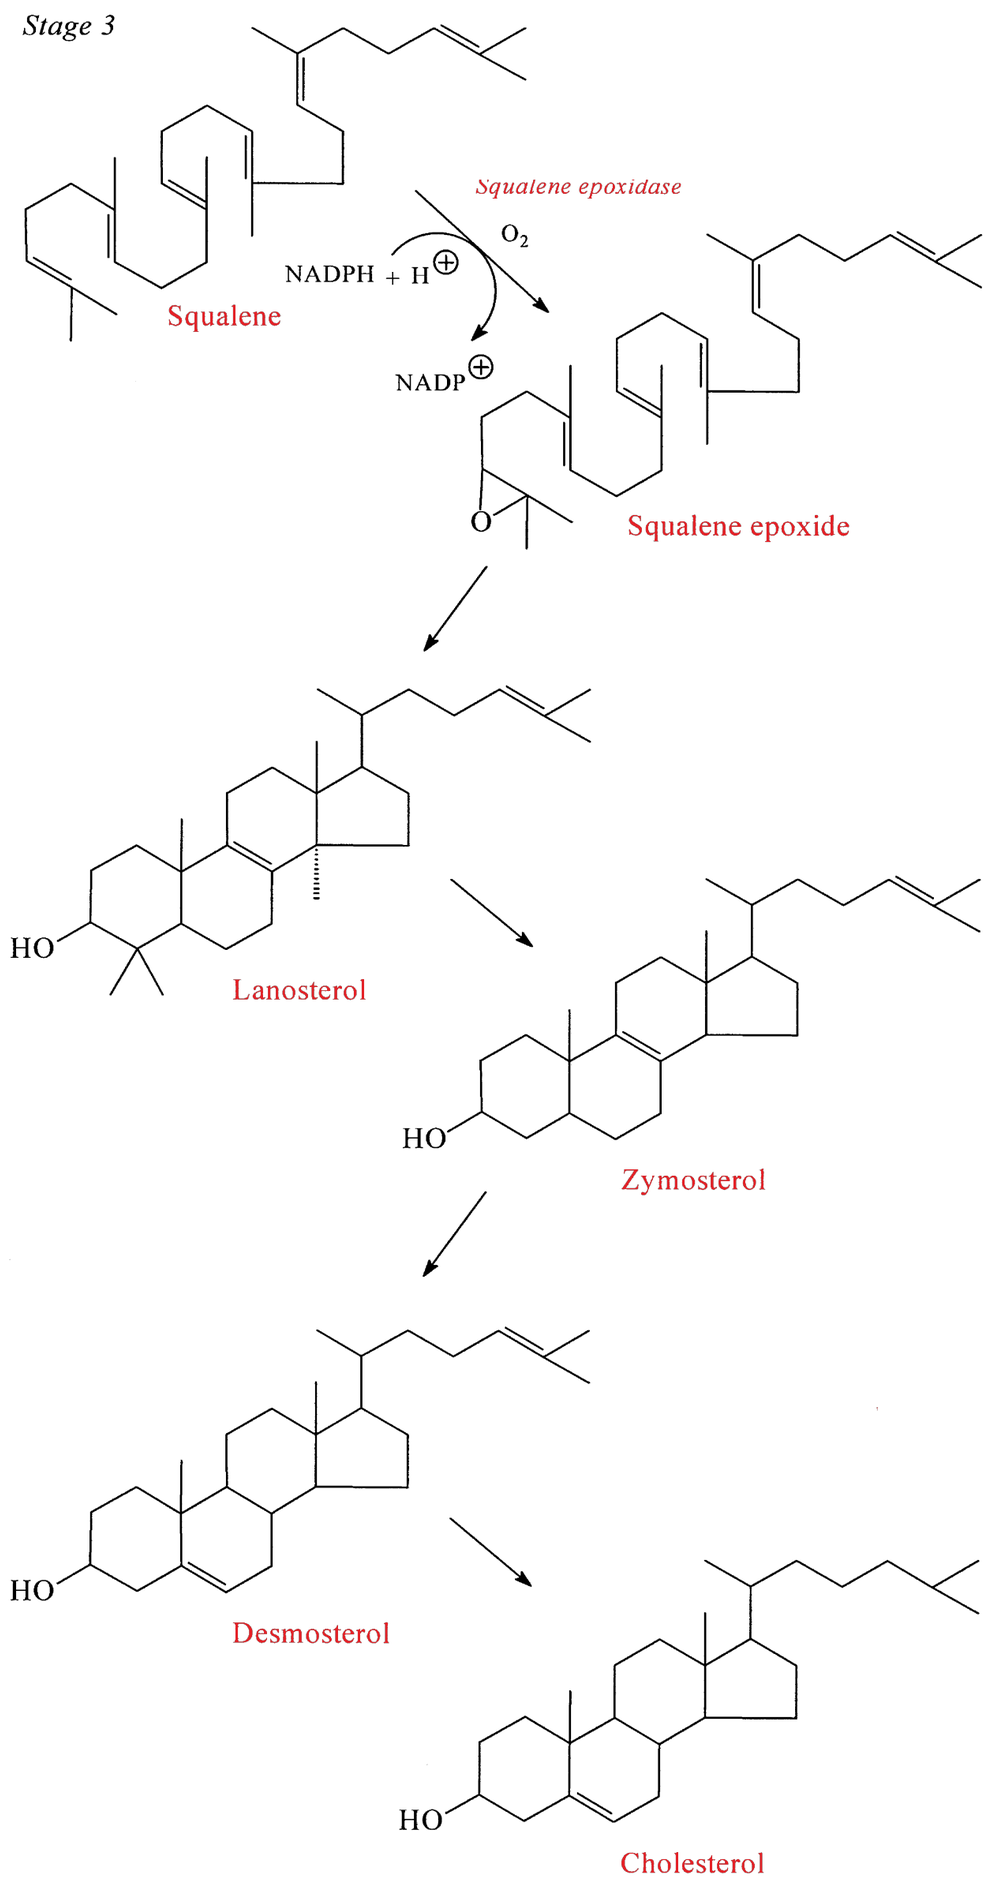

Figure 23-4 Cholesterol biosynthesis (stage 3).

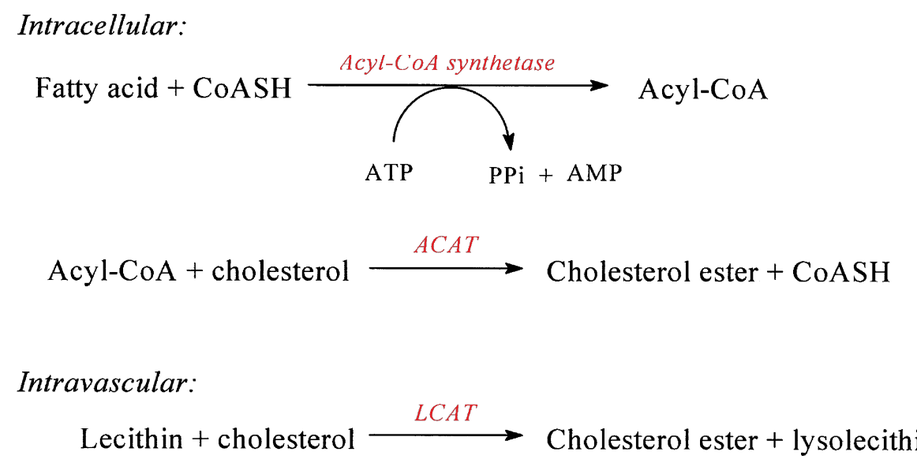

Figure 23-5 Intracellular and intravascular esterifcation of cholesterol mediated by acylcholesterol acyltransferase (ACAT) and lecithin cholesterol acyltransferase (LCAT), respectively.

cholesterol, or about 400 mg/day, is converted in the liver into bile acids (Figure 23-6). About 90% of these bile acids are reabsorbed in the lower third of the ileum and are returned to the liver by the enterohepatic circulation. Bile acids that enter the large intestine are partially deconjugated by bacterial enzymes to secondary bile acids. Cholic acid is converted, for example, to deoxycholic acid, and chenodeoxycholic acid is converted to lithocholic acid.

Not all cholesterol delivered to the liver is converted to bile salts. Much of it is resecreted into the circulation on lipoproteins, and the remainder is directly excreted into the bile unchanged, where it is solubilized into mixed micelles by bile acids and phospholipids. When the amount of cholesterol in bile exceeds the capacity of these solubilizing agents, it is possible for cholesterol to precipitate and form gallstones.

Fatty Acids

RCOOH is the general chemical formula for a fatty acid, where "R" is an alkyl chain. Fatty acid chain lengths vary and are commonly classified as short-chain (2 to 4 carbon atoms), medium-chain (6 to 10 carbon atoms), or long-chain (12 to 26 carbon atoms) fatty acids. Those of importance in human nutrition and metabolism are included in the long-chain class and contain an even number of carbon atoms.

Fatty acids are further classified according to their degree of saturation. Saturated fatty acids have no double bonds (C=C) between their carbon atoms; monounsaturated fatty acids contain one double bond; and polyunsaturated fatty acids contain multiple double bonds (Figure 23-7). T e double bonds in polyunsaturated fatty acids are usually three carbon atoms apart. Fatty acids from fish, such as

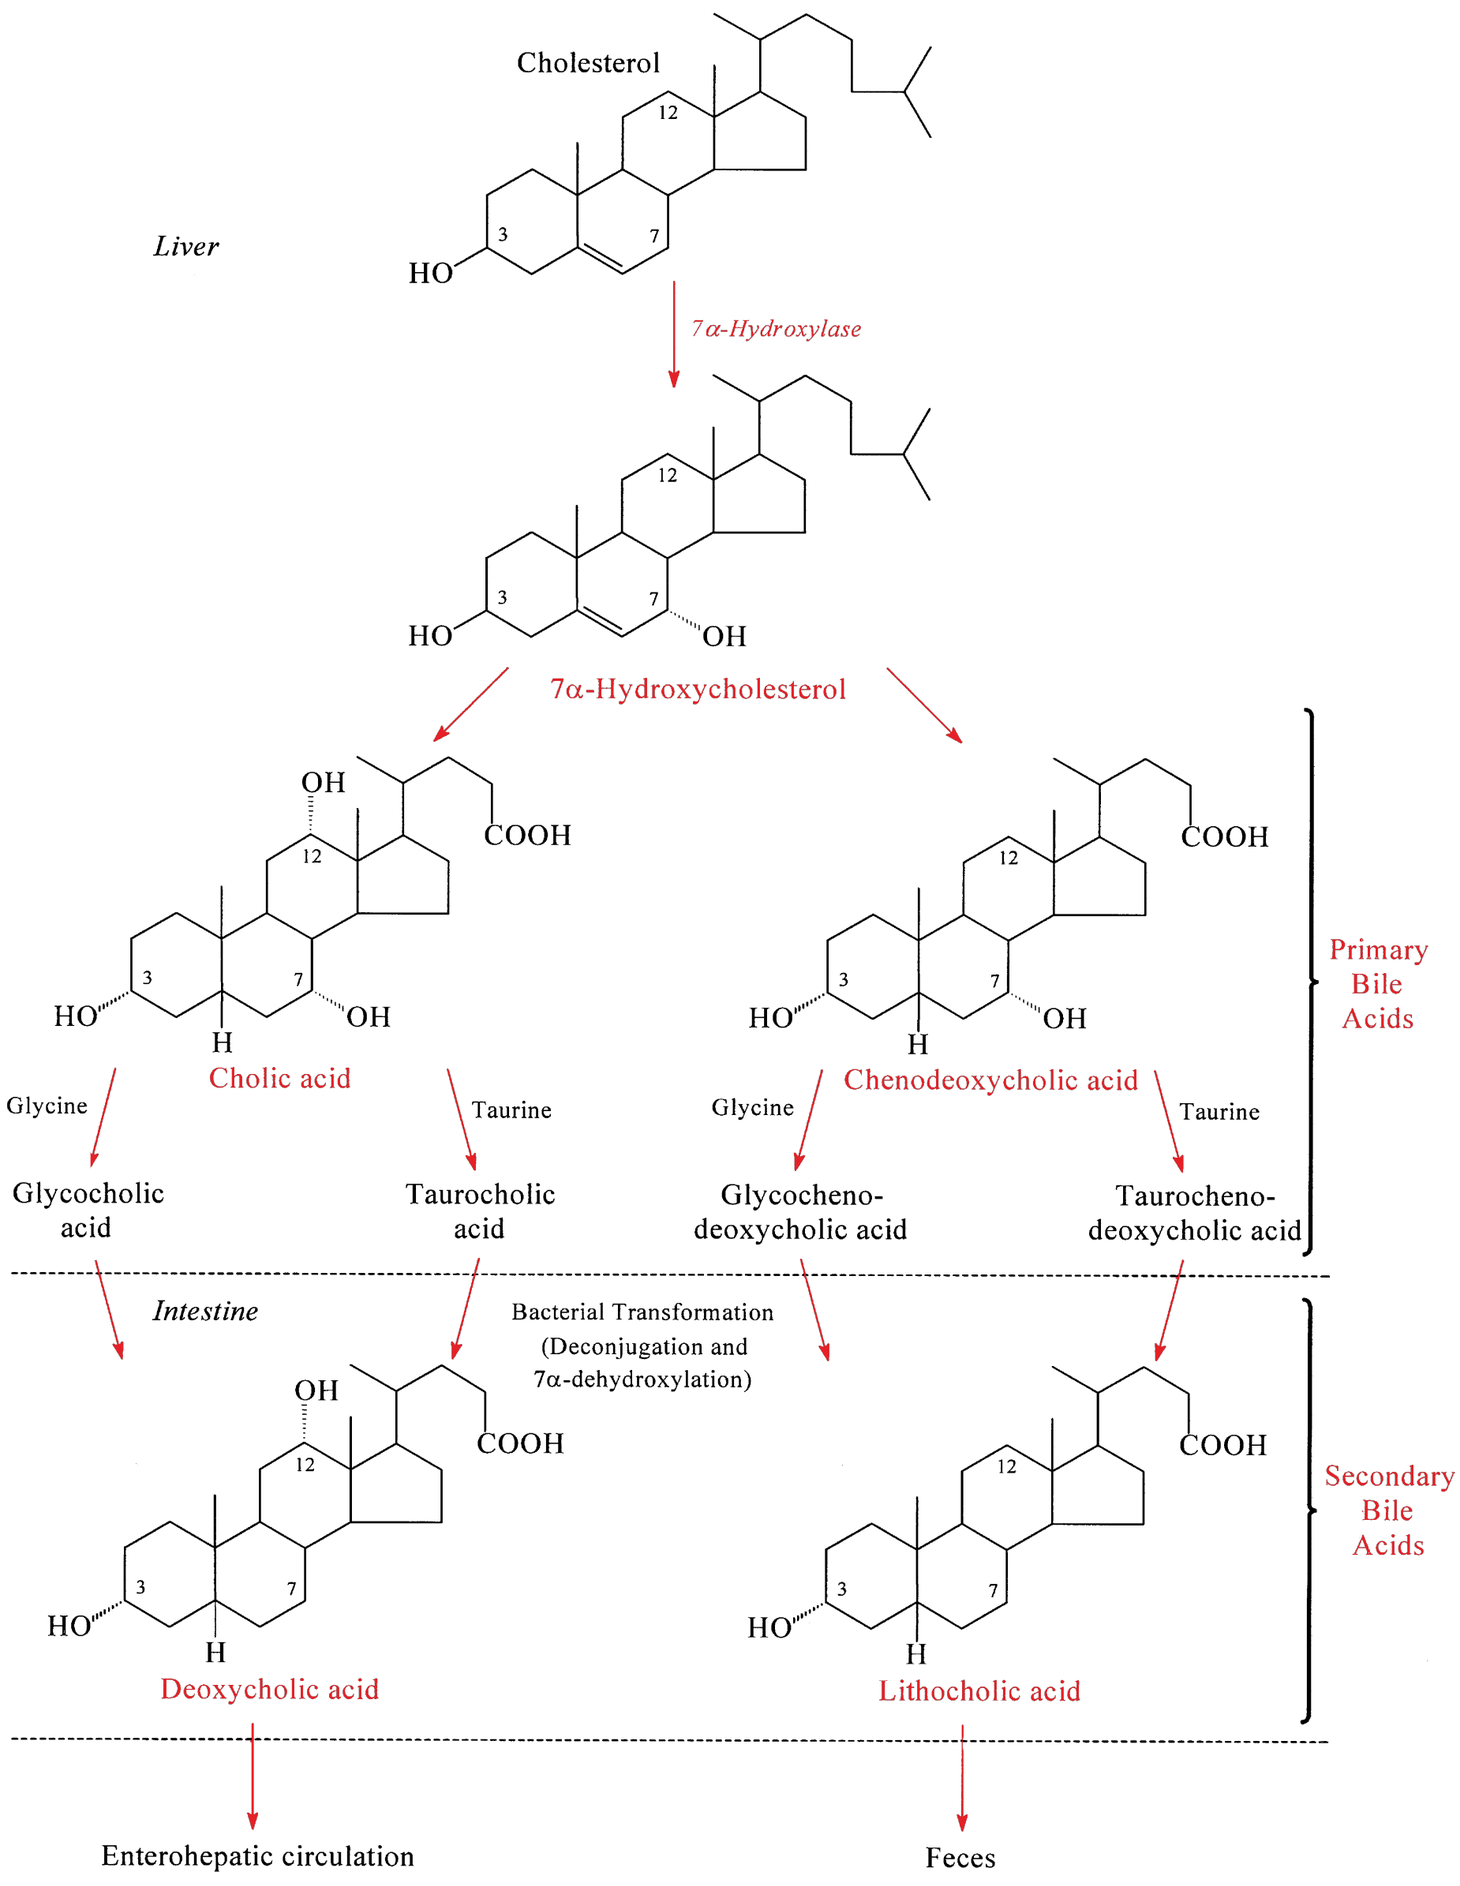

Figure 23-6 Bile acid synthesis.

salmon, possess up to six unsaturated double bonds and usually are more than 20 carbon atoms long. Unsaturated fatty acids are prone to oxidation by the nonenzymatic reaction of oxygen with their double bonds. Numbering of the carbon atoms in fatty acids is done from the carboxyl terminal end (Δ-numbering system) or from the methyl terminal end (η- or ω-numbering system; Table 23-1). In addition, carbon atoms may be labeled with Greek symbols, with α being adjacent to the carboxyl group and ω being farthest away. In the Δ-system, fatty acids are abbreviated according to the (1) number of carbon atoms, (2) number of double bonds, and (3) position(s) of double bond(s). For example, linoleic acid would be written as $C_{18}:2^{9,12}$ and contains 18 carbons and two unsaturated bonds between carbons 9 and 10 and carbons 12 and 13. When the η- or ω-system is used, linoleic acid would be abbreviated as C_{18}:2n–6, where only the first carbon forming the unsaturated pair is written. T e Geneva or systematic classification, which is based on their chemical names, is a third common nomenclature system for fatty acids (see Table 23-1).

In saturated fatty acids, the chain is extended and flexible; the carbon atoms rotate freely around their longitudinal axis. Unsaturated fatty acids, however, have fixed 30° bends in their chains at each double bond. Depending on the plane in which this bend occurs, the cis or the trans isomer is produced. In mammals, all naturally occurring unsaturated fatty acids are of the cis variety. Trans fatty acids in our diet result primarily from catalytic hydrogenation in which unsaturated double bonds are chemically reduced to raise their melting point. This process is used to "harden" or solidify fats in the manufacture of certain foods, such as margarine.

Most fatty acids are also synthesized by the body except for essential fatty acids such as linoleic acid ($C_{18}:2^{9,12}$), which is made only by plants. Linoleic acid is also converted to arachidonic acid, which is a precursor for prostaglandin synthesis.

Fatty acids exist in the circulation in an unesterified or free state, the latter primarily bound to albumin, or in various esterified forms, such as triglycerides, phospholipids, or cholesteryl esters. T e free fatty acid carboxyl group has a pK_a of approximately 4.8; thus free fatty acid molecules exist primarily in their ionized forms. T e normal concentration of free fatty acids in human plasma is 0.3 to 1.1 mmol/L (8 to 31 mg/dL) and is very sensitive to physiological energy demands and the availability of alternative forms of metabolic fuel, such as glucose.

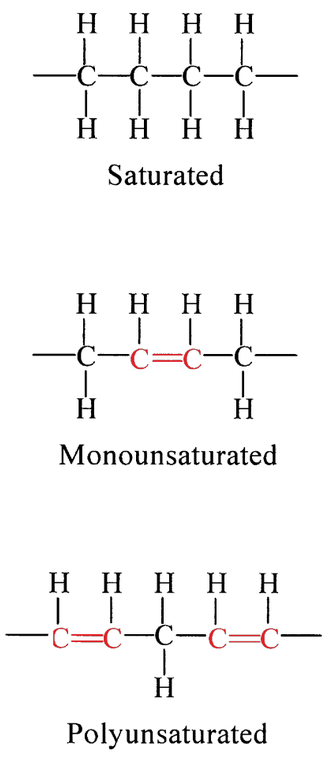

Figure 23-7 Saturated and unsaturated fatty acids.

TABLE 23-1 Fatty Acids Commonly Found in Human Tissue

Common Name	Systematic Name	D-Numbering	h-(ω) Numbering
Lauric	Dodecanoic	12:0	12:0
Myristic	Tetradecanoic	14:0	14:0
Palmitic	Hexadecanoic	16:0	16:0
Palmitoleic	9-Hexadecanoic	$16:1^{9}$	16:1n-7
Stearic	Octadecanoic	18:0	18:0
Oleic	9-Octadecanoic	$18:1^{9}$	18:1n-9
Linoleic*	9,12-Octadecadienoic	$18:2^{9,12}$	18:2n-6
Linolenic*	9,12,15-Octadecatrienoic	$18:3^{9,12,15}$	18:3n-3
Arachidic	Eicosanoic	20:0	20:0
Arachidonic	5,8,11,14-Eicosatetraenoic	$20:4^{5,8,11,14}$	20:4n-6

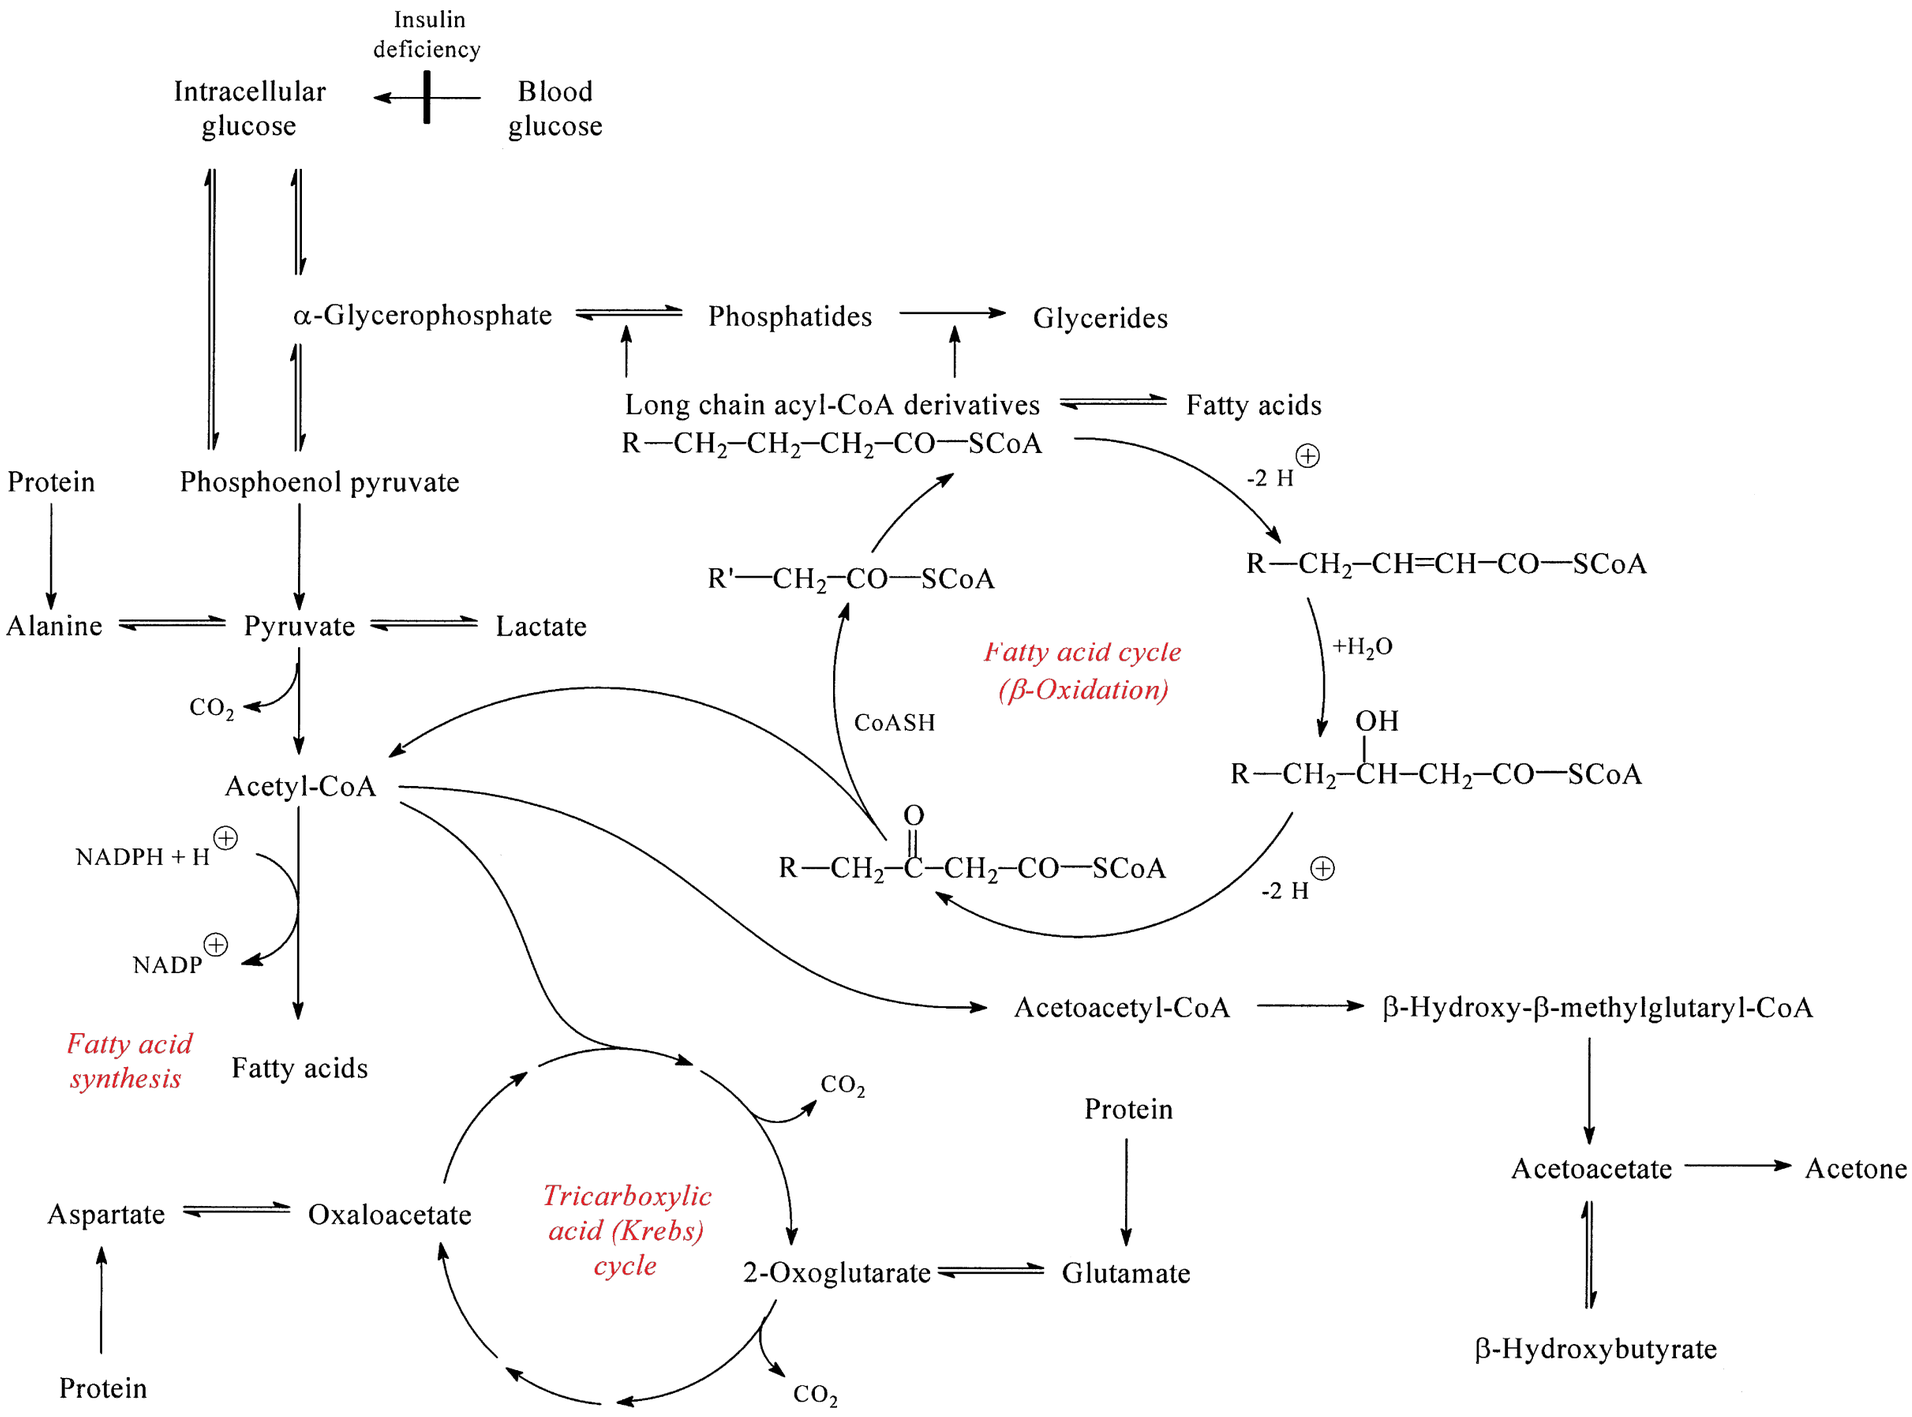
*Essential fatty acids.

Fatty Acid Catabolism

Fatty acids are catabolized in the mitochondria and produce energy by a series of reactions known as β-oxidation. T is process is repeated to shorten the fatty acid chain by two carbon atoms at a time from the carboxy terminal end of the molecule. For example, one mole of palmitic acid (C_{16}) is converted to eight moles of acetyl-CoA. Acetyl-CoA does not normally accumulate in the cell but is condensed enzymatically with oxaloacetate, derived largely from carbohydrate metabolism (Figure 23-8), to yield citrate, a major component of the tricarboxylic acid cycle (Krebs cycle). T e Krebs cycle is a common pathway for the final oxidation of nearly all metabolic fuels, whether derived from carbohydrate, fat, or protein, and ultimately results in the production of adenosine triphosphate (ATP), the main energy storage molecule in the body. Triglycerides contain three fatty acid molecules and are, therefore, a relatively efficient storage form of metabolic energy. Furthermore, energy storage by triglycerides is efficient in terms of space because it does not require any water for hydration, unlike carbohydrates.

Ketone Formation

During prolonged starvation, or when carbohydrate metabolism is impaired, as in uncontrolled diabetes mellitus, the formation of acetyl-CoA exceeds the supply of oxaloacetate. The resulting acetyl-CoA excess is diverted to an alternative pathway in the mitochondria for the formation of (1) acetoacetic acid, (2) β-hydroxybutyric acid, and (3) acetone—the three compounds known collectively as ketone bodies (Figure 23-9). Ketosis, therefore, develops from excessive production of acetyl-CoA, as the body attempts to obtain necessary energy from stored fat in the



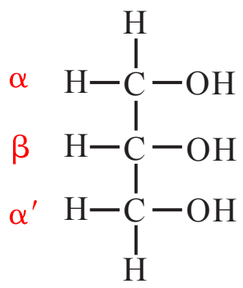


Figure 23-8 Metabolic relations among intermediates of carbohydrate, fat, and protein metabolism. Note that acetyl-CoA is produced from both carbohydrate and fat. The glucogenic amino acids, derived from protein metabolism, enter glycolytic paths as α-keto acids. Ketogenic amino acids enter as acetyl-CoA.

absence of an adequate supply of carbohydrate metabolites (see Chapter 22).

Acylglycerols (Glycerol Esters)

Glycerol is a three-carbon alcohol that contains a hydroxyl group on each of its carbon atoms (Figure 23-10).

The two terminal carbon atoms in the glycerol molecule are chemically equivalent and are designated α and α′. The center carbon is labeled β. A common alternative labeling system uses the numeral 1 for the α-carbon, 2 for the β-carbon, and 3 for the α′-carbon. The class of acylglycerol is determined by the number of fatty acyl groups present: (1) one fatty acid—monoacylglycerols (monoglycerides); (2) two fatty acids—diacylglycerols (diglycerides); and (3) three fatty acids—triacylglycerols (triglycerides). For example, 1-monoglyceride indicates that a fatty acid is attached to the α-carbon. This numbering system applies to all acylglycerols, including the phosphoglycerides (Figure 23-11).

Triglycerides constitute 95% of tissue storage fat and are the predominant form of glyceryl esters found in plasma. The fatty acid residues found in (1) monoglycerides, (2) diglycerides, or (3) triglycerides vary considerably and usually include different combinations of long-chain fatty acids (see Table 23-1). In general, triglycerides from plant sources, such as corn, sunflower, and safflower, tend to be enriched in unsaturated fatty acids and are liquid oils at room temperature. Triglycerides from animals, especially ruminants, tend to have saturated acids and are solids at room temperature.

Dietary triglycerides are digested in the duodenum and are absorbed in the proximal ileum. Through the action of pancreatic and intestinal lipases and in the presence of bile acids, they are first hydrolyzed to glycerol, monoglycerides, and fatty acids. After absorption, these components of triglycerides are reassembled as triglycerides in the intestinal epithelial cells and then are packaged with cholesterol and apo B-48 to form chylomicrons. Chylomicrons are secreted into the lymphatic system and eventually reach the circulation. Triglycerides are the main metabolic fuel carried by

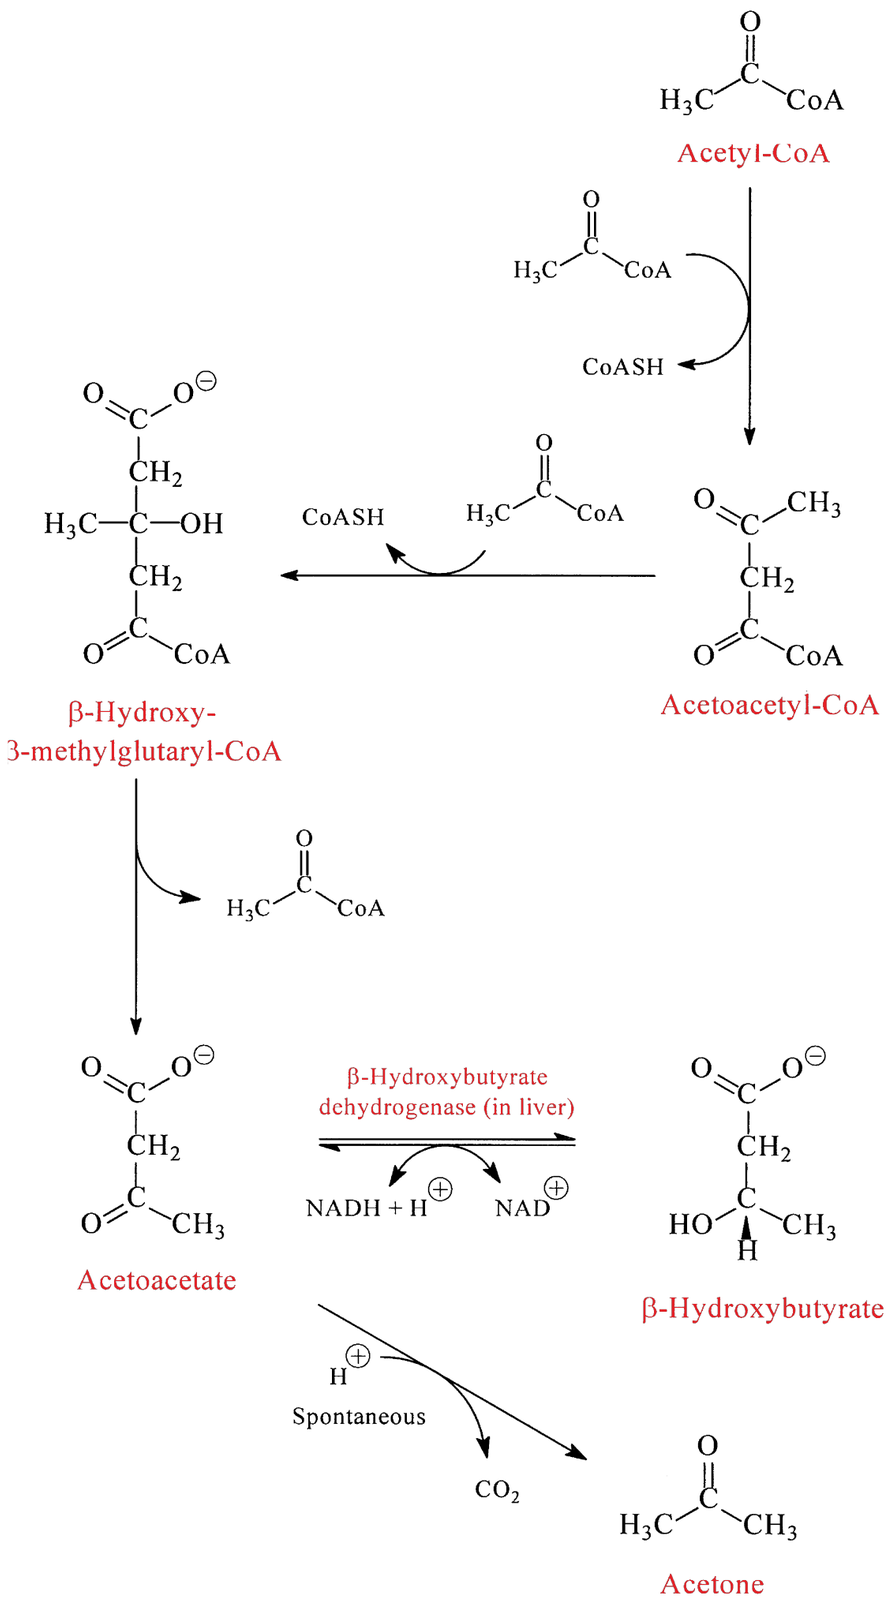

Figure 23-9 Formation of ketone bodies.

chylomicrons; they are delivered to the liver and peripheral cells after they have been hydrolyzed to fatty acids by lipases.

Another major class of acylglycerols includes those containing phosphoric acid at the third (α′) carbon atom, which are referred to as phosphoglycerides (see Figure 23-11). In their simplest form, the A group consists of a hydrogen atom and the molecule is called diacylphosphoglyceride. Usually, the A group is in alcohol, such as (1) choline, (2) serine, (3) inositol, or (4) ethanolamine. If the A group is choline, for example, the molecule is referred to as phosphatidylcholine (lecithin). As the types of fatty acid residues R_1 and R_2 are varied, numerous types of phospholipids are formed. T ese phosphoglycerides are named according to the fatty acid acyl esters attached at C-1 and C-2 of the glycerol. Saturated fatty acids are typically esterified to the C-1 position, whereas polyunsaturated fatty acids are often attached to the C-2 position. In inner mitochondrial membranes, more complex phosphoglycerides, known as cardiolipins, are found. T ey are derived from two phosphoglyceride molecules joined by a glycerol bridge.

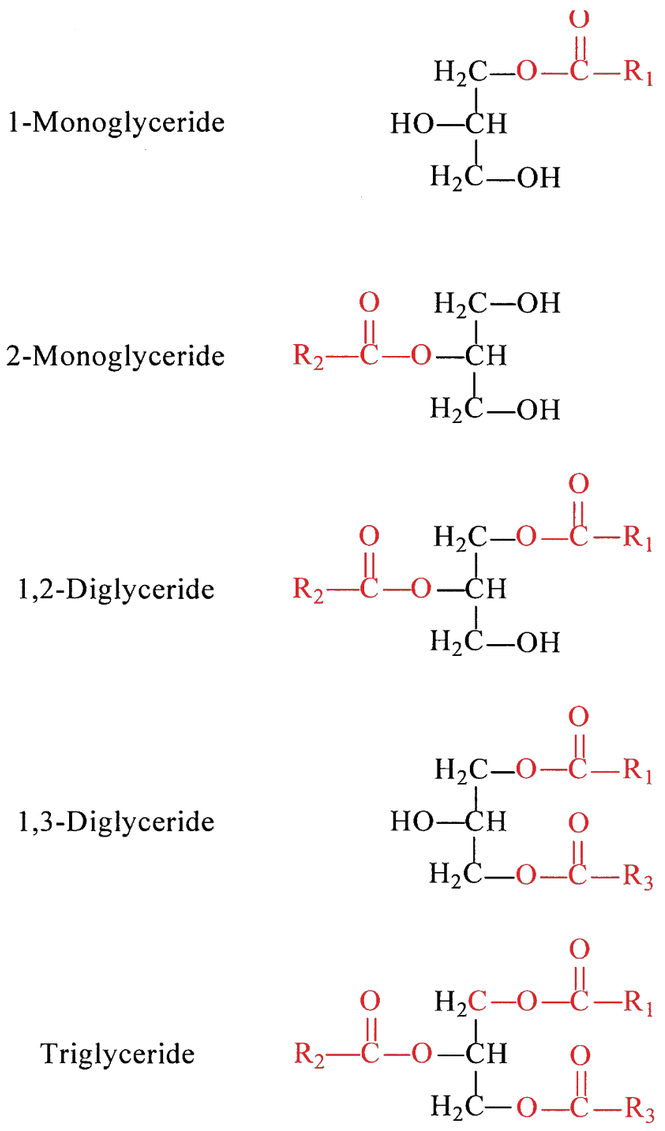

Figure 23-10 Structure and classifcation of glycerol esters (acylglycerols). R_1, R_2, and R_3 are fatty acids of varying chain length.

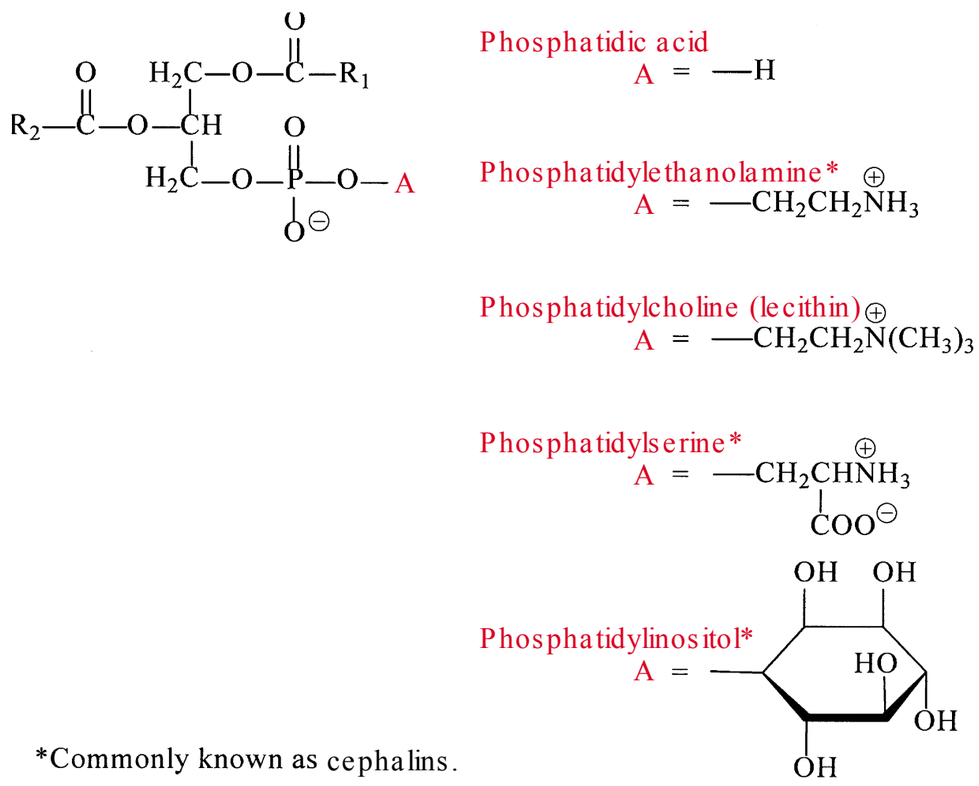

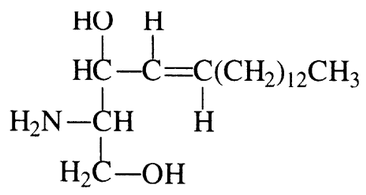

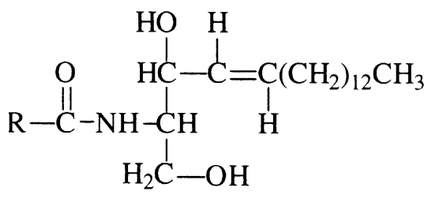

Figure 23-11 Structures of phosphoglycerides and common alcohol groups associated with them. R_1 and R_2 are fatty acids of varying carbon atom lengths.

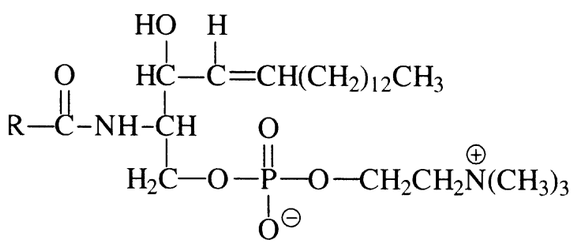
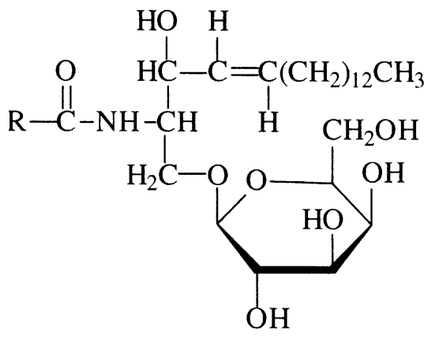
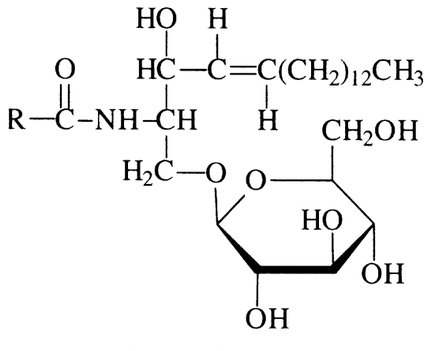
Sphingolipids



Sphingolipids make up a fourth class of lipids derived from the amino alcohol sphingosine (Figure 23-12). T is dihydric 18-carbon alcohol contains an amino group at C-17. A fatty acid containing 18 or more carbon atoms is attached to the amino group through an amide linkage to form a ceramide. T is is an intermediate structure in the formation of (1) sphingomyelin, (2) galactosylceramide,



Sphingosine



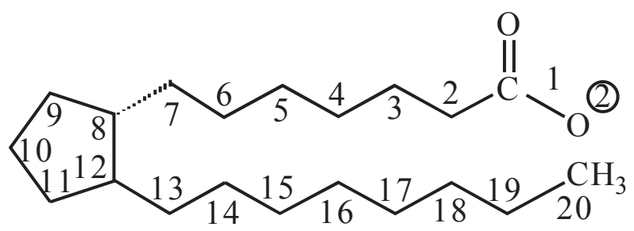
Ceramide

Sphingomyelin

Galactosylceramide

Glucosylceramide

Figure 23-12 Structures of sphingolipids.



and (3) glucosylceramide (see Figure 23-12). In addition, the sugar-containing ceramides have a sulfate group that is usually attached to the 2-position of the galactose residue to form the sulfatides. The glycosyl ceramides have additional monosaccharide moieties, such as (1) galactose, (2) N-acetylgalactosamine, and (3) N-acetylneuraminic acid, to form complex globosides and gangliosides. Gangliosides are especially abundant in the membranes of the gray matter of the brain, whereas glycosphingolipids have a more general role in cellular interactions and serve as a source of blood group and tumor antigens.

Prostaglandins

Prostaglandins and related compounds, such as thromboxanes and leukotrienes, are derivatives of fatty acids, primarily arachidonate. These bioactive lipids exert diverse physiological actions (Table 23-2) at concentrations as low as 1 μg/L.

TABLE 23-2 Prostaglandin-Mediated Effects

Site of Action	Physiological Response
Arterial smooth muscle	Alters blood pressure
Uterine muscle	Induces labor, therapeutic abortion
Lower gastrointestinal tract	Increases motility
Bronchial smooth muscle	Causes bronchospasm
Platelets	Increase coagulability
Capillaries	Increase permeability
Stomach	Enhances gastric acid secretion
Adipose tissue	Inhibits triglyceride lipolysis

The prostaglandins are a series of C_{20} unsaturated fatty acids that contain a cyclopentane ring; the parent fatty acid has been given the trivial name prostanoic acid. By convention, prostaglandins are abbreviated PG, with the class designated by a capital letter (A, B, E, F, G, H, and I), followed by a number and, in some cases, a Greek letter (Figure 23-13). The number after the capital letter is usually written as a subscript and is used to designate the number of unsaturated bonds in the PG sidechains and not within the ring structure itself. Sixteen naturally occurring prostaglandins have been described (Table 23-3), but only seven, along with two thromboxanes, are commonly found in the body. These are termed primary prostaglandins.

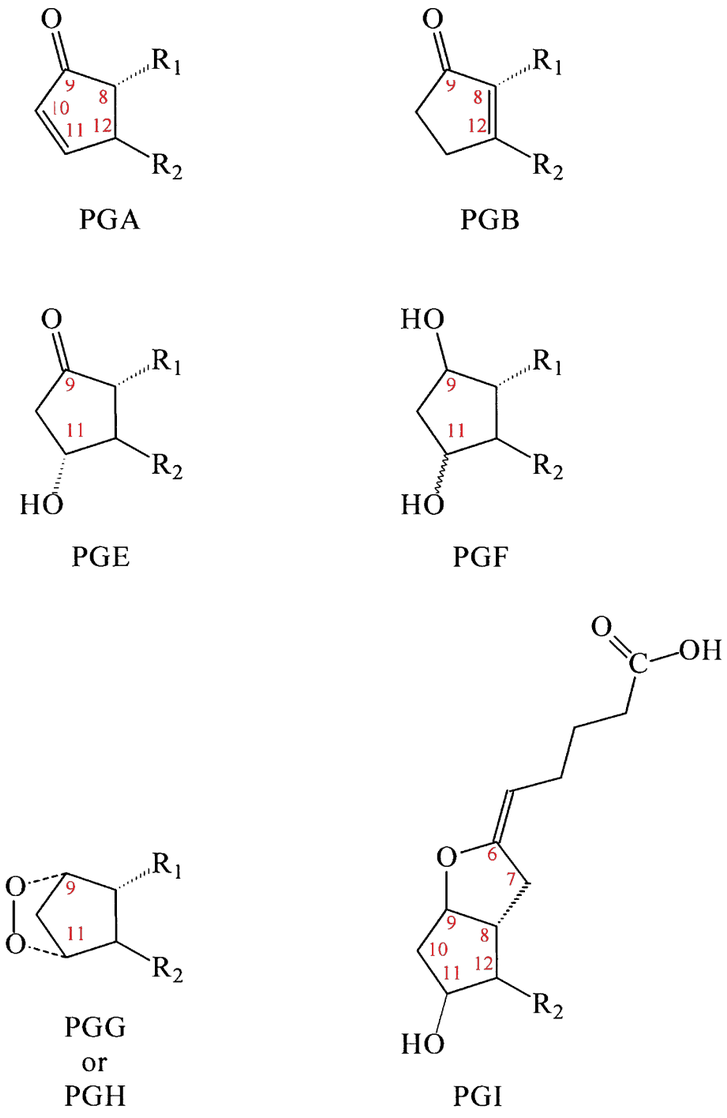


Figure 23-13 Major prostaglandin classes (series). R_1 and R_2 are prostaglandin sidechains.

TABLE 23-3 Naturally Occurring Prostaglandins (PGs)

Primary PG	Other PGs
PGE_1	PGA_1
$PGF_{1\alpha}$	PGA_2
PGE_2	19α-OHPGA$_1$
$PGF_{2\alpha}$	19α-OHPGA$_2$
PGG_2	PGB_1
PGH_2	PGB_2
PGI_2	19α-OHPGB$_2$
Thromboxane A_2	PGE_3
Thromnane B_2	$PGF_{3\alpha}$

Although prostaglandins have hormone-like action, they are different from conventional hormones in that they are synthesized at the site of action and are made in almost all tissues. Linoleic acid (C_{18}:2^{9,12}) is the precursor of two of the three 20-carbon fatty acids that form prostaglandins; linolenic acid (C_{18}:2^{9,12,15}) is the other precursor. Both of these fatty acids are considered essential because they are not synthesized in the body and therefore must be present in the diet. Once formed, prostaglandins have short-lived effects and are catabolized within seconds. Inactivation of prostaglandin appears to be mediated by two enzymes: 15α-hydroxy-prostaglandin dehydrogenase and Δ^{13}-prostaglandin reductase. Prostaglandins are not stored, but the precursor C_{20} fatty acids are present in tissue attached to the C-2 position of phosphoglycerides. When prostaglandin synthesis is stimulated, the C_{20} precursor is hydrolyzed from phospholipids by phospholipase A_2. Release of the C_{20} fatty acid appears to be the rate-limiting step in prostaglandin synthesis and is stimulated by various mediators, such as bradykinin, thrombin, or angiotensin II.

Once released, arachidonic acid follows one of two pathways. The lipoxygenase route produces 12-l-hydroperoxy-5,8,10,14 eicosatetraenoic acid (HPETE); HPETE spontaneously decomposes to 12-l-hydroxy-5,8,10,14 eicosatetraenoic acid (HETE) (Figure 23-14). The alternative pathway is mediated by cyclo-oxygenase (COX) to produce the endoperoxides PGG_2 and PGH_2. Nonsteroidal anti-inflammatory drugs (NSAIDs, such as aspirin, ibuprofen, naproxen, and indomethacin) inhibit the COX enzymes, thereby decreasing prostaglandin synthesis.

PGI_2, or prostacyclin, is derived from arachidonic acid (see Figure 23-13) in the vascular endothelium. It has a powerful vasodilatory action, especially on the coronary arteries, and inhibits platelet aggregation. Thromboxane A_2 is synthesized from arachidonic acid but is also produced by platelets. It has the opposite effect of prostacyclin because it stimulates the contraction of arterial smooth muscle and enhances platelet aggregation. It has a half-life of about 30 seconds and is rapidly converted to its inactive metabolite, thromboxane B_2. Thromboxanes are slightly different in structure from the other prostaglandins in that they contain six-sided rings of five carbon atoms and one oxygen atom (Figure 23-15).

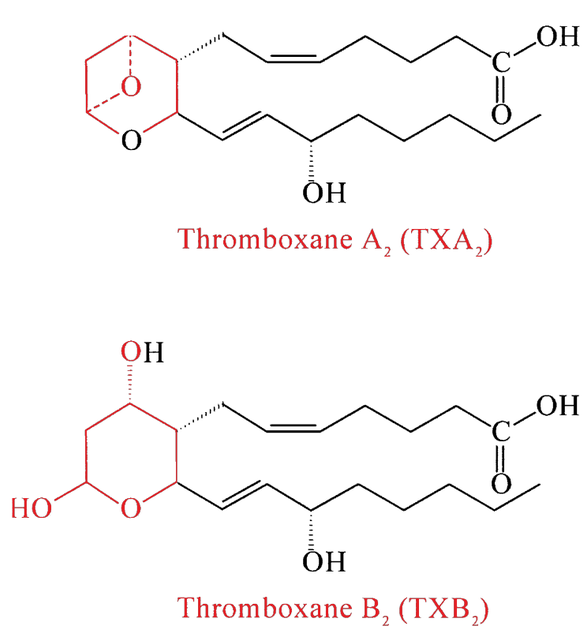

Figure 23-15 Structures of thromboxanes.

Terpenes

Terpenes are polymers of the five-carbon isoprene unit and include vitamins A, E, and K and the dolichols, which play important roles in protein glycation.

Lipoproteins [1,5,7]

Lipids synthesized in the liver and in the intestine are transported in the plasma in macromolecular complexes known as lipoproteins. Lipoproteins are typically spherical particles with nonpolar neutral lipids (triglycerides and cholesterol esters) in their core and more polar amphipathic lipids (phospholipids and free cholesterol) at their surface (Figure 23-16). They also contain one or more specific proteins, called apolipoproteins, on their surface.

Classification

Lipoproteins have different physical and chemical properties (Table 23-4) because they contain different proportions of lipids and proteins (Table 23-5). Traditionally, lipoproteins have been categorized on the basis of differences in their hydrated densities, as determined by ultracentrifugation.

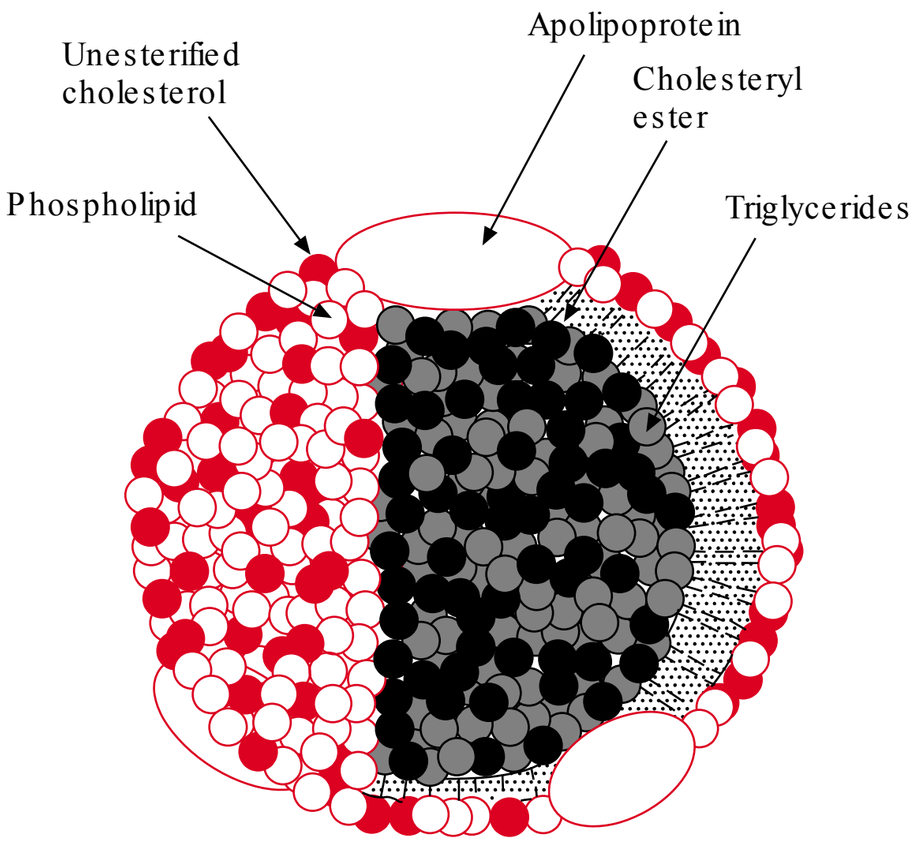

Figure 23-16 Structure of a typical lipoprotein particle.

These categories include (1) chylomicrons, (2) very-low density lipoprotein (VLDL), (3) intermediate-density lipoprotein (IDL), (4) low-density lipoprotein (LDL), (5) high-density lipoprotein (HDL), and (6) **lipoprotein(a)** [Lp(a)]. In general, the larger lipoproteins contain more core lipids, triglycerides, and cholesteryl esters and are lighter in density and contain a smaller percentage of protein. In the fasting state, most plasma triglycerides are present in VLDL, but 2 to 6 hours after a meal, most triglycerides are transported on chylomicrons. LDL carries about 70% of total plasma cholesterol but very little triglyceride (see Table 23-5). HDL typically contains about 20% to 30% of plasma cholesterol.

Lp(a) is a distinct class of lipoprotein (Table 23-6) that is structurally related to LDL because both lipoproteins possess one molecule of apo B-100 per particle with similar lipid compositions. Unlike LDL, Lp(a) also contains a carbohydrate-rich protein [apo(a)], which is covalently bound to the apo B-100 through a disulfide linkage. Apo(a) exhibits a significant sequence homology with plasminogen and a high degree of variation in polypeptide chain length (Figure 23-17). Apo(a) contains a tandem array of a protein motif called a kringle domain with different-sized apo(a) molecules (polymorphisms) reflecting the inclusion of variable numbers of kringle 4 type 2 domains.

Lipoproteins have been electrophoretically separated, and this forms the basis for their nomenclature. For example,

HDL, High-density lipoprotein; IDL, intermediate-density lipoprotein; LCAT, lecithin cholesterol acyltransferase; LDL, low-density lipoprotein; Lp(a), lipoprotein(a); LPL, lipoprotein lipase; VLDL, very low-density lipoprotein.

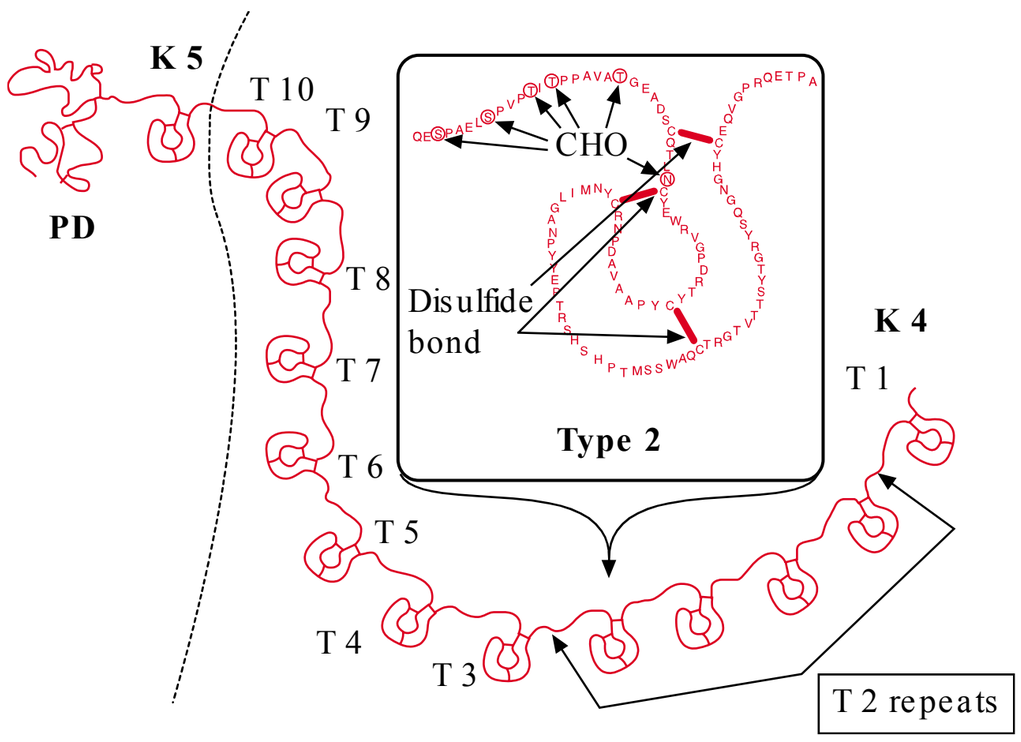

Figure 23-17 Structure of lipoprotein(a).

at pH 8.6, HDL migrates with the α-globulins, LDL with the β-globulins, and VLDL and Lp(a) between the α- and β-globulins, in the pre–β-globulin region. IDL forms a broad band between β- and pre–β-globulins. Chylomicrons remain at the application point. Traditionally, lipoprotein classes were referred to by their electrophoretic locations as pre–β-lipoprotein, VLDL; β-lipoprotein, LDL; and α-lipoprotein, HDL. Electrophoresis provided the foundation for an early original phenotypical classification system (Types 1 to 5) for familial dyslipidemias.

Apolipoproteins

Apolipoproteins are the major protein components of lipoproteins (see Table 23-6). Each class of lipoprotein carries several apolipoproteins in differing proportions. Apo A-I is the major protein in HDL. Apo B-100 is the main protein on LDL and Lp(a), and apo B-48, which is produced from apo B-100 messenger RNA (mRNA) by an RNA editing process, is found on chylomicrons. Both apo B-100 and apo B-48 are found at one molecule per particle, are firmly bound, and do not exchange between particles, as the other apolipoproteins do. Apolipoproteins perform the following major functions: (1) modulate the activity of enzymes that act on lipoproteins, (2) maintain the structural integrity of the lipoprotein complex, and (3) facilitate the uptake of lipoprotein by acting as ligands for specific cell-surface receptors. Most apolipoproteins contain amphipathic helices, which are α-helices with one face containing hydrophobic amino acids and the other face containing polar or charged amino acids. T is feature enables apolipoproteins to bind to lipids and still interact with the surrounding aqueous environment.

Metabolism of Lipoproteins[1,5,7]

Lipoprotein metabolism is commonly divided into (1) exogenous, (2) endogenous, (3) intracellular-cholesterol transport, and (4) reverse-cholesterol transport pathways.

Exogenous Pathway

The role of the exogenous pathway—transport of dietary lipids from the intestine to the liver and peripheral cells—is largely mediated by chylomicrons (Figure 23-18). Nascent chylomicrons, which are 90% triglcycerides by mass, are first assembled by the microsomal transfer protein (MTP) in the endoplasmic reticulum of enterocytes by combining triglycerides and other lipids with apo B-48. Chylomicrons are secreted into the lymph and, after entering the circulation, acquire from HDL additional apolipoproteins, such as apo E and apo C-II. Apo E is a ligand for uptake by the liver, whereas C-II is a potent activator of lipoprotein lipase (LPL), which is attached to the luminal surface of endothelial cells and rapidly hydrolyzes the triglycerides on chylomicrons to free fatty acids. Liberated fatty acids combine with albumin and are taken up by muscle cells as an energy

Copyright 1986, American Medical Association.)

source or by adipose cells for energy storage as triglycerides. As a consequence of lipolysis, chylomicrons are transformed into smaller chylomicron remnant particles, which are rapidly removed by the liver.

Endogenous Pathway

The function of the endogenous pathway is to transfer hepatically derived lipids, especially triglycerides, to peripheral cells for energy metabolism. It is mediated by the apo B-100–containing lipoproteins (Figure 23-19). Hepatically derived lipids represent lipids that were synthesized by the liver or dietary lipids that were transferred to the liver by the exogenous pathway. VLDL, which contains approximately 55% triglcycerides by mass and includes one molecule of apo B-100, is the principal apo B–containing lipoprotein that is secreted by the liver. As it does on chylomicrons, the apo C-II present on the surface of VLDL activates LPL on endothelial cells. This leads to hydrolysis of VLDL triglycerides and release of free fatty acids, which are taken up by cells. The progressive lipolysis of triglycerides from the core of VLDL transforms it to IDL and eventually to LDL. The triglycerides on LDL is further depleted by the cholesterol ester transfer protein (CETP), which removes from LDL and exchanges it for cholesteryl esters from HDL. Although almost all cells express the LDL receptor, most LDL is eventually returned to the liver via the LDL receptor, which recognizes apo B-100. Cholesterol returned to the liver is (1) reused for the secretion of lipoproteins, (2) used in the production of bile salts, or (3) excreted directly into the bile.

Intracellular-Cholesterol Transport Pathway

The intracellular-cholesterol transport pathway maintains cellular homeostasis of cholesterol. Although cholesterol is a necessary and critical component of all cell membranes, excess cholesterol will alter the biophysical properties of membranes and eventually will become toxic to the cell. Besides through biosynthesis, all cells receive cholesterol via uptake of extracellular lipoproteins by cell surface receptors, such as the LDL receptor (Figure 23-20). Most lipoprotein receptors deliver intact lipoprotein particles to lysosomes, where they are degraded. Cholesteryl esters are converted to free cholesterol by lysosomal acid lipase. Because most cells do not catabolize cholesterol further, any cholesterol delivered to the cell is (1) used for membrane biogenesis, (2) stored in intracellular lipid drops after reesterification by ACAT, or (3) removed from the cell by the reverse-cholesterol transport pathway. In addition, cells have a complex mechanism involving both transcriptional and posttranscriptional regulation, so that any excess intracellular cholesterol will inhibit cholesterol biosynthesis and expression of the LDL receptor.

Reverse-Cholesterol Transport Pathway

The function of the reverse-cholesterol transport pathway is to remove excess cellular cholesterol from peripheral cells and

Copyright 1986, American Medical Association.)

return it to the liver for excretion. This process is largely mediated by HDL (Figure 23-21). Cholesterol is actively pumped out of cells by the ABCA1 transporter onto lipid-poor apo A-I, which binds to cells. This process results in the formation of disc-shaped nascent HDL, which is made in the liver and in the intestine. Discoidal HDL interacts with ABCA1 in peripheral cells, such as macrophages, and removes additional cholesterol. LCAT, which esterifies cholesterol on HDL, plays a key role in reverse-cholesterol transport, because cholesteryl esters are much more hydrophobic than cholesterol and remain trapped in the core of HDL until they are removed by the liver. The esterification of cholesterol on HDL converts the disc-shaped nascent HDL to spherical HDL. Spherical HDL, the main form of HDL in the circulation, acts as an extracellular acceptor for cholesterol that may be removed from cells by other mechanisms.

In the next stage of the reverse-cholesterol transport pathway, the liver selectively removes cholesteryl esters from the lipid-rich spherical HDL via binding of the HDL to the SR-BI receptor and lets the lipid-depleted HDL return to the circulation for additional rounds of cholesterol removal from peripheral cells. CETP also plays an important role in this pathway because a significant fraction of cholesterol that is removed from cells by HDL is transferred as cholesteryl esters onto LDL by CETP and is eventually removed from the circulation by hepatic LDL receptors.

Clinical Significance[4,6,9]

The clinical significance of lipids is primarily associated with their contribution to **coronary heart disease (CHD)** and various lipoprotein disorders. CHD is a disease in which plaque builds up inside the coronary arteries that supply oxygen-rich blood to heart muscle. Numerous studies have established that when total cholesterol and LDL cholesterol (LDL-C) concentrations are high, the incidence and prevalence of CHD are also high. In contrast to LDL-C, increased HDL cholesterol (HDL-C) concentrations have been shown to be protective for CHD in both epidemiological and clinical trial studies. Because atherosclerosis begins at an early age and can take decades to manifest clinically, measurement of plasma lipids and lipoproteins is a valuable means of identifying individuals at risk for CHD and determining the most appropriate therapy.

Genetic Disorders of Lipoprotein Metabolism

Most patients with dyslipidemia do not have a single readily identifiable genetic mutation. Because of the complexity of lipoprotein metabolism, a multitude of environmental factors and common genetic polymorphisms that vary in importance, depending on the individual, probably account for most cases of hypercholesterolemia. Many secondary causes of dyslipidemia are a consequence of relatively common disorders or conditions (Table 23-7). Although rare, established genetic causes

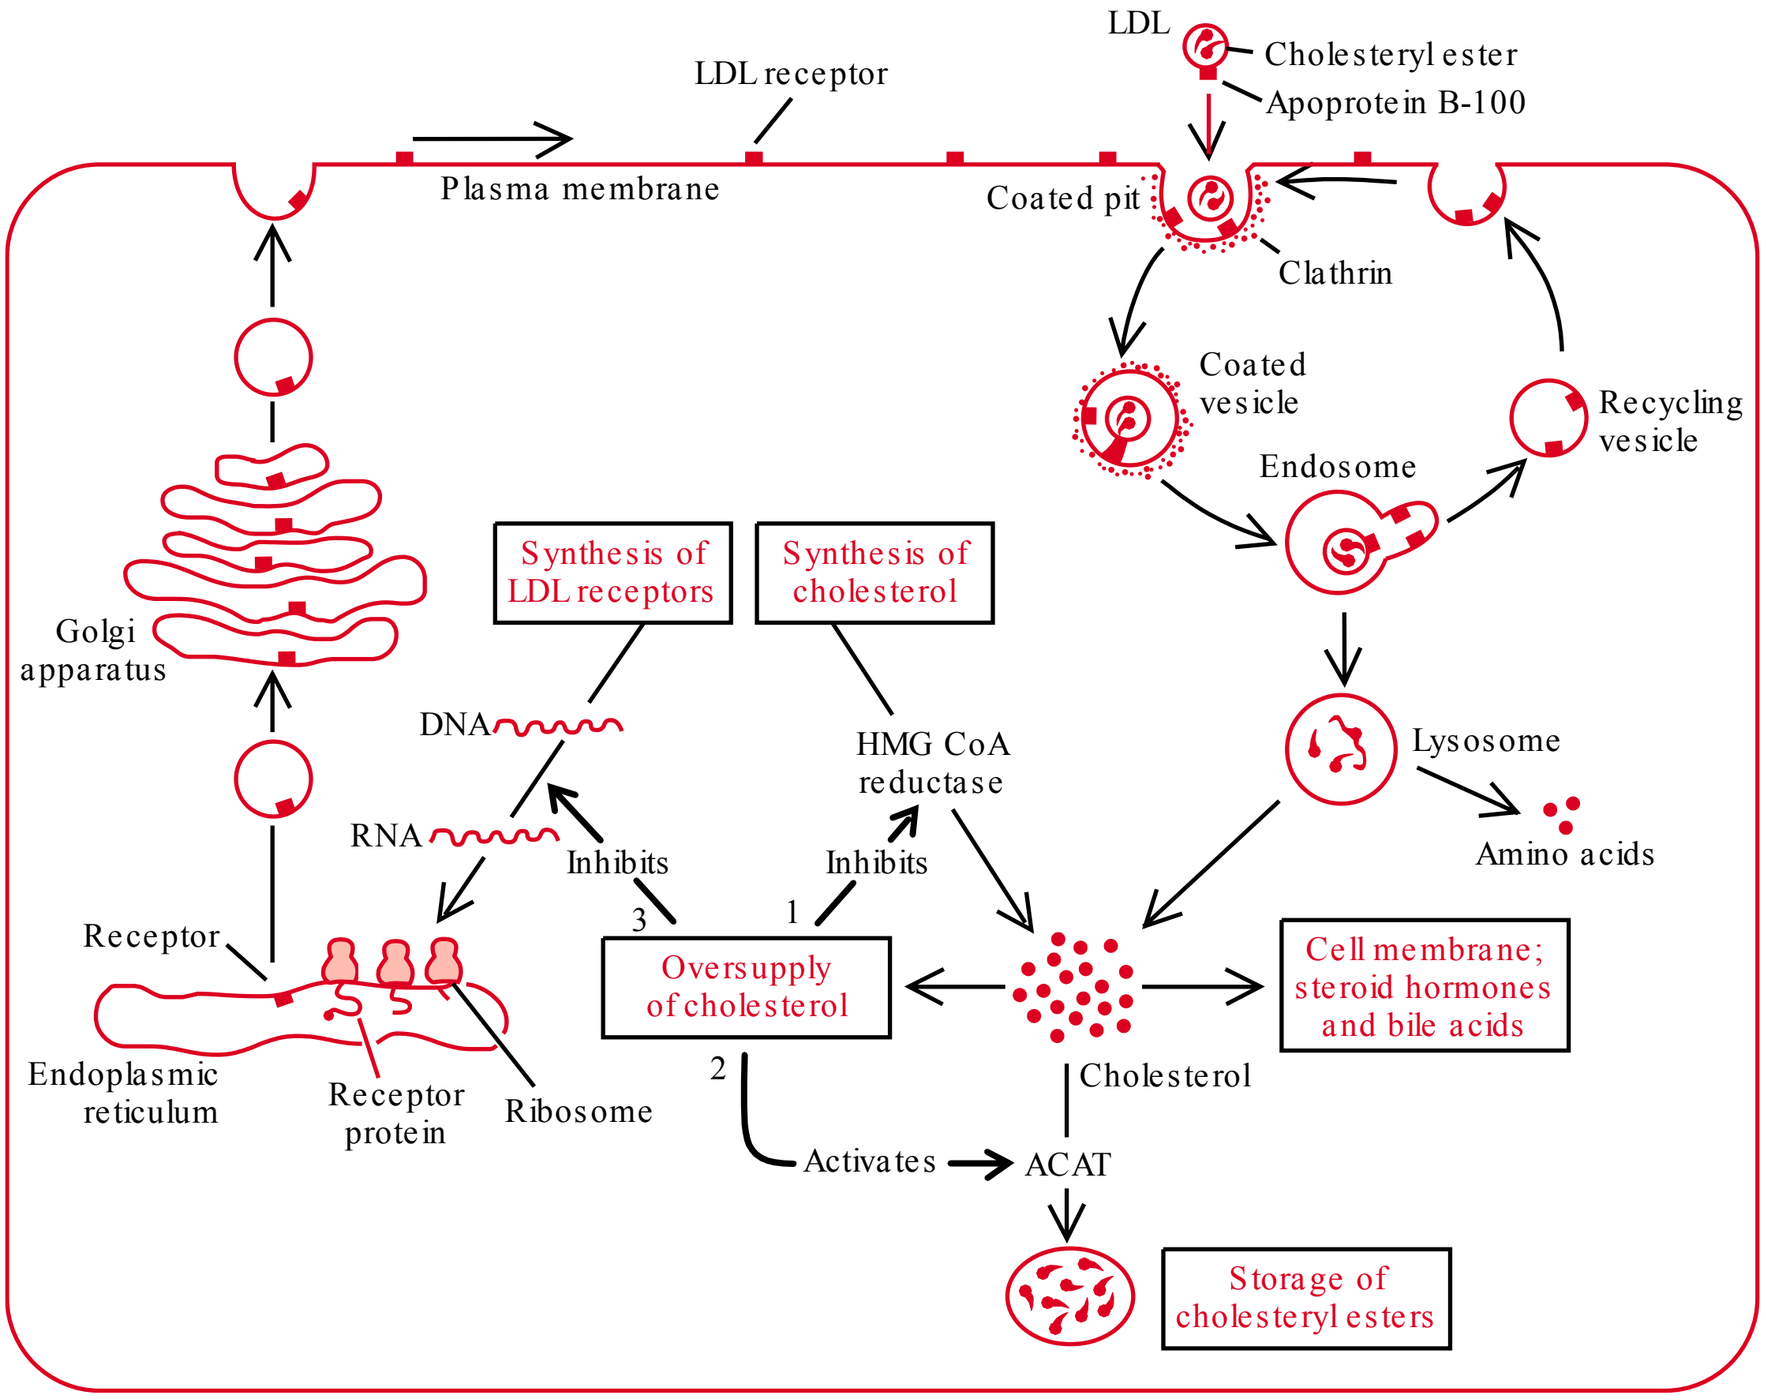

Figure 23-20 Intracellular-cholesterol transport pathway. ACAT, Acyl-CoA cholesterol acyltransferase; HMG-CoA reductase, 3-hydroxy-3-methylglutaryl coenzyme A reductase; LDL, low-density lipoprotein. Because of the presence of apolipoprotein B-100 on its surface, the LDL particle is recognized by a specifc LDL receptor in a coated pit and is taken into the cell in a coated vesicle (top right). Coated vesicles fuse together to form an endosome. The acidic environment of the endosome causes the LDL particle to dissociate from the receptors, which return to the cell surface. The LDL particles are taken to a lysosome, where apolipoprotein B-100 is broken down into amino acids and cholesterol ester is converted to free cholesterol for cellular requirements. The cellular cholesterol concentration is self-regulated. Oversupply of cholesterol will lead to (1) a decreased rate of cholesterol synthesis by inhibiting HMG-CoA reductase, (2) increased storage of cholesteryl esters by activating ACAT, and (3) inhibition of the synthesis of new LDL receptors by suppressing the transcription of the receptor gene into mRNA. (From Brown MS, Goldstein JL. How LDL receptors influence cholesterol and atherosclerosis. Sci Am 1984;251:58-66. Copyright 1984 by Scientifc American, Inc. All rights reserved.)

of dyslipidemia have been identified and are illustrative of the role of lipid metabolism in the development of atherosclerosis.

Defciency in Lipoprotein Lipase Activity

Deficient lipoprotein lipase activity due to mutations in the LPL gene is a rare autosomal recessive disorder characterized by hyperchylomicronemia (type I pattern),* with triglyceride concentrations reaching as high as 10,000 mg/dL (113 mmol/L). LPL is critical for the hydrolysis of triglycerides on chylomicrons and their subsequent conversion to chylomicron remnants. T is disorder is often first diagnosed in childhood, usually after recurrent episodes of severe abdominal pain and repeated attacks of pancreatitis. Eruptive xanthomas (a skin condition in which certain fats build up under the surface of the skin) and lipemia retinalis (a condition that occurs in patients when their plasma triglyceride concentrations exceed 2000 and 4000 mg/dL [22.6 to 45.2 mmol/L]) may be seen. T e concentration of triglycerides often shows great fluctuation in response to diet and other factors that are not well understood. Individuals with this disorder are not predisposed to atherosclerotic disease, most likely because the chylomicron particles are too large to enter the vessel wall. T e diagnosis is made by determination of LPL activity in plasma collected after heparin is injected into patients to release the LPL that is

*Both Roman and Arabic numerals are used to denote the individual conditions, but most often, Roman numerals are used. In this chapter, Roman symbols are used.

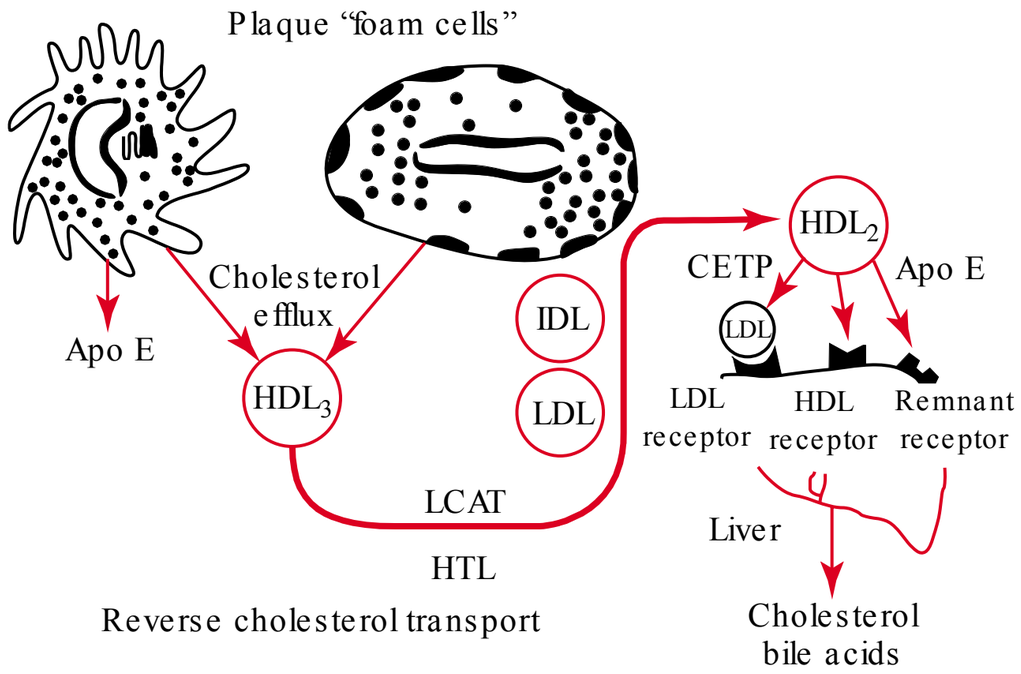

Figure 23-21 Reverse-cholesterol transport pathway. ABCA1, ATP binding cassette transporter A1; ABCG1, ATP binding cassette transporter G1; APOA-1, apolipoprotein A-1; CETP, cholesteryl ester transfer protein; HDL, high-density lipoprotein; LCAT, lecithin cholesterol acyltransferase; LDL, low-density lipoprotein; LDL-R, LDL-receptor; SR-B1, scavenger receptor B-1. After formation in the liver and intestine, nascent discoidal HDL removes cholesterol from peripheral cells by the ABCA1 transporter. Additional cholesterol can also be removed by HDL by the ABCG1 transporter and by a passive diffusion mechanism. LCAT esterifes the cholesterol content of HDL to prevent it from reentering the cells. Cholesterol esters are delivered to the liver by the SR-B1 receptor or by the LDL-R after transfer to LDL by CETP.

bound to heparin sulfates and other glycosaminoglycans on the surface of endothelial cells.

Mutations in apo C-II, the main activator of LPL, also result in impairment of chylomicron catabolism, although this usually is less severe than with LPL gene mutations. The diagnosis of this rare autosomal recessive condition is made by demonstrating low LPL activity in post-heparin plasma that is restored after the addition of apo C-II to the LPL assay mixture.

Familial Combined Hyperlipidemia

Familial combined hyperlipidemia (FCHL) accounts for as many as 10% to 15% of individuals with premature CHD. Families with FCHL often have increased plasma concentrations of total and LDL-C (type IIa) or triglyceride (type IV), or both (type IIb). Lipoprotein patterns also vary within an individual over time. In all cases, apo B-100 concentrations are increased because of overproduction. LDL particles in these patients tend to be small and dense because of a decreased lipid-to-protein ratio. LDL-C is usually only modestly increased to about 190 mg/dL (2.14 mmol/L), which is less than what is typically observed in heterozygous familial hypercholesterolemia (FH) (350 mg/dL; 3.95 mmol/L). The concentration of triglycerides usually is between 200 and 400 mg/dL (2.26 and 4.52 mmol/L) but may be significantly higher. The underlying genetic basis of FCHL is not known; it is mostly likely a polygenetic disorder.

Familial Hypertriglyceridemia

Familial hypertriglyceridemia (FHTG) is characterized by a moderate increase in serum triglycerides. Overproduction of large VLDL particles with abnormally high triglyceride content is thought to be responsible for this disorder, but decreased lipolysis is sometimes a contributory factor. Because of the hypertriglyceridemia, plasma HDL-C is often notably decreased. This disorder is inherited in an autosomal dominant pattern with delayed expression, but it is a polygenic disorder with an estimated frequency in the population of about 1 in 500.

TABLE 23-7 Causes of Secondary Hyperlipidemia and Dyslipoproteinemia

Disorder	Cause
Exogenous	Drugs: corticosteroids, isotretinoin (Accutane), thiazides, anticonvulsants, β-blockers, anabolic steroids, certain oral contraceptives
	Alcohol
	Obesity
Endocrine and metabolic	Acute intermittent porphyria
	Diabetes mellitus
	Hypopituitarism
	Hypothyroidism
	Lipodystrophy
	Pregnancy
Storage disease	Cystine storage disease
	Gaucher disease
	Glycogen storage disease
	Juvenile Tay-Sachs disease
	Niemann-Pick disease
	Tay-Sachs disease
Renal	Chronic renal failure
	Hemolytic-uremic syndrome
	Nephrotic syndrome
Hepatic	Benign recurrent intrahepatic cholestasis
	Congenital biliary atresia
Acute and transient	Burns
	Hepatitis
	Acute trauma (surgery)
	Myocardial infarction
	Bacterial and viral infections
Others	Anorexia nervosa
	Starvation
	Idiopathic hypercalcemia
	Klinefelter syndrome
	Progeria (Hutchinson-Gilford syndrome)
	Systemic lupus erythematosus
	Werner syndrome

Type V Hyperlipoproteinemia

Type V hyperlipoproteinemia is characterized by an increase in both chylomicrons and VLDL and typically presents in adults. Although its exact cause is unknown, it appears to be associated with increased production and/or decreased removal of VLDL. The activity of LPL in these individuals may be normal or low, and the plasma concentration of apo C-II is normal. Clinical presentations include (1) eruptive xanthomas, (2) lipemia retinalis, (3) pancreatitis, and (4) abnormal glucose

tolerance. Most of these patients have a modestly increased risk of cardiovascular disease.

Dysbetalipoproteinemia (Type III)

Dysbetalipoproteinemia, also called type III hyperlipoproteinemia, is caused by a defect in the removal of lipoprotein remnants from both chylomicrons and VLDL. Apo E present on the surface of lipoprotein remnant particles interacts with specific hepatic receptors and facilitates the removal of these particles. Apo E exists in three common polymorphisms or variants, designated E_2, E_3, and E_4. Some individuals with dysbetalipoproteinemia are homozygous for the apo E_2 isoform, which does not efficiently bind to hepatic remnant receptors, thus leading to accumulation of remnant particles. Although rare, genetic mutations in the APOE gene have been associated with the disorder. The remnant particles that accumulate are enriched in cholesterol, have a density less than 1.006 g/mL, and are commonly referred to as β-VLDL, or floating β-lipoprotein. Dysbetalipoproteinemia has a late onset and may manifest in patients with a secondary cause of dyslipidemia or obesity. The most distinctive clinical feature of dysbetalipoproteinemia is the presence of palmar xanthomas—yellow fat deposits in the creases of the palms. Tuberous and tuberoeruptive xanthomas may occur but are not unique to this syndrome. Premature atherosclerosis commonly develops, particularly in the lower extremities. The incidence of dysbetalipoproteinemia is approximately 0.1% in the general population. Apo E_2 homozygosity, however, is seen in about 1% of the population in North America; thus the occurrence of defective alleles is necessary but is not sufficient to produce the disorder.

Familial Hypercholesterolemia

FH is caused by defects in the LDL receptor pathway, which binds and removes LDL from the circulation. LDL thus accumulates in the plasma, resulting in its increased deposition in the skin, tendons, and arteries, where it causes atherosclerosis. LDL particles tend to be larger and carry increased amounts of cholesterol. Triglyceride concentration may be normal or only slightly increased, and HDL-C concentration is slightly decreased. Most of these patients have gene defects in the LDL receptor gene (LDLR). Less commonly, defects in two other genes, RHOA (formely called ARH-1) and PCSK9, which code for proteins involved in internalization or processing of the LDL receptor, may cause FH. Mutations in the LDL receptor gene (LDLR) and in PCSK9 are inherited in an autosomal co-dominant pattern. Homozygous FH patients are severely affected, whereas heterozygotes usually have a milder phenotype but are still clinically affected. Defects in RHOA are inherited in an autosomal recessive pattern.

Heterozygous FH due to mutations in the LDL receptor gene is one of the most common genetic disorders, with an estimated incidence of 1 in 500 in the United States. The mean plasma LDL-C in children and adult heterozygotes is usually two to three times that of normal individuals, whereas LDL-C of homozygotes is usually fourfold to sixfold above normal. In heterozygotes, xanthomas appear toward the end of the second decade of life, and clinical manifestations of atherosclerotic disease often are noted during the fourth decade. In homozygotes, cutaneous xanthomas often develop by 4 years of age, if they are not already present at birth. Left untreated, death from myocardial infarction generally occurs in homozygotes before the end of the second or third decade of life.

Familial Defective Apolipoprotein B-100

Familial defective apo B-100 is the result of mutations in the gene APOB, which reduce its affinity for the LDL receptor. LDL-C is increased, but triglycerides and HDL-C are usually within reference intervals. Like those with FH, these individuals have an increased incidence of CHD. Clinical differentiation between this disorder and heterozygous FH is sometimes difficult, but management of the two disorders is similar. The frequency of this mutation is 1:500 to 1:600 in hypercholesterolemic individuals from populations of European descent, but it is very rare in non-Europeans.

Hypoalphalipoproteinemia

Hypoalphalipoproteinemia, or low HDL-C, is caused by several genetic defects and is often but not always associated with an increased incidence of CHD. Mutations or deletions of the APOA1 gene are a rare cause of hypoalphalipoproteinemia. LCAT deficiency is also associated with low HDL. These patients often have cloudy corneas as a result of infiltration of lipid, as well as glomerulosclerosis because of the production of abnormal lipoprotein particles that become trapped in the glomerulus.

Tangier disease is a rare autosomal recessive disorder that is associated with a notable reduction in HDL. The major clinical signs of Tangier disease are (1) hyperplastic orange tonsils, (2) splenomegaly, and (3) peripheral neuropathy. Deposition of cholesteryl esters is increased in various tissues of the body, particularly macrophages, which form foam cells. Tangier disease is caused by mutations in the ABCA1 gene for the ABCA1 transporter, which mediates the first step of the reverse-cholesterol transport pathway—efflux of cholesterol from cells (see Figure 23-20).

Adult Management of Lipoprotein Disorders[4,13]

The initial diagnosis of a dyslipoproteinemia and determination of the best treatment approach for a patient have been based largely on measurements of (1) total cholesterol, (2) triglyceride, (3) HDL-C, and (4) LDL-C; this is commonly referred to as a lipid panel. Lipid and lipoprotein test results, however, must be interpreted in the context of a medical history if the risk for developing CHD is to be established. Medical history and other laboratory test results are also important for determining whether a dyslipoproteinemia is the result of a primary lipoprotein disorder or is a consequence of one or more of the secondary causes of hyperlipidemia (see Table 23-7), which, if present, should also be addressed. In contrast to most other laboratory tests, hypercholesterolemia is defined on the basis of findings from epidemiological studies that were used to establish a desirable concentration for reducing CHD risk (Table 23-8), rather than a reference study of normal

TABLE 23-8 Adult Treatment Panel (ATP) III Classification of LDL, Total, and HDL Cholesterol (mg/dL)

LDL cholesterol	<100	Optimum
	100-129	Near or above optimum
	130-159	Borderline high
	160-189	High
	≥190	Very high
Total cholesterol	<200	Desirable
	200-239	Borderline high
	≥240	High
HDL cholesterol	<40	Low
	≥60	High

HDL, High-density lipoprotein; LDL, low-density lipoprotein.
Modified from executive summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 2001;285:2486-97.

BOX 23-1 Major Risk Factors (Exclusive of LDL Cholesterol)

- Cigarette smoking
- Hypertension (blood pressure ≥140/90 mm Hg or on antihypertensive medication)
- Low HDL cholesterol (<40 mg/dL)*
- Family history of premature CHD (CHD in male first-degree relative <55 years; CHD in female first-degree relative <65 years)
- Age (men ≥45 years; women ≥55 years)

Modified from executive summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 2001;285:2486-97.

*HDL cholesterol ≥60 mg/dL counts as a "negative" risk factor; its presence removes one risk factor from the total count.
HDL, High-density lipoprotein; LDL, low-density lipoprotein.

individuals.† Cholesterol screening is recommended every 5 years for all adults over 20 years of age and should involve measurements of fasting (1) total cholesterol, (2) triglyceride, (3) HDL-C, and (4) calculated or measured LDL-C. If a fasting sample is not available initially, then only total cholesterol and HDL-C should be considered.

Next, an assessment should be made of the risk for CHD. This is based on clinical evidence of existing CHD or the presence of conditions that are closely associated with CHD, such as (1) symptomatic carotid artery disease, (2) peripheral vascular disease, and (3) abdominal aortic aneurysm, which are called CHD risk equivalents. Risk assessment for CHD is also based on the presence of known risk factors for CHD, such as (1) hypertension, (2) smoking, and (3) family history (Box 23-1). Low HDL-C is considered a risk factor, whereas high HDL-C is considered a negative risk factor.

†Several tables of population distributions of lipids have been published in Remaly AT, Rifai N, Warnick GR. Lipids, lipoproteins, apolipoproteins, and other cardiovascular risk factors. In: Burtis CA, Ashwood ER, Bruns DE, eds. Tietz fundamentals of clinical chemistry and molecular diagnostics, 5th edition. Philadelphia: Saunders, 2012:751-754.

BOX 23-2 Therapeutic Life-Style Changes for the Prevention of CHD

- Diet
  - Saturated fat <7% of calories, cholesterol <200 mg/day
  - Consider increased viscous (soluble) fiber (10 to 25 g/day) and plant stanols/sterols (2 g/day) as therapeutic options to enhance LDL lowering
- Weight management
- Increased physical activity

Modified from executive summary of the Third Report of the National Cholesterol Educational Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 2001;285:2486-97.

Therapeutic life-style changes (Box 23-2) serve as the cornerstone of therapy for lipid disorders. The concentration of LDL-C is used both to decide the most appropriate therapy and to monitor the effectiveness of treatment. Adult treatment guidelines for hypercholesterolemia are illustrated in Table 23-9. Note that aggressiveness of treatment depends on the risk category of the patient and his or her starting LDL-C concentration. Patients at highest risk for CHD (10-year risk >20%) and those who already have clinical evidence of CHD or a CHD risk equivalent have the lowest LDL-C treatment threshold and the lowest LDL-C target goal. Ideally, for such patients, LDL-C should be below 100 mg/dL (2.59 mmol/L) after therapy; this will likely involve some type of drug treatment. Patients in an intermediate risk category (10-year risk <20%) have a higher concentration for their LDL-C target goal and, in some cases, depending on their starting LDL-C, may be treated only by therapeutic life-style changes. For patients in the lowest risk category (0 to 1 risk factors), desirable LDL-C is <160 mg/dL (4.14 mmol/L), and drug therapy should be considered only if initial LDL-C is above 190 mg/dL (2.15 mmol/L). Specific recommendations have been put forth for the frequency of monitoring lipids and lipoprotein tests, and for when drug therapy should be tried for patients who do not reach their LDL-C target treatment goals with just therapeutic life-style changes.

Increased triglycerides and low HDL-C are considered conditions that independently alter the risk for CHD and may alter the recommended treatment. In both cases, however, the primary goal of therapy should be to lower LDL-C and secondarily to improve the increased triglycerides or low HDL, if these conditions persist after LDL-C is lowered. Each patient at risk for CHD should also be assessed for the presence of metabolic syndrome and should be treated for underlying causes and associated symptoms. Other newly developed lipoprotein tests, such as (1) Lp(a), (2) remnant lipoproteins, and (3) small dense LDL, and other markers, such as (4) C-reactive protein (CRP), and (5) homocysteine, may also be valuable in CHD risk stratification, particularly for patients who are at borderline or intermediate risk, based on conventional lipid and lipoprotein tests.

A wide variety of pharmacological agents for cholesterol lowering in adults are prescribed individually or in

TABLE 23-9 LDL Cholesterol Goals and Cut Points for Therapeutic Life-Style Changes (TLC) and Drug Therapy in Different Risk Categories

Risk Category	LDL Goal (mg/dL)	LDL Concentration at Which to Initiate Therapeutic Life-Style Changes (mg/dL)	LDL Concentration at Which to Consider Drug Therapy (mg/dL)
CHD or CHD risk equivalents (10-year risk >20%)	<100	≥100	≥300 (100-129; drug optional)
2+ risk factors (10-year risk ≤20%)	<130	≥130	10-year risk 10%-20%: ≥130 10-year risk <10%: ≥160
0-1 risk factor (10-year risk <10%)	<160	≥160	≥190 (160-189; LDL-lowering drug optional)

CHD, Coronary heart disease; LDL, low-density lipoprotein.
Modified from executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 2001;285:2486-97.

combination to lower LDL-C, including (1) bile acid–binding resins (cholestyramine and colestipol), (2) niacin, (3) gemfibrozil, (4) ezetimibe, and (5) HMG-CoA reductase inhibitors (e.g., atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, simvastatin, pitavastatin); agents in the latter group have been found to reduce LDL-C by as much as 40%. Some of these drugs are better tolerated by individual patients than others; all have demonstrated long-term safety in adults and have been shown to decrease CHD risk. Niacin has been the most effective therapy for raising HDL-C, but the value of raising HDL-C has been called into question by trials of the CETP inhibitors, which dramatically increase HDL-C but have not decreased CHD events.

Management of Lipoprotein Disorders in Pediatrics[9,13]

Because the process of atherosclerosis begins in children, and CHD risk factors that start in childhood, such as obesity and dyslipidemia, often persist into adulthood, it is important to identify children at risk for CHD, with the expectation that early intervention will be the most effective way to prevent future disease. T is goal has to be tempered by the concern that unlike in adults, clinical studies supporting the long-term effectiveness and safety of any type of therapy, particularly the use of lipid-lowering medications in children, are limited.

T e 2011 guidelines for cardiovascular health and risk reduction in the pediatric population from the National Heart, Lung and Blood Institute (NHLBI) are integrated guidelines that make age-specific recommendations on the multiple risk factors that contribute to CHD. T ey are aimed at primary care physicians and other health professionals who treat children. T ey provide guidance not only on the diagnosis and management of dyslipidemias but also on how to monitor (1) family history, (2) tobacco exposure, (3) degree of physical activity, (4) diet, (5) growth charts, (6) blood pressure, and (7) diabetes, as well as (8) how to educate children and parents on healthy lifestyles.

Previous guidelines did not recommend universal lipid testing and instead relied upon identifying children at risk on the basis of family history of CHD or dyslipidemia. Although family history integrates (1) genetic, (2) behavioral, and (3) environmental factors, it is often inadequate and has been shown to miss as many as half of children at risk for CHD. Current guidelines recommend universal lipid screening between ages 9 and 11, and then later between 18 and 21 years of age. Age 9 to 11 was chosen because lipids often change after puberty, and because this is the age at which children with severe lipid disorders should first be considered as possible candidates for drug therapy. Age 18 to 21 was chosen as a second time to screen because some lipid disorders do not become manifest until late teenage years or young adulthood, and because after this point in time, many individuals may not participate in lipid screening until many years later, when advanced disease has already developed. Because it is more convenient, particularly for young children, it is recommended that a nonfasting sample be analyzed to determine non–HDL-C. It is simply calculated as total cholesterol minus HDL-C and has been shown in both children and adults to be just as effective as LDL-C as a CHD risk marker. For other ages, lipid testing is recommended on a fasting sample, only if children have a strong family history of CHD and/or have a parent with a dyslipidemia or a condition that puts them at high risk for CHD, such as diabetes.

As in adult guidelines, recommended interventions are calibrated to the degree of CHD risk; and life-style changes, such as low-fat diet and increasing physical activity, are recommended first for all patients (Figure 23-22). If, after a 3-month period, life-style changes prove ineffective in reaching the LDL-C target goal, which varies depending on the overall risk, then drug treatment with a statin and/or a bile acid sequestrant should be considered for children 10 years of age or older. All children, even those younger than age 10, who present with a marked increase in serum lipids (LDL-C >250 mg/dL [6.46 mmol/L]) may have a genetic lipid disorder, should be referred to a lipid specialist, and may require additional types of drugs or other treatment approaches, such as LDL apheresis in the case of FH. Because of the high prevalence of obesity in the pediatric population, the most common pattern of dyslipidemia in children consists of (1) a moderate to severe increase in triglycerides, (2) a mild increase in LDL-C, and (3) decreased HDL-C. In general,

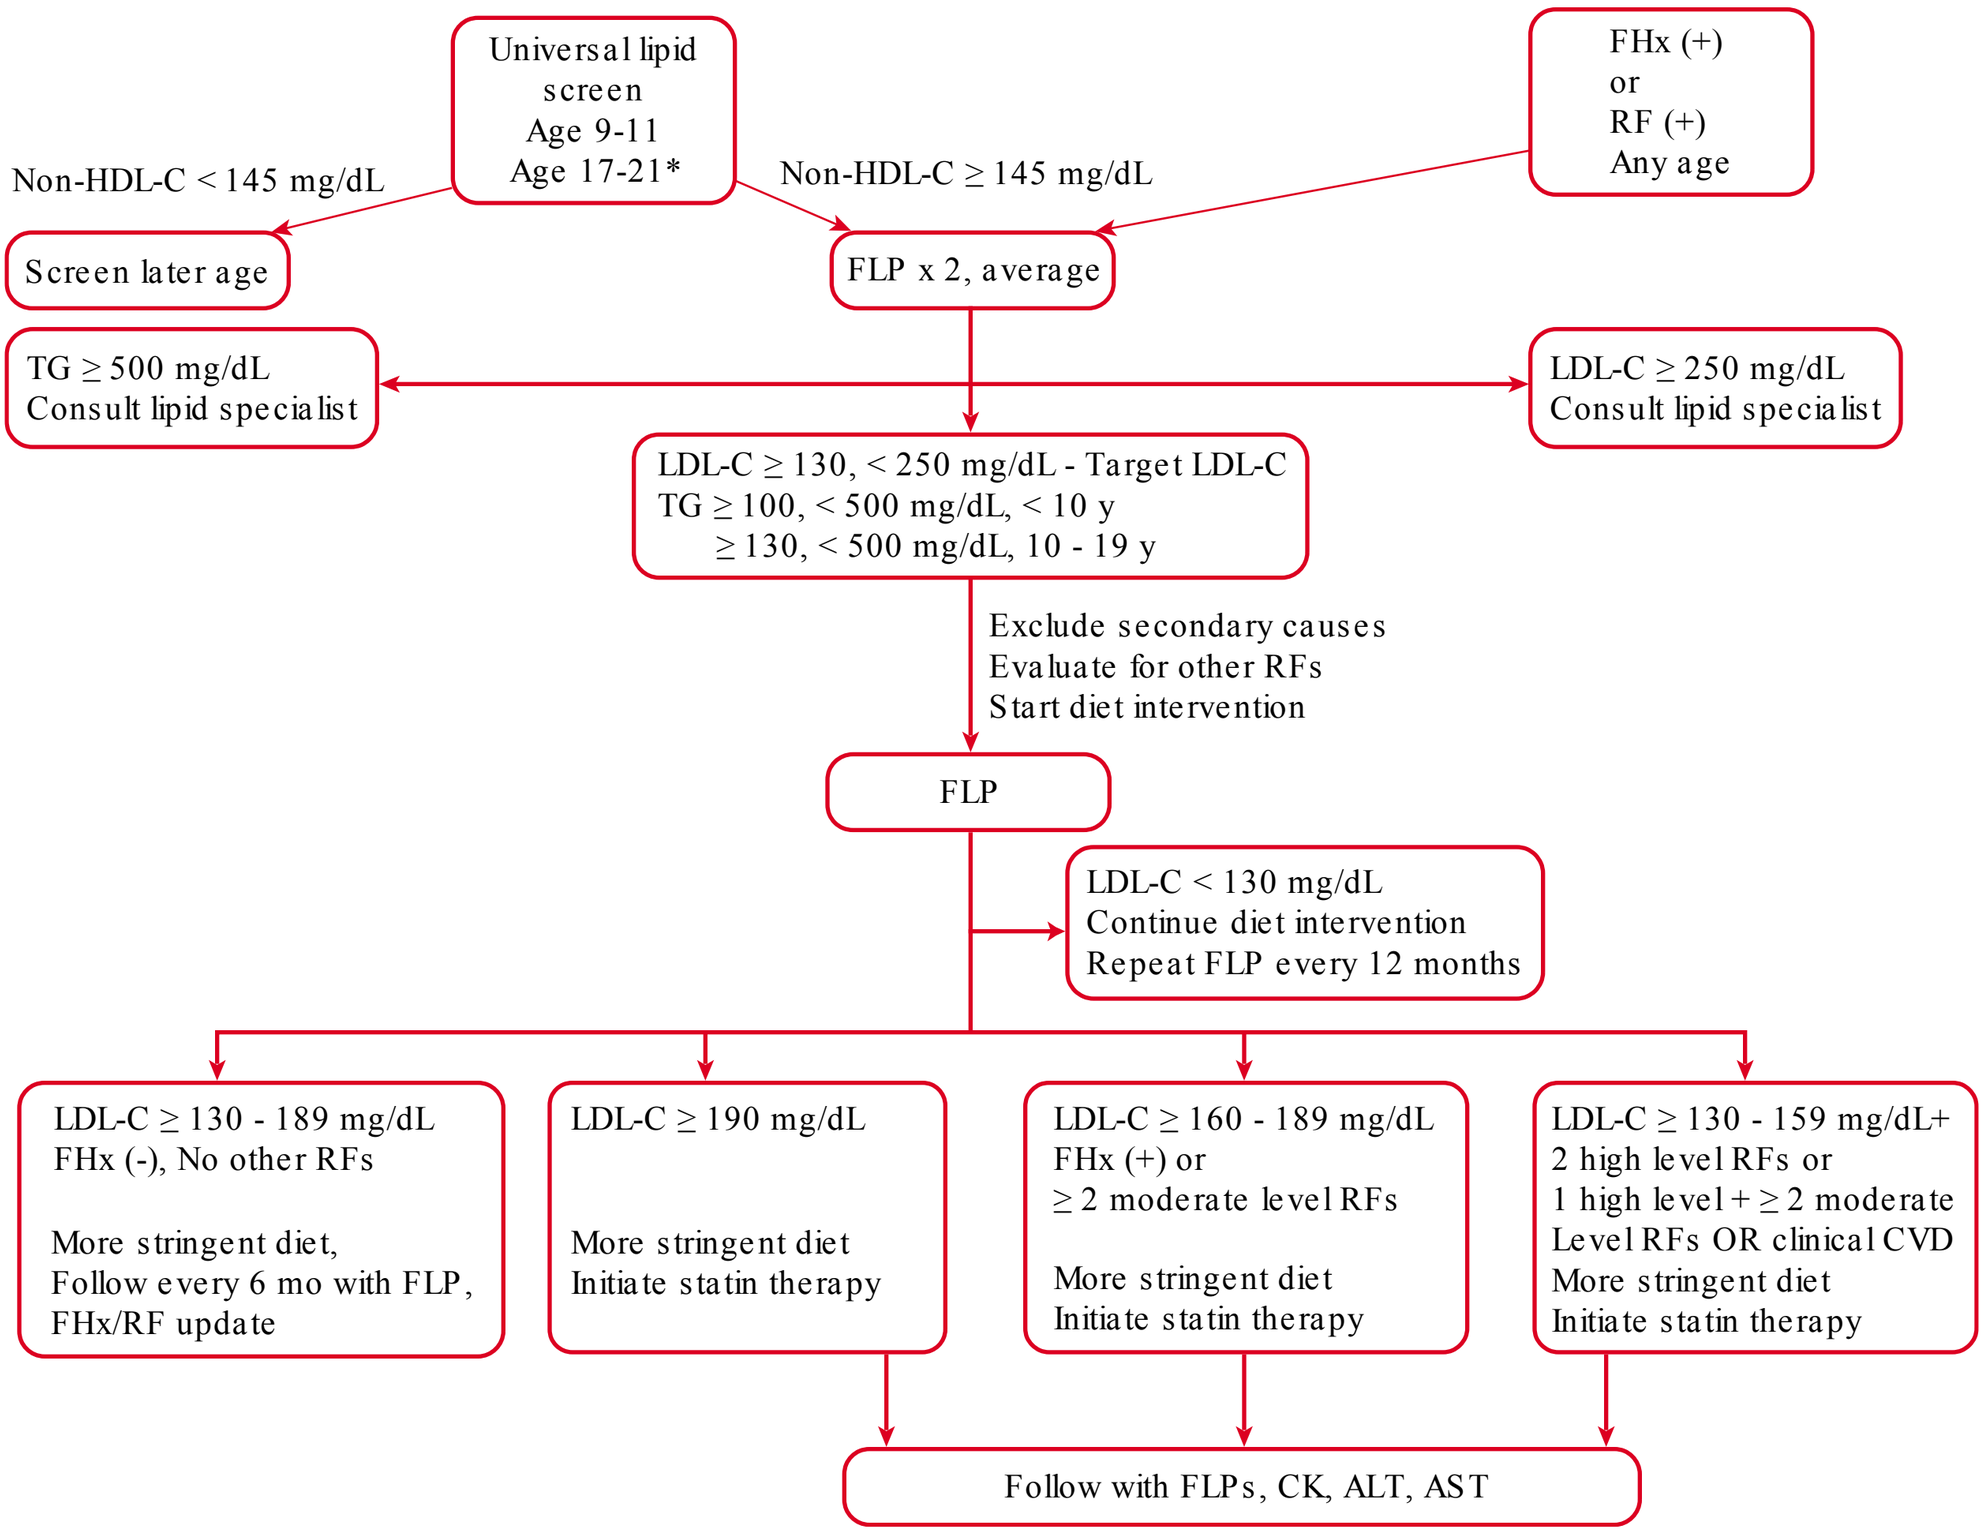

Figure 23-22 Algorithm for assessment of coronary heart disease (CHD) risk in children based on lipid screening. (Modifed from Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents. Summary report. Pediatrics 2011;128:S1-S44.) *For ages 19 to 21, non–HDL-C ≥190 mg/dL is the recommended cut point. FHx(+), Positive family history; RF, risk factor; FLP, fasting lipid profle. Other positive risk factors or risk equivalents for cardiovascular disease include RF(+). ALT, Alanine aminotransferase; AST, aspartate aminotransferase; CK, creatine kinase.

patients respond well to changes in diet and weight loss and often do not require drug therapy. Children who present with a marked increase in triglycerides to over 500 mg/dL (>5.65 mmol/L) may have a primary genetic defect, such as LPL deficiency, are at risk for pancreatitis, and should be seen by a lipid specialist. It is recommended that children treated with lipid-lowering drugs start with the lowest possible dose; when placed on statins, hepatic transaminases and creatine kinase should be measured to monitor for hepatic and muscle toxicity. Decisions about placing a child on a lipid-lowering drug should be based on an average of at least two fasting serum lipid profiles that are at least 2 weeks apart but no more than 3 months apart.

Analysis of Lipids, Lipoproteins, and Apolipoproteins[2,3,8,10,12]

As risk-related cutoff points (see Table 23-9) were developed, much effort has gone into improvement and standardization of lipid and lipoprotein assays to ensure their proper performance (Table 23-10) and to ensure comparability of test results between different methods and different clinical laboratories, thus reducing misclassification of patients' CHD risk.

TABLE 23-10 National Cholesterol Education Program Recommendations for Analytical Performance of Lipid and Lipoprotein Measurements

		Consistent With	
	Total Error (%)	Bias (%)	CV (%)
Cholesterol	8.9	≤±3	≤3
Triglycerides	≤15	≤±5	≤5
HDL cholesterol	≤13	≤±5	≤4
LDL cholesterol	≤12	≤±4	≤4

CV, Coefficient of variation; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Cholesterol Assays

Enzymatic methods have become the assays of choice for the routine measurement of cholesterol. A commonly used three-step procedure is shown below. Enzyme reagents are mixed with serum or plasma and are incubated under controlled conditions for color development; absorbance is measured in the visible portion of the spectrum, generally at about 500 nm. The reagents typically use a bacterial cholesteryl ester hydrolase to cleave cholesteryl esters:

$$\text{Cholesteryl ester} + H_2O \xrightarrow{\text{Cholesteryl ester hydrolase}} \text{cholesterol} + \text{fatty acid} \qquad (1)$$

The 3-OH group of cholesterol is then oxidized to a ketone in an oxygen-requiring reaction catalyzed by cholesterol oxidase:

$$\text{Cholesterol} + O_2 \xrightarrow{\text{oxidase}} \text{choles-4-en-3-one} + H_2O_2 \qquad (2)$$

H_2O_2 is measured in a peroxidase-catalyzed reaction that forms a colored dye:

$$H_2O_2 + \text{phenol} + \text{4-aminoantipyrine} \xrightarrow{\text{Peroxidase}} \text{quinoneimine dye} + 2\ H_2C \qquad (3)$$

Enzymatic methods are subject to interference from other colored compounds or from those that compete with the oxidation reaction, such as (1) bilirubin, (2) ascorbic acid, and (3) hemoglobin. Assays are usually linear up to about 600 to 700 mg/dL (15.54 to 18.13 mmol/L).

Triglycerides

Triglycerides are also routinely measured with enzyme reagents. Several different enzyme sequences have been used. With all of these methods, the first step is the lipase-catalyzed hydrolysis of triglycerides to glycerol and fatty acids.

$$\text{Triglyceride} + 3\ H_2O \xrightarrow{\text{Lipase}} \text{glycerol} + 3\ \text{fatty acids} \qquad (4)$$

Glycerol is then phosphorylated in an ATP-requiring reaction catalyzed by glycerokinase:

$$\text{Glycerol} + \text{ATP} \xrightarrow{\text{Glycerokinase}} \text{glycerophospate} + \text{adenosine diphosphate (ADP)} \qquad (5)$$

With the most commonly used methods, glycerophosphate is oxidized to dihydroxyacetone and H_2O_2 in a glycerophosphate oxidase–catalyzed reaction:

$$\text{Glycerophosphate} + O_2 \xrightarrow{\text{Glycerophosphate oxidase}} \text{dihydroxyacetone} + H_2O_2 \qquad (6)$$

and H_2O_2 formed in the reaction is measured as described in reaction (3).

Enzymatic triglyceride methods are fairly specific in that they do not detect glucose or phospholipids. They are linear in the concentration range up to about 700 mg/dL (7.91 mmol/L) and, when automated, are operated with coefficients of variation in the range of approximately 2% to 3%. Because glycerol is a product of normal metabolic processes, it is present in serum. Thus the measured quantity of triglycerides in serum is overestimated slightly, if not corrected for endogenous glycerol. In healthy individuals, endogenous glycerol represents the equivalent of less than 10 mg/dL (0.11 mmol/L) of triglyceride; therefore the error due to glycerol is not usually clinically significant. Some laboratories employ an alternative triglyceride assay, in which the endogenous glycerol is first "blanked out" by adjustment of the calibrators to compensate for an average bias or by enzymatic consumption of glycerol in a prereaction step before triglycerides are measured.

High-Density Lipoprotein Cholesterol

The concentration of cholesterol associated with HDL is determined after the non-HDL lipoproteins are physically removed or effectively masked.

Traditionally, non-HDL lipoproteins—VLDL, IDL, Lp(a), LDL, and chylomicrons—were precipitated with polyanions. Polyanions react with positively charged groups on lipoproteins, and this interaction is further facilitated in the presence of divalent cations, such as magnesium, to create a precipitate. The precipitate is removed by centrifuging for at least 45,000 g-minutes, and cholesterol is measured enzymatically in the supernatant. Several polyanion-divalent cation combinations have been used, including (1) heparin sulfate-$MnCl_2$, (2) dextran sulfate–$MgCl_2$, and (3) phosphotungstate-$MgCl_2$. HDL-C assays are considered inaccurate in samples containing triglyceride concentrations above 400 mg/dL (4.52 mmol/L). To minimize this problem, such samples are pretreated to remove or reduce interference by triglyceride-rich lipoproteins, which do not fully precipitate. Techniques used to pretreat samples include (1) centrifugation, (2) filtration, and (3) dilution. The preferred anticoagulant for lipoprotein measurements is ethylenediaminetetraacetic acid (EDTA) because it inhibits the oxidation of lipids and the proteolysis of apolipoproteins. However, it causes a slight dilution of about 3% when compared with lipoprotein measurements on serum, upon which current cut points are based.

Direct HDL-C assays, also known as homogeneous assays, are most commonly used to measure HDL-C. In contrast to precipitation-based assays, no physical separation of HDL from non-HDL fractions occurs. Instead, HDL-C is selectively measured by effective masking or promoting the consumption of cholesterol from non-HDL fractions so that it does not react with the enzymes used to measure cholesterol on HDL. This is achieved by a variety of methods, depending on the type of assay. For example, some assays involve the use of antibodies or various polymers or complexing agents, such as cyclodextrin, that shield the cholesterol in the non-HDL fractions from reacting with cholesterol-measuring enzymes. Some

assays depend on modifications of cholesteryl esterase and cholesterol oxidase that make them more selective for HDL-C. Finally, some assays use a blanking step that enzymatically consumes cholesterol from non-HDL fractions. Unlike with the other HDL-C assays, no sample pretreatment step is performed with direct assays and thus they can be fully automated. However, these assays sometimes show relatively poor performance compared with reference methods on dyslipidemic samples, particularly those with high triglycerides.

Low-Density Lipoprotein Cholesterol

Until recently, LDL-C was determined indirectly. In the most widely used indirect method, (1) total cholesterol, (2) triglycerides, and (3) HDL-C are measured in a fasting sample, and LDL-C is calculated from the primary measurements by the empirical Friedewald equation:

$$\text{LDL Cholesterol} = [\text{Total cholesterol}] - [\text{HDL Cholesterol}] - [\text{Triglyceride}]/5 \quad (7)$$

where all concentrations are given in milligrams per deciliter. Triglycerides/2.22 is used when LDL-C is expressed in millimoles per liter. The factor (triglycerides)/5 is an estimate of the VLDL cholesterol concentration and is based on the average ratio of triglycerides to cholesterol in VLDL.

In practice, the Friedewald equation should not be used (1) in samples that have triglyceride concentrations above 400 mg/dL (4.52 mmol/L), (2) in samples that contain significant quantities of chylomicrons (nonfasting specimen), or (3) in patients with dysbetalipoproteinemia. In these cases, the factor (triglyceride)/5 does not provide an accurate estimate of VLDL cholesterol, and this leads to large errors in calculated LDL-C. As with HDL-C, several methods are now used for the direct measurement of LDL-C. In general, these assays yield results similar to those obtained by calculating LDL-C and performing the β-quantification reference method, which is based on ultracentrifugation, but performance may not be as good on high-triglyceride samples. Evidence suggests that different direct assays may not be specific and may include some of the other apo B–containing lipoproteins or may miss some LDL subfractions, such as the more atherogenic small, dense LDLs.

Measurement of Apolipoproteins

Immunoturbidimetric and immunonephelometric assays are typically used in measuring apo A-I and apo B-100. Alternatively, more sensitive techniques, such as enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay (RIA), are usually more suitable for apolipoproteins that are present in significantly lower concentrations, such as apo C-I and apo C-II. Considerable effort has been expended in the past to standardize apo A-I and B-100 measurements, leading to significant improvement in the overall performance of these assays. Immunoassays for total apo E are not commonly done, but genotyping of apo E is used to identify the apo E_4 isoform, which is associated with increased cholesterol and risk for Alzheimer's disease.

Lipoprotein(a)

Although Lp(a) particles typically carry only a relatively small fraction of total cholesterol, these lipoprotein particles are particularly pro-atherogenic. Therefore, Lp(a) is often measured in individuals with a normal lipid panel but with a history of premature cardiovascular disease and/or a strong family history of cardiovascular disease. Turbidimetric, nephelometric, RIA, and ELISA methods are all currently used for Lp(a) measurement. Most of these assays, except for ELISA, are based on the use of polyclonal antibodies. Sandwich-type ELISAs are usually based on the use of a combination of monoclonal and polyclonal antibodies to apo B and apo(a). The immunoreactivity of antibodies directed to the repeat kringle 4 type 2 domain in apo(a) makes some Lp(a) assays vary as a function of apo(a) size. These assays tend to underestimate apo(a) concentration in samples with apo(a) of smaller size than the apo(a) present in the assay calibrator, and to overestimate the apo(a) concentration in samples with larger apo(a). Traditionally, Lp(a) concentrations have been reported in terms of total Lp(a) particle mass, or, alternatively, in terms of Lp(a) protein. If the purpose is to provide Lp(a) values that are independent of apo(a) size, it is recommended that the Lp(a) assay use antibodies directed to an apo(a) domain other than kringle 4 type 2, or to the apo B-100 component of Lp(a). This would allow the values to be expressed in nanomoles per liter. At present, Lp(a) measurements are not well standardized, but a value of about 30 mg/dL of total Lp(a) particle mass has traditionally been used as a cutoff, above which increased concentrations of Lp(a) are associated with increased risk of CHD. Because Lp(a) values vary among ethnic groups, reference values ideally should be population based. For example, African Americans in general have significantly higher Lp(a) concentrations than Caucasians.

Sources of Variation and Bias in Test Measurement

Concentrations of various lipoproteins and their constituent parts—lipids and apolipoproteins—vary within individuals (see Chapter 6). Analytical variations for such measurements are relatively small—generally about 2% to 3% coefficients of variation (CVs) for cholesterol and —but some direct measurements of LDL-C and HDL-C do not meet National Cholesterol Education Program (NCEP) guidelines for analytical performance (see Table 23-10) on dyslipidemic samples. In contrast, physiological variations are much larger and contribute to the vast majority of overall variation in lipid and lipoprotein concentrations.[14] For this reason, a patient's usual lipid or lipoprotein concentration is not reliably established from a single measurement, and the NCEP Laboratory Standardization Panel has made several specific recommendations for reducing the effects of preanalytical factors and specimen-processing procedures on lipid and lipoprotein testing.

Advanced Testing for Risk of Cardiovascular Disease[2,11]

Despite the strong association of lipid concentrations with CHD risk, it has been long recognized that half of all myocardial infarctions occur among individuals with a normal lipid

panel. Consequently, a wide variety of alternative or emerging biochemical markers and assays have been identified for possible use in better assessing cardiovascular risk. Some are based on lipids, such as LDL-P and HDL-P, which represent measurement of LDL and HDL particle number, respectively, and are performed by nuclear magnetic resonance (NMR). Some studies have shown that these tests may be superior to LDL-C and HDL-C as cardiovascular biomarkers, but findings are inconsistent. Other alternative tests are based on factors besides lipids that contribute to the development of atherosclerosis, such as plasma concentration of the amino acid homocysteine. At this time, no consensus has been reached on how most of these alternative tests are best utilized, but many studies now support the use of high-sensitivity C-reactive protein (hsCRP), a marker for inflammation, particularly for patients at intermediate risk of cardiovascular disease.

High-Sensitivity C-Reactive Protein

CRP was discovered in 1930 and was subsequently shown to be an acute-phase reactant. It is routinely monitored as an indication of infection and autoimmune disease (see Chapter 18).

Numerous epidemiological studies have demonstrated that increased serum CRP concentrations are positively associated with risk of future CHD events. These findings support the hypothesis that (1) inflammation, (2) atherothrombosis, (3) diabetes, and (4) hypertension are interrelated and share common pathogenic mechanisms.

Prospective epidemiological studies have shown that a single hsCRP measurement is a strong predictor of (1) myocardial infarction, (2) stroke, (3) peripheral vascular disease, and (4) sudden cardiac death, even in individuals with no history of heart disease. It has also been shown in prospective studies that hsCRP can be used to more accurately classify patients at intermediate risk of CHD. National guidelines for the measurement of hsCRP as a marker of CHD risk have been issued jointly by the American Heart Association and the Centers for Disease Control and Prevention (AHA/CDC). The Canadian Cardiovascular Society guidelines included hsCRP in the risk assessment of CHD and as a secondary target for treatment. An algorithm for the assessment of CHD risk that employs both hsCRP and LDL-C is shown in Figure 23-23.

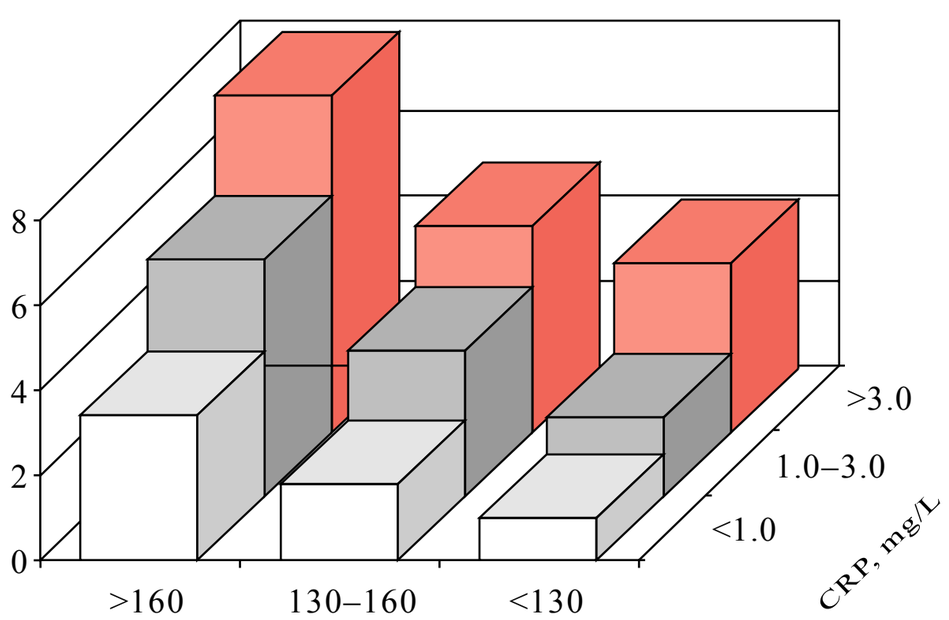

Figure 23-23 Algorithm for assessment of coronary heart disease (CHD) risk employing C-reactive protein (CRP) and low-density lipoprotein (LDL) cholesterol. (From Rifai N, Ridker PM. Population distributions of C-reactive protein in apparently healthy men and women in the United States: implication for clinical interpretation. Clin Chem 2003;49:666-9.)

Several pharmacological agents that have demonstrated cardioprotective ability, such as aspirin and statins, lower the risk of CHD that is associated with increased hsCRP concentration. In a large primary prevention trial, the reduction in risk of future myocardial infarction associated with assignment to aspirin was 56% among those with baseline hsCRP concentrations in the highest quartile and declined proportionately with hsCRP values in the lowest quartile. This suggests that aspirin may prevent ischemic events through anti-inflammatory and antiplatelet effects. All statin drugs have been shown to reduce hsCRP. Data from JUPITER, a randomized clinical trial of statin and placebo in individuals with high hsCRP but low LDL-C, show great benefit from statin therapy in terms of reducing cardiovascular events.

Methods have been developed to detect the low concentrations of hsCRP required for prediction of vascular risk. Of various techniques used to lower the limits of detection of CRP assays, the most successful approach has been to amplify the light-scattering properties of the antigen-antibody complex by covalently coupling latex particles to a specific antibody—a procedure that is easily automated on standard laboratory instrumentation. Many commercial hsCRP assays with low detection limits (<0.3 mg/L) are available, some with within-laboratory analytical imprecision of <10%.

Although it is an acute-phase reactant, hsCRP exhibits a relatively low degree of intraindividual variability in clinically stable patients. The AHA/CDC panel recommends two hsCRP measurements taken 2 or more weeks apart, with the average value used to estimate vascular risk. Furthermore, because hsCRP values are unaffected by food intake and exhibit almost no circadian variation, fasting specimens are not required.

Data from several large U.S. and European cohorts indicate that the distribution of circulating hsCRP concentrations appears comparable among men and women not using postmenopausal hormone replacement therapy (HRT), with the 50th percentile for both genders seen at about 1.5 mg/L. Concentrations of hsCRP are higher in women who use oral HRT than in women who do not. Reference values of <1, 1 to 3, and >3 mg/L, which correspond to approximate tertiles of the CRP distribution in healthy adults, are recommended by the AHA/CDC panel for classification of individuals into low, moderate, and high cardiovascular risk groups in primary prevention settings.

Review Questions

1. Which of the following formulas shows the correct calculation for indirectly measuring LDL-C (Friedewald's formula)?
   a. LDL-C = HDL-C + (Triglyceride/5)
   b. LDL-C = Total cholesterol − (HDL-C) − (Triglyceride/5)
   c. LDL-C = Total cholesterol + HDL-C + (Triglyceride/5)
   d. LDL-C = HDL-C − (Triglyceride/5)

2. The protein component of a lipoprotein is referred to as a(n):
   a. terpene.
   b. apolipoprotein.
   c. prostaglandin.
   d. phospholipid.
3. The lipoprotein that contains a carbohydrate-rich protein covalently bound to apo B-100 and a special protein motif called the "kringle" domain is:
   a. LDL.
   b. HDL.
   c. chylomicron.
   d. lipoprotein(a).
4. What lipoprotein transports mostly cholesteryl esters through the blood?
   a. LDL
   b. VLDL
   c. Chylomicrons
   d. Lipoprotein(a)
5. The enzyme that is critical for hydrolysis of triglycerides on chylomicrons for their conversion to chylomicron remnants is:
   a. cholesterol oxidase.
   b. glycerol kinase
   c. lipoprotein lipase.
   d. HMG-CoA reductase.
6. The rate-limiting enzyme in cholesterol biosynthesis that is inhibited by statin drugs is:
   a. cholesterol oxidase.
   b. glycerol kinase
   c. lipoprotein lipase.
   d. HMG-CoA reductase.
7. Which of the following lipid metabolic pathways has a role in transferring hepatically derived lipids, particularly triglyceride, to peripheral cells for energy metabolism?
   a. Exogenous pathway
   b. Endogenous pathway
   c. Intracellular-cholesterol transport pathway
   d. Reverse-cholesterol transport pathway
8. The formation of mixed micelles containing unesterified cholesterol, fatty acids, monoglycerides, phospholipids, and bile acids is referred to as:
   a. emulsification.
   b. denaturation.
   c. esterification.
   d. saturation.
9. With regard to lipids, a carboxyl (−COOH) with a long sidechain (R) containing an even number of carbon atoms that is important in human nutrition and metabolism is a type of lipid referred to as a(n):
   a. acylglycerol.
   b. ester.
   c. fatty acid.
   d. terpene.
10. In the laboratory analysis of triglycerides, the initial step in all methods is:
    a. phosphorylation of glycerol catalyzed by glycerokinase.
    b. oxidation of cholesterol by cholesterol oxidase.
    c. hydrolysis of triglyceride by lipase.
    d. reduction of phenol and H_2O_2 by peroxidase.

CHAPTER

24 Electrolytes and Blood Gases

Mitchell G. Scott, Ph.D., Vicky A. LeGrys, Ph.D., Dr.A., M.T.(A.S.C.P.), C.L.S.(N.C.A.), and Emily I. Schindler, M.D., Ph.D.

Objectives

1. Define the following terms:
   - Anion
   - Blood gas
   - Cation
   - Colligative property
   - Ion-selective electrode
   - Electrolyte
   - Electrolyte exclusion effect
   - FO_2Hb
   - Osmolality
   - Oxygen dissociation curve
   - Oxygen saturation
   - P_{50}
   - pH
   - Partial pressure
   - Pulse oximetry/Co-oximetry
   - SO_2
   - Sweat chloride test
2. For each of the following electrolytes, state and describe the biochemistry, physiological functions, localization, clinical significance, method of laboratory analysis and possible analytical interferences:
   - Bicarbonate
   - Chloride
   - Potassium
   - Sodium
3. Compare direct and indirect ion-selective electrode testing, including uses of and interferences in each method.
4. Discuss the measurement of sweat chloride, including reasons for performing, details of the three phases of testing, critical issues in each phase, and specimen requirements.
5. Describe the following methods of electrolyte/blood gas determination, including specific electrolyte(s) assessed with each, the principle of the method, specimen requirements, and possible interferences:
   - Coulometry-amperometry
   - Osmometry
   - Potentiometry
   - Sweat testing
   - Tonometry
6. List and describe the four colligative properties of a solution, including the relationship of each property to the addition of solute; state and calculate the formula for urine and plasma osmolality determination.
7. State the formula that demonstrates the relationship between total concentration of CO_2, bicarbonate, and hydrogen ion concentration.
8. State the Henderson-Hasselbalch equation and explain each of its components; characterize its application in blood gas measurements.
9. List the three essential properties of arterial blood required for adequate oxygen delivery to tissues; state the normal arteriovenous difference interval in PO_2.
10. State and explain the three approaches to determining oxygen saturation; state and calculate the formula for determining hemoglobin oxygen saturation given the concentrations of oxyhemoglobin and deoxyhemoglobin.
11. List and describe three causes of decreased arterial FO_2Hb; list and describe one cause of decreased PO_2.
12. For blood gas determinations, describe each of the following:
    - Specimen requirements
    - Preferred anticoagulant
    - Collection technique
    - Specimen transport
13. List the analytical problems that arise in the analysis of pH, PO_2, and PCO_2 with inappropriate specimen collection or transport techniques
14. Diagram a generic blood gas analyzer; state and describe the methods or calculations used to measure pH, PO_2, and PCO_2, including noninvasive and continuous monitoring methods; describe two types of controls used for blood gas analysis.
15. Assess and solve case studies involving electrolyte and blood gas analysis.

Key Words and Definitions

Anemic hypoxia Hypoxia (a reduced supply of oxygen to the tissues) resulting from a decrease in amount of hemoglobin or number of erythrocytes in the blood.

Blood gases PCO_2 and PO_2 (partial pressures of carbon dioxide and oxygen), usually in whole blood.

Colligative properties Properties of solutions that depend on the number of particles in the solution; examples include (1) osmotic pressure, (2) boiling point elevation, (3) freezing point depression, and (4) vapor pressure lowering.

Key Words and Definitions—cont'd

Cystic fibrosis (CF) Inherited disorder of a transmembrane conductance regulator protein (CFTR) that leads to chronic pancreatic and obstructive pulmonary disease.

Cystic fibrosis transmembrane conductance regulator (CFTR) A transmembrane protein produced by the CFTR gene.

Electrolytes Charged low-molecular-mass molecules present in plasma and cytosol, usually ions of (1) sodium, (2) potassium, (3) calcium, (4) magnesium, (5) chloride, (6) bicarbonate, (7) phosphate, (8) sulfate, and (9) lactate.

Electrolyte exclusion effect Electrolytes are excluded from the fraction of total plasma volume that is occupied by solids, which leads to underestimation of electrolyte concentration by some methods.

Hemoglobin (Hb) An oxygen-carrying, heme-containing protein abundant in red blood cells.

Henderson-Hasselbalch equation Equation that defines the relationship between pH, bicarbonate, and the partial pressure of dissolved carbon dioxide gas:

$$pH = pK' + \log \frac{cHCO_3^-}{(\alpha + PCO_3)}$$

Ion-selective electrode (ISE) A type of special-purpose, potentiometric electrode consisting of a membrane selectively permeable to a single ionic species. The potential produced at the membrane–sample solution interface is proportional to the logarithm of the ionic activity or concentration.

Osmolal gap A difference between the observed and calculated osmolalities in serum analysis. The calculated osmolar values include sodium concentration multiplied by 1.86, plus glucose and blood urea nitrogen, plus 9.

Osmometry Technique for measuring the concentration of dissolved solute particles in a solution.

Osmotic pressure The pressure required to stop osmosis through a semipermeable membrane between a solution and pure solvent.

Oximetry A technique used to determine the oxygen saturation of arterial blood.

Oxygen dissociation curve The sigmoidal curve obtained when SO_2 of blood is plotted against PO_2.

Oxygen saturation (SO_2) The fraction (percentage) of functional hemoglobin that is saturated with oxygen.

Oxyhemoglobin An hemoglobin that contains bound O_2.

P_{50} PO_2 for a given blood sample at which the hemoglobin of the blood is half saturated with O_2; P_{50} reflects the affinity of hemoglobin for O_2.

Partial pressure The substance (mole) fraction of gas times the total pressure; i.e., the partial pressure of oxygen, PO_2, is the fraction of oxygen gas times the barometric pressure.

pH The negative logarithm of hydrogen ion activity.

Pilocarpine iontophoresis Noninvasive method that uses electricity to force the drug pilocarpine into the skin for the purpose of inducing sweating at the site.

Point-of-care testing (POCT) Clinical testing that occurs next to the patient, usually with a handheld device and an unprocessed specimen collected immediately before testing.

Sweat chloride The concentration of chloride in sweat; increased sweat chloride is characteristic of cystic fibrosis.

Water homeostasis The body process that maintains a balance of water intake and output.

Maintenance of **water homeostasis** is paramount to life for all organisms. In humans, the maintenance of water homeostasis is primarily a function of the four major **electrolytes**: Na^+, K^+, Cl^-, and HCO_3^-. These electrolytes also have a role in acid-base balance and muscle function, as well as serving as cofactors for enzymes. Abnormal electrolyte concentrations may be the cause or the consequence of a variety of medical disorders. Because of their physiological and clinical interrelationships, this chapter discusses determination of (1) **electrolytes**, (2) **osmolality**, (3) sweat testing, (4) **blood gases** and **pH**, and (5) blood oxygenation.

Electrolytes

Electrolytes may be classified as anions, negatively charged ions that move toward an anode, or cations, positively charged ions that move toward a cathode. Important physiological electrolytes include Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, HCO_3^-, $H_2PO_4^-$, and HPO_4^{2-}. The major electrolytes (Na^+, K^+, Cl^-, HCO_3^-) occur primarily as free ions, whereas significant amounts (>40%) of Ca^{2+}, Mg^{2+}, and trace elements are bound by proteins, mainly albumin. Determination of body fluid concentrations of the four major electrolytes (Na^+, K^+, Cl^-, and HCO_3^-) is commonly referred to as an "electrolyte profile."

Specimens for Electrolyte Determination

Serum and plasma are the specimens typically analyzed for their electrolyte content. Capillary blood is another sample commonly analyzed. Heparinized whole blood arterial or venous specimens obtained for blood gas and pH determinations may also be used with direct **ion-selective electrodes (ISEs)**. Differences in values between serum and plasma and between arterial and venous samples have been documented, but only the difference between serum and plasma K^+ is considered clinically significant. Heparin, either the lithium or ammonium salt, is required if plasma or whole blood is assayed. Use of plasma or whole blood provides the advantage of shortening turnaround time because it is not necessary to wait for the blood to clot. Furthermore, plasma or whole blood provides a distinct advantage in determining K^+ concentrations, which are invariably higher in serum depending on platelet count.[13] Grossly lipemic blood can be a source of

analytical error (see "Electrolyte Exclusion Effect," later in this chapter), with some methods requiring ultracentrifugation of lipemic serum or plasma before analysis. Hemolysis of red blood cells will cause erroneously high K^+ results. In addition, unhemolyzed specimens that are not promptly processed may have increased K^+ concentrations because of K^+ leakage from red blood cells when whole blood is stored at 4 °C.

Collection of urine specimens for Na^+, K^+, or Cl^- assays should be done without the addition of preservatives. Other types of specimens used for electrolyte assays include (1) body fluid aspirates, (2) feces, (3) gastrointestinal fluid, and (4) sweat samples.

Sodium

Sodium is the major cation of extracellular fluid. Because it represents approximately 90% of the ≈154 mmol of inorganic cations per liter of plasma, Na^+ is responsible for almost one-half the osmotic strength of plasma. The daily diet of the adult male in the United States contains 3 to 6 g (90 to 250 mmol) of Na^+ (7 to 14 g of NaCl), which is nearly completely absorbed from the GI tract.[3] The body requires only 1 to 2 mmol/d, and the excess is excreted by the kidneys, which are the ultimate regulators of the amount of Na^+ (and thus water) in the body. The processes by which the kidneys regulate sodium balance are discussed in detail in Chapter 35.

Specimens

For sodium analysis, (1) serum, (2) plasma, and (3) urine specimens may be stored at 4 °C or may be frozen. Erythrocytes contain only one-tenth of the Na^+ present in plasma, so hemolysis does not cause significant errors in serum or plasma Na^+ values. Lipemic samples should be ultracentrifuged and the infranatant analyzed unless a direct ISE is used (see "Electrolyte Exclusion Effect").

Determination of Sodium in Body Fluids

Sodium may be determined (1) by atomic absorption spectrophotometry (AAS), (2) electrochemically with an Na^+-ISE, or (3) spectrophotometrically. Today, ISE methods are by far the most common. Because sodium and potassium are routinely assayed together, methods for their analysis are described together later in this chapter.

Reference Intervals

A typical reference interval for serum Na^+ is 136 to 145 mmol/L. The interval for premature newborns at 48 hours is 128 to 148 mmol/L, and the value for umbilical cord blood from full-term newborns is ≈127 mmol/L. Urinary sodium excretion varies with dietary intake, but for an adult male on an average diet containing 7 to 14 g of NaCl per day, an interval of 120 to 240 mmol/d is typical. A large diurnal variation in Na^+ excretion has been noted, with the rate of Na^+ excretion during the night being only 20% of the peak rate during the day.

Potassium

Potassium is the major intracellular cation. In tissue cells, its average concentration is 150 mmol/L, and in erythrocytes, the concentration is 105 mmol/L. High intracellular concentrations are maintained by the Na^+, K^+ adenosine triphosphate (ATP)ase pump, which is fueled by oxidative energy and continually transports K^+ into the cell against a concentration gradient. Diffusion of K^+ out of the cell into the extracellular fluid (ECF) and plasma occurs whenever pump activity is decreased.[10] The importance of these considerations for sample integrity in analysis of K^+ is discussed later. The body requirement for K^+ is satisfied by an average dietary intake of 2.4 to 4.4 g/d (60 to 120 mmol/d). Potassium absorbed from the gastrointestinal tract is rapidly distributed, and a small amount is taken up by cells, with most excreted by the kidneys.

Specimens

Comments made earlier on specimens for Na^+ analysis are generally applicable to those for K^+ analysis. However, potassium concentrations in plasma and whole blood are 0.1 to 0.7 mmol/L lower than those in serum, and most reference intervals for serum K^+ are 0.2 to 0.5 mmol/L higher than those for plasma K^+. The extent of this difference depends on the platelet count, because additional K^+ in serum is primarily a result of platelet rupture during coagulation.[13] This variability in the amount of additional K^+ in serum makes plasma the specimen of choice and emphasizes the necessity of noting on reports whether serum or plasma was assayed and using the appropriate reference interval.

Specimens for determining K^+ concentrations in serum or plasma must be collected by methods that minimize hemolysis because release of K^+ from as few as 0.5% of erythrocytes will increase K^+ values by 0.5 mmol/L. An increase in K^+ of 0.6% has been estimated for every 10 mg/dL of plasma **hemoglobin (Hb)** caused by hemolysis.[3] Therefore it is imperative that any visible hemolysis be noted with reported K^+ values with a comment that results are falsely elevated. Whenever hemolysis is suspected, a portion of the specimen should be centrifuged and visually inspected.

Preanalytical errors that are clinically significant have been observed for K^+ determinations when blood samples are not processed in a timely manner expediently. If a whole blood specimen is maintained at 4 °C versus 25 °C before separation, glycolysis is inhibited, and the energy-dependent Na^+, K^+-ATPase will not maintain the Na^+/K^+ gradient. An increase in plasma K^+ will occur as a result of K^+ leakage from erythrocytes and other cells.

The opposite effect, namely, a falsely decreased K^+ value, has been observed when an unseparated sample is stored at 37 °C because glycolysis occurs and K^+ shifts intracellularly. Even at room temperature, leukocytosis will initially cause falsely decreased K^+ concentrations. For reliable K^+ determinations, it is recommended to (1) collect blood with heparin, (2) maintain it near 25 °C, and (3) separate the plasma within minutes by high-speed centrifugation without cooling. In practical terms, separation within 1 hour when samples are maintained at room temperature is unlikely to introduce great error.

Finally, skeletal muscle activity causes K^+ ions to move from muscle cells into plasma that results in a marked elevation in plasma K^+ values, such as when an upper arm tourniquet is

not released before the beginning of blood draw after a patient clenches his fist repeatedly.[8]

Reference Intervals

Reported reference intervals for serum vary from 3.5 to 5.1 mmol/L for adults and from 3.7 to 5.9 for newborns. For plasma, a frequently cited interval is 3.4 to 4.8 mmol/L for adults. Cerebrospinal fluid concentrations are ≈70% those of plasma. Urinary excretion of K^+ varies with dietary intake, but a typical interval observed in an average diet is 40 to 90 mmol/d. Fecal excretion has been reported as 18.2 ± 2.5 mmol/d, but in severe diarrhea, gastrointestinal loss may be as much as 60 mmol/d.

Methods for the Determination of Sodium and Potassium

Ion-selective electrodes and spectrophotometric assays are the techniques of choice to measure sodium and potasium.

Ion-Selective Electrodes

Analyzers connected to ISEs usually contain Na^+ electrodes with glass membranes and K^+ electrodes with liquid ion exchange membranes that incorporate valinomycin. These are potentiometric devices (see Chapter 10) that determine the change in electromotive force (E, potential) in a circuit between a measurement electrode (the ISE) and a reference electrode, as the selected ion interacts with the membrane of the ISE. Operationally, the measuring system is calibrated by the introduction of calibrator solutions containing defined amounts of Na^+ and K^+. The potentials of the calibrators are determined, and the $\Delta E/\Delta$ log concentration responses are stored in microprocessor memory as a comparison for calculating unknown concentration when E of the unknown is measured. Frequent calibration, initiated by the user or by microprocessor-controlled uptake of sample from a reservoir of the calibrator, is typical of most current ISE systems. Some instruments, particularly **point-of-care testing (POCT)** devices and many blood gas analyzers, are designed to measure Na^+ and K^+ in whole blood.

Both indirect and direct methods are used with ISE electrodes. With indirect ISE methods, the sample is introduced into the measurement chamber after mixing with a large volume of diluent. Indirect ISE methods are used most commonly on today's automated, high-throughput clinical chemistry systems. With direct ISE methods, the sample is presented to the electrodes without dilution. This approach became possible with the miniaturization of electrodes. Direct ISEs are most common in blood gas analyzers and point-of-care devices in which whole blood is directly presented to the electrodes.

Errors observed in the use of ISEs are due to (1) lack of selectivity, (2) repeated protein coating of the ion-sensitive membranes, or (3) contamination of the membrane or salt bridge by ions that compete or react with the selected ion and thus alter the electrode response.

Spectrophotometric Methods

Spectrophotometric methods fall into two categories: (1) those based on enzyme activation, and (2) those that detect the spectral shift produced when Na^+ or K^+ binds to a macrocyclic chromophore. The high cost of reagents for these methods and the fact that few problems are associated with ISE methods have resulted in small "niche" use of these methods, primarily with smaller instruments used in physicians' offices or clinics.

Electrolyte Exclusion Effect[1]

The electrolyte exclusion effect describes the exclusion of electrolytes from the fraction of the total plasma volume that is occupied by solids. The volume of total solids (primarily protein and lipid) in an aliquot of plasma is approximately 7%, so that ≈93% of plasma volume is actually water. The main electrolytes (Na^+, K^+, Cl^-, and HCO_3^-) are confined to the water phase. When a fixed volume of total plasma (e.g., 10 µL) is pipetted for dilution before indirect ISE analysis, only 9.3 µL of plasma water that contains the electrolytes is added to the diluent. Thus a concentration of Na^+ determined by indirect ISE to be 140 mmol/L is the concentration in the total plasma volume, not in the plasma water volume. In fact, if the plasma contains 93% water, the concentration of Na^+ in plasma water is [140 × (100/93)], or 150 mmol/L. This is negative "error" in plasma electrolyte analysis has been recognized for many years. Even though it is the electrolyte concentration in plasma water that is physiological (the Na^+ concentration of normal saline is indeed 150 mmol/L), it was assumed that the volume fraction of water in plasma is sufficiently constant that this difference could be ignored. In fact, all electrolyte reference intervals are based on this assumption and actually reflect concentrations in total plasma volume, not in water volume. Indeed, virtually all concentrations measured in the clinical chemistry laboratory are related to the total sample volume rather than to the water volume. This electrolyte exclusion effect becomes problematic when pathophysiological conditions are present that alter the plasma water volume, such as hyperlipidemia or hyperproteinemia. In these settings, falsely low electrolyte values are obtained whenever samples are diluted before analysis, as with an indirect ISE method (Figure 24-1).[1]

It is the dilution of total plasma volume and the assumption that plasma water volume is constant that render the indirect ISE the method subject to the electrolyte exclusion effect. Direct ISE methods still determine the concentration relative to activity but do not require sample dilution. Because no dilution occurs, activity is directly proportional to the concentration in the water phase, not the concentration in the total volume. To ensure that results from direct ISEs are equivalent to those from indirect ISEs, most direct ISE methods actually operate in what is commonly referred to as the "flame mode."* In this mode, the directly measured concentration in plasma water is multiplied by the average water volume fraction of plasma (0.93). Although the latter may vary widely, as long as the activity of the specific ion is constant, the concentration of the ion in the water phase

*In the "flame mode", results were obtained with the traditional technique of flame photometry. Results for these analytes were expressed in terms of substance concentration. In current practice, the technique of flame photometry is no longer used in clinical laboratories.

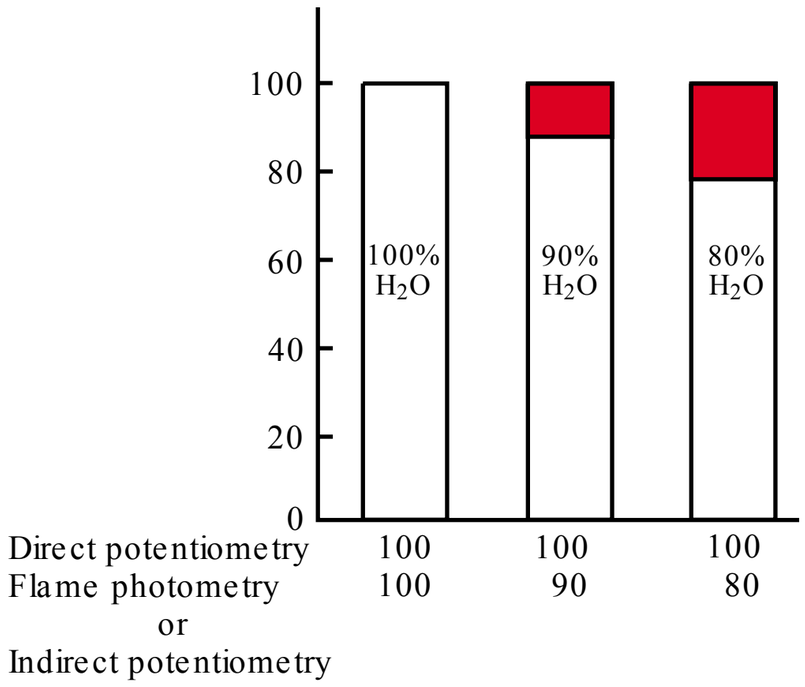

Figure 24-1 Predicted influence of water content on sodium measurements for a 100 mmol/L NaCl solution by direct ion-selective electrode (ISE) versus flame emission photometry or indirect ISE. Red areas represent nonaqueous volumes, which could consist of lipids, proteins, or even a slurry of latex or sand particles. (Adapted from Apple FS, Koch DD, Graves S, Ladenson JH. Relationship between direct-potentiometric and flame-photometric measurement of sodium in blood. Clin Chem 1982;28:1931-5.)

becomes independent of the relative proportions of water and total solids if the ion is not bound by proteins. Therefore direct ISE methods are free of electrolyte exclusion effects.

Most clinical chemists and physicians have reached the conclusion that direct ISE methods for electrolyte analysis are the methods of choice. However, it is clear that results from direct methods will continue to be converted to total plasma volume concentrations by use of the "flame mode," and indeed this is the recommendation of the Clinical Laboratory and Standard Institute (CLSI). Table 24-1 and Table 24-2 summarize methods that are and are not subject to electrolyte exclusion effects, respectively.

TABLE 24-1 Methods Measuring Concentration in the Whole Sample Volume and Thus Subject to Electrolyte Exclusion Effect

Method	Analytes
Atomic absorption spectrometry	Ca^{2+}, Mg^{2+}, and others
Amperometry/coulometry	Cl^-
Indirect potentiometry	Na^+, K^+, Ca^{2+}, Cl^-

TABLE 24-2 Methods Measuring Activity, Molality, or Concentration in the Water Phase and Thus Not Subject to Electrolyte Exclusion Effect

Method	Analytes
ISEs with undiluted sample	H^+ (pH), Na^+, K^+, Ca^{2+}, Cl^-, Li^+
Gas electrodes	CO_2 (PCO_2), O_2 (PO_2)
	HCO_3^- (calculated from pH and PCO_2)
Freezing point depression	H_2O (osmolality)

ISE, Ion-selective electrode.

Chloride

Chloride is the major extracellular anion; like Na^+, it is significantly involved in the maintenance of (1) water distribution, (2) osmotic pressure, and (3) anion-cation balance in the ECF. In contrast to its high ECF concentrations (≈103 mmol/L), the concentration of Cl^- in the intracellular fluid of erythrocytes is 45 to 54 mmol/L, and only 1 mmol/L in the intracellular fluid in most other tissue cells. Chloride ions are almost completely absorbed from the intestinal tract and excreted by the kidneys.

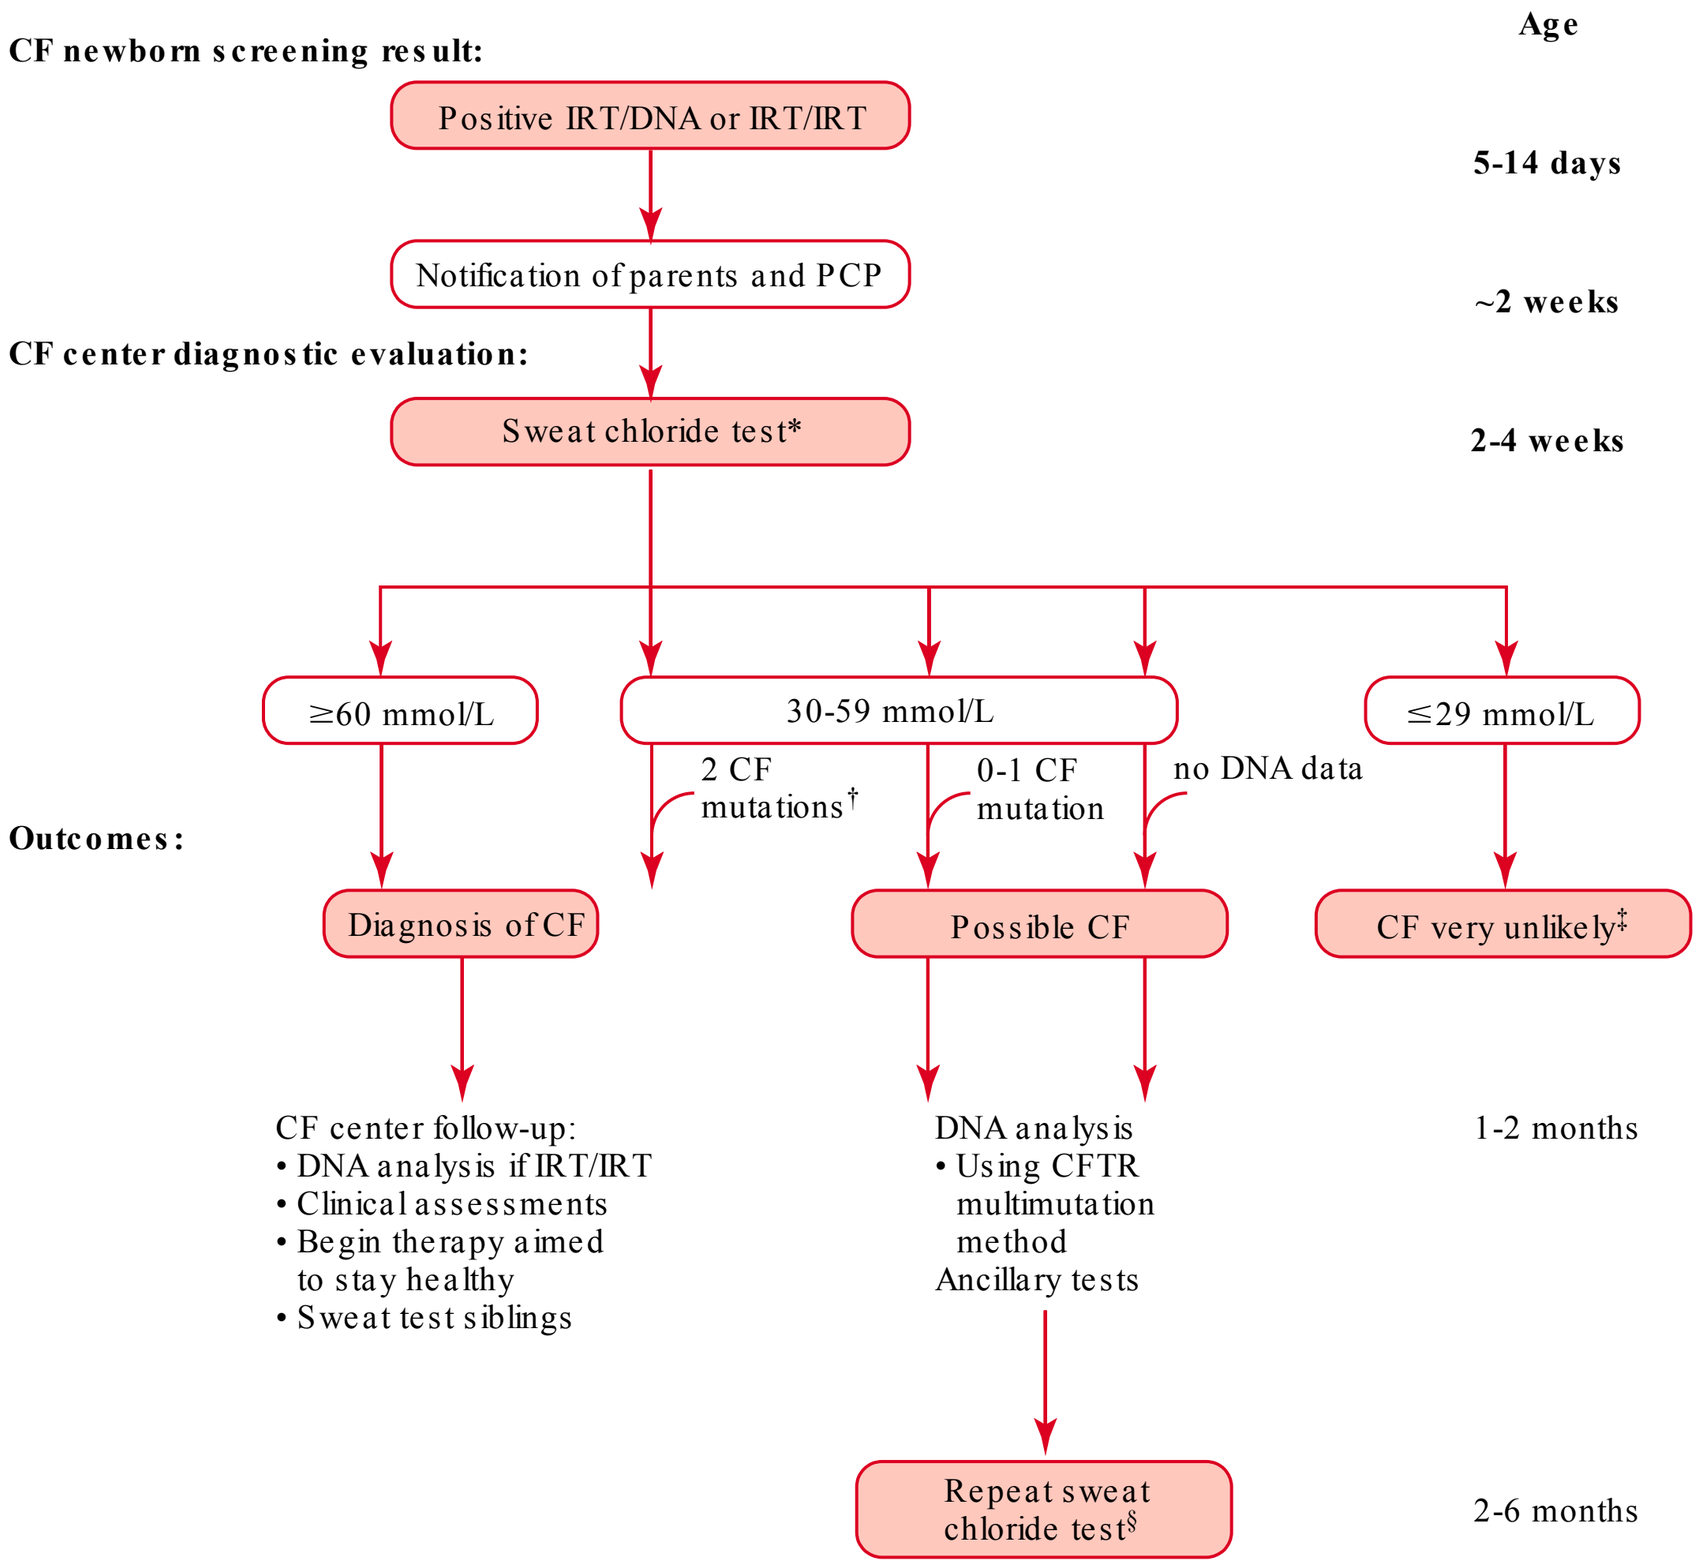
Specimens

Chloride most often is measured in (1) serum. (2) plasma, (3) urine, or (4) sweat. Even gross hemolysis does not significantly alter serum or plasma Cl^- concentration because the erythrocyte concentration of Cl^- is approximately half that of plasma. Because very little Cl^- is protein bound, change in posture or stasis, or the use of tourniquets, has little effect on its plasma concentration.

Methods for Determination of Chloride in Body Fluids

Historically, chloride was measured in body fluids and solids by mercurimetric titration and spectrophotometric methods. As these methods are no longer used, coulometric-amperometric titration and ISEs are now the methods of choice

Coulometric-Amperometric Titration



Reactions in coulometric-amperometric determinations of Cl^- depend on the generation of Ag^+ from a silver electrode at a constant rate and on the reaction of Ag+ with Cl^- in the sample to form insoluble silver chloride (AgCl):

$$Ag^+ + Cl^- \rightarrow AgCl$$

After the stoichiometric point is reached, excess Ag^+ in the mixture triggers shutdown of the Ag^+ generation system. A timing device records elapsed time between the start and stop of Ag^+ generation. Because the time interval is proportional to the amount of Cl^- in the sample, the concentration of Cl^- is then calculated. Applications of the coulometric-amperometric principle (often called the Cotlove chloridometer technique) are the most precise methods for measuring Cl^- over the entire range of concentrations found in body fluids.

Ion-Selective Electrode Methods

Solvent polymeric membranes that incorporate quaternary ammonium salt anion exchangers, such as tri-n-octylpropylammonium chloride decanol, are used to construct Cl^--selective electrodes in clinical analyzers. Although they are by far the most common methods of measuring Cl^- in clinical laboratories, these electrodes often suffer from membrane instability and lot-to-lot inconsistency in terms of selectivity for other anions. Anions that tend to be problematic include other halides and organic anions, such as SCN^-, which are particularly problematic because of their ability to solubilize in the polymeric organic membrane of these electrodes.

*If the baby is at least 2 kg and more than 36 weeks gestation at birth, perform bilateral sweat sampling/analysis with either Gibson-Cooke or Macroduct® method; repeat as soon as possible if sweat quantity is less than 75 mg or 15 μl, respectively.

†CF mutation refers to a CFTR mutant allele known to cause CF disease.

‡The disease is very unlikely; however, if there are 2 CF mutations in trans, CF may be diagnosed.

§After a repeat sweat test, further evaluation depends on the results as implied above.

Figure 24-2 Diagnostic algorithm for cystic fibrosis (CF) after newborn screening. (From Farrell PM, Rosenstein BJ, White TB, et al; Cystic Fibrosis Foundation. Guidelines for diagnosis of cystic fibrosis in newborns through older adults: Cystic Fibrosis Foundation consensus report. J Pediatr 2008;153:S4-S14.)

Reference Intervals

Reported reference intervals for Cl^- in serum or plasma vary from 98 to 107 mmol/L to 100 to 108 mmol/L. Serum values vary little during the day. Spinal fluid Cl^- concentrations are ≈15% higher than those in serum. Urinary excretion of Cl^- varies with dietary intake, but an interval of 110 to 250 mmol/d is typical.

Measurement of Sweat Chloride (Sweat Testing)

Analysis of sweat for increased chloride concentration is used to confirm the diagnosis of **cystic fibrosis (CF)**. CF is the most common lethal genetic disorder of the Caucasian population, with a wide spectrum of clinical presentations, including chronic obstructive pulmonary disease and pancreatic insufficiency. CF is caused by a defect in the **cystic fibrosis transmembrane conductance regulator protein (CFTR)**, a protein that normally regulates electrolyte transport across epithelial membranes. More than 1500 mutations of CFTR have been identified. Although direct mutational analysis is available, it is not informative in all cases, and a quantitative **sweat chloride** test remains the standard for diagnostic testing. In an effort to standardize testing, the CLSI developed the guidelines document C34-A3.[5]

Sweat testing is often performed in conjunction with newborn screening programs (Figure 24-2). Newborn screening for CF occurs throughout the United States and the world.

Most newborn screening protocols begin with an immunoreactive trypsinogen assay (IRT) from a dried blood spot and are followed by a second IRT or DNA testing.[7] Infants with a positive newborn screening test are referred for a quantitative sweat chloride test, which has resulted in an increase in the number of sweat tests performed on individuals younger than 2 months of age.

The sweat test is performed in three phases: (1) sweat stimulation by **pilocarpine iontophoresis**, (2) collection of the sweat, and (3) qualitative or quantitative analysis of sweat chloride, sodium, or conductivity.

Sweat Stimulation and Collection

Because of transient increases in sweat electrolytes shortly after birth, individuals should be at least 48 hours old before a sweat chloride test is performed. The child should be (1) physiologically and nutritionally stable, (2) thoroughly hydrated, and (3) free of acute illness. The skin should be free of cuts, rashes, and inflammation to avoid contamination of the sweat sample with serous fluid. For example, sweat testing never should be performed over an area of eczema.

Stimulation. To stimulate sweat, localized sweating is produced by pilocarpine iontophoresis into an area of the skin. Iontophoresis uses a small electrical current to deliver pilocarpine into the sweat glands from the positive electrode, while an electrolyte solution at the negative electrode completes the circuit. Note: Although the Occupational Safety and Health Administration (OSHA) does not list sweat as potentially infectious, laboratory personnel should practice the same universal precautions they would use with any other body fluid.

Collection. After iontophoresis, sweat is collected onto (1) preweighed gauze pads, (2) filter paper, (3) Macroduct coils,[11] or (4) Nanoduct conductivity sensor cells using techniques to minimize evaporation and contamination. If sweat is collected onto gauze or filter paper, the electrodes usually are made of copper and are slightly smaller than the stimulation and collection area. The composition of the electrolyte solution should be selected to avoid contamination with the sweat sample. Before collection is performed, the gauze or filter paper used for sweat collection should be placed into a weighing vial with a secure sealing lid, and the vial labeled and weighed with an analytical balance. For a detailed procedure for stimulation and collection, the reader should refer to the CLSI document C34-A3.[5]

Alternatively for sweat stimulation, the electrodes and the current source are integrated, as they are in the Wescor Macroduct and Nanoduct systems (http://www.wescor.com/; accessed September 30, 2015), which use gel reagents containing pilocarpine. In the Macroduct system, sweat is collected in a disposable microbore-tubing coil collector.[11] After sufficient sweat has been collected, the sweat is transferred from the coil into a sealable microsample cup. The Nanoduct system employs an integrated conductivity cell sensor in the single-use collection device.

Critical Issues Associated With Sweat Stimulation and Collection. During collection, the analyst must (1) avoid evaporation and contamination of the sample, (2) collect a sufficient amount of sample, and (3) minimize skin reactions. Determination of and adherence to a minimum sweat weight or volume are critical to obtain valid sweat testing results. The requirement for a minimum amount ensures an appropriate sweat rate and sweat electrolyte concentration and is independent of the instrument used to measure sweat electrolytes. Unfortunately, many laboratorians misunderstand the necessity of collecting the correct volume, leading to false-positive and false-negative sweat tests, which have significant implications for patient care.

Sweat electrolyte concentration is related to sweat rate. At low sweat rates, sweat electrolyte concentration decreases and the opportunity for sample evaporation increases. To ensure a valid result, the average sweat rate should exceed 1 g/m^2/min. To standardize and simplify the collection process, the size of the (1) electrodes, (2) reagent pads, and (3) collection material must be approximately the same. Insufficient samples must not be pooled for analysis.

When the acceptable rate is applied to the parameters described in the CLSI document, the minimum acceptable sample for analysis from a single site with use of 2 × 2-inch gauze or filter paper for stimulation and collection is 75 mg of sweat collected within 30 minutes.When the collection process deviates from standard parameters, the minimum acceptable sweat volume or weight changes, and sweat should be collected for only 30 minutes. If the collection time exceeds 30 minutes, the requirement for the amount of sweat needed to ensure adequate stimulation must increase. Extending the collection time allows additional opportunity for sweat evaporation and, practically, does not significantly increase the sweat yield.

Acquiring the minimum sample should not be a problem with most patients if the the CLSI[5] and the manufacturer's recommendations are followed. On average, the percentage of insufficient samples should not exceed 5% for patients older than 3 months of age and 10% for patients 3 months of age or younger.[5,12] If the laboratory collects sweat from two sites (bilateral testing), the test is considered QNS (quantity not sufficient) only when both sites are inadequate. Insufficient sweat samples result from several factors, such as (1) age, (2) race, (3) skin condition, and (4) hydration status. Also, collecting an adequate amount of sweat is more challenging in patients younger than 1 month of age.[12] For this reason, it is recommended that sweat testing in asymptomatic individuals be performed when the infant (1) is at least 2 weeks of age, (2) was more than 36 weeks' gestation at birth, and (3) weighs more than 2 kg.[5,12] If an adequate sweat sample is not obtained, the test should be repeated as soon as is practical.

Burns to the patient's skin after iontophoresis are extremely rare but have occurred at either electrode. If the burn occurs at the site of pilocarpine stimulation, sweat should not be collected.

Qualitative Tests

A qualitative sweat test represents a screening test for CF. Individuals who have positive or borderline results should

then undergo quantitative sweat chloride testing. Examples of screening tests include Wescor Sweat-Chek and Nanoduct for conductivity. Screening tests may or may not measure the amount of sweat collected and may report a result as positive, negative, or borderline or give an actual concentration of sweat analytes. Although a variety of systems are used for sweat testing, problems have been documented for several methods, making them inappropriate for clinical use. For example, older conductivity analyzers using unheated collection cups and direct application chloride electrodes are not recommended as diagnostic procedures because problems have been reported with (1) sample evaporation, (2) condensation, and (3) the ability to quantify sweat samples adequately.

The Cystic Fibrosis Foundation has approved the Wescor Macroduct Sweat-Chek for screening at clinical sites, such as community hospitals, using the criterion that an individual who has a sweat conductivity of 50 mmol/L or greater should be referred to an accredited CF care center for a quantitative sweat chloride test. Note that sweat conductivity methods produce values that are approximately 15 mmol/L higher than those associated with sweat chloride concentration. Because of this difference, laboratories should not report conductivity results as if they were chloride results. In addition to conductivity results (in mmol/L), the report should include sweat conductivity reference intervals.

Quantitative Tests

The diagnosis of CF includes a quantitative measurement of sweat chloride, which consists of (1) collection of sweat into gauze, filter paper, or Macroduct coils; (2) evaluation of the amount collected in weight (milligrams) or volume (microliters); and (3) subsequent measurement of the sweat chloride concentration.[9] In general, chloride concentration is determined by coulometric titration with a chloridometer. If a laboratory chooses to quantify sweat chloride with an automated analyzer that employs an ISE, these methods must be validated systematically for accuracy, precision, and lower limit of detection. For any given method, the lower limit of the analytical measurement range for sweat chloride on unadulterated sweat should be less than or equal to 10 mmol/L.

Reference Intervals for Sweat Chloride

Reference intervals for sweat chloride must be stratified by patient age.[9]

Infants

For infants 6 months of age or younger, the following reference intervals are recommended.[9]

≤29 mmol/L: CF unlikely
30 to 59 mmol/L: intermediate
≥60 mmol/L: indicative of CF

However, as data continue to be generated from newborn screening programs, these reference intervals may have to be adjusted.

Beyond Infancy

For individuals older than 6 months, the following reference intervals are recommended[9]:

≤39 mmol/L: CF unlikely
40 to 59 mmol/L: intermediate chance of CF
≥60 mmol/L: indicative of CF

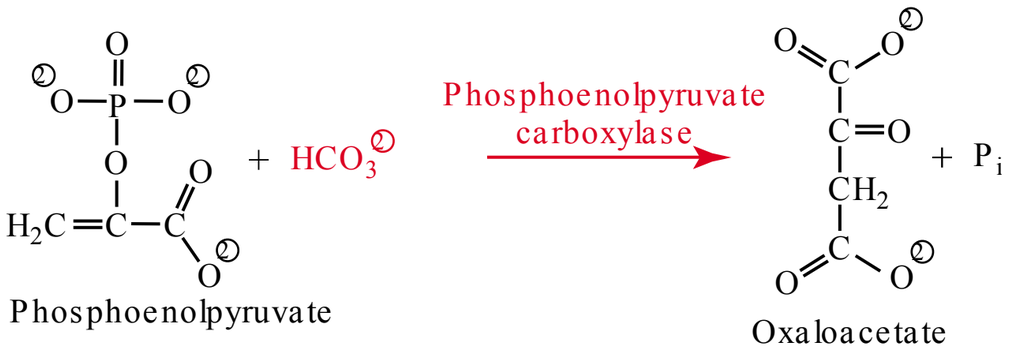
A healthy sweat chloride concentration alone is insufficient to rule out the diagnosis; it should be interpreted in light of the clinical picture and with the knowledge that "normal" concentrations have been associated with CF. Several mutations of the CF gene are associated with intermediate or normal sweat chloride concentrations.

Quality Assurance

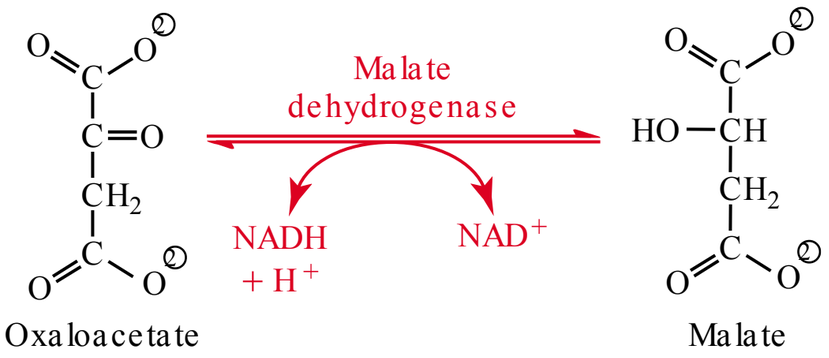
Laboratories that provide high-quality sweat testing should (1) select appropriate methods, (2) have sufficient testing volumes to ensure familiarity with the test, and (3) limit testing personnel to a small number of well-trained individuals. To monitor the accuracy and precision of the analytical process, two concentrations of controls should be performed daily when patient samples are analyzed. Sweat chloride concentrations greater than 160 mmol/L are not physiologically possible and represent specimen contamination or analytical error. An important part of a quality assurance plan includes method validation and external validation of sweat analysis accuracy through participation in proficiency testing, such as that offered by the College of American Pathology (CAP). The reader is referred to reference 12 for additional suggestions on developing a robust quality assurance program for sweat chloride testing and techniques to minimize QNS collections.

Bicarbonate (Total Carbon Dioxide)

Total carbon dioxide is measured in the clinical laboratory by (1) acidification of a serum or plasma sample and measurement of carbon dioxide released by the process or (2) alkalinization and measurement of total bicarbonate.



Specimens



The same sample types used for Na^+ or K^+ may be assayed. Given a specimen in a vacuum draw tube, the concentration of total CO_2 is most accurately determined when the assay is done as promptly as possible after collection and centrifugation of the blood in the unopened tube. Ambient air contains far less CO_2 than does plasma, and dissolved CO_2 will escape from the specimen into the air, with a consequent decrease in the CO_2 value of up to 4 to 5 mmol/L in the course of 1 hour.

Methods for Determination of Serum or Plasma Total Carbon Dioxide

Methods used for total CO_2 measurement with today's automated instruments may be electrode based or enzymatic. With indirect electrode-based methods, the amount of released gaseous CO_2 after acidification is determined by a PCO_2 electrode. Direct ISE methods for total CO_2 are no longer common on automated analyzers because of problems with specificity. With enzymatic methods for CO_2, the specimen is first

alkalinized to convert all CO_2 and carbonic acid to HCO_3^-. The enzymatic reactions lead to decreased absorbance of NADH at 340 nm that is proportional to the total CO_2 content.

Reference Intervals

The reference interval for total carbon dioxide in healthy adults is 22 to 30 mmol/L but is method dependent.

Principles of Osmotic Pressure and Osmosis

Osmometry is a technique for measuring the concentration of solute particles that contribute to the osmotic pressure of a solution. **Osmotic pressure** governs the movement of solvent (water in biological systems) across membranes that separate two solutions. Different membranes vary in pore size and thus in their ability to select molecules of different size and shape. Examples of biologically important selective membranes are those enclosing the glomeruli of the kidney and capillary vessels that are permeable to water and to essentially all small molecules and ions, but not to larger protein molecules. Differences in the concentrations of osmotically active molecules that are unable to cross a membrane cause those molecules that are able to cross the membrane to move to establish an osmotic equilibrium. This movement of solute and permeable ions exerts osmotic pressure.

Colligative Properties

In addition to increasing osmotic pressure when the solute is added to the solvent, the vapor pressure of the solution is lowered below that of the pure solvent. As a result of the change in vapor pressure, the boiling point of the solution is raised above and the freezing point of the solution is lowered below that of the pure solvent. These four properties of solutions—(1) increased osmotic pressure, (2) lowered vapor pressure, (3) increased boiling point, and (4) decreased freezing point—are called **colligative properties**. All are directly related to the total number of solute particles per mass of solvent. The term osmolality expresses concentrations relative to mass of the solvent (1 osmolal solution is defined to contain 1 Osmol/kg H_2O), whereas the term osmolarity expresses concentrations per volume of solution (1 osmolar solution is defined to contain 1 Osmol/L solution). Osmolality (Osmol/kg H_2O) is a thermodynamically more exact expression because solution concentrations expressed on a weight basis are temperature independent, whereas those based on volume vary with temperature. Although the term osmolarity is often used in the medical literature, osmolality is what the clinical laboratory measures.

An electrolyte in solution dissociates into two (in the case of NaCl) or three (in the case of $CaCl_2$) particles; therefore the colligative effects of such solutions are multiplied by the number of dissociated ions formed per molecule. However, because of incomplete electrolyte dissociation and associations between solute and solvent molecules, many solutions do not behave in the ideal case, and a 1-molal solution may give an osmotic pressure lower than is theoretically expected. The osmotic activity coefficient is a factor used to correct for deviation from the "ideal" behavior of the system:

$$\text{Osmolality} = \frac{\text{osmol}}{\text{Kg } H_2O} = \phi nC$$

where Φ = osmotic coefficient, n = number of particles into which each molecule in the solution potentially dissociates, and C = molality in mol/kg H_2O.

Glucose has an osmotic coefficient of 1.00, whereas the Φ for sodium chloride is 0.93 at the concentrations found in serum—thus the derivation of 1.86 × Na^+ (mmol) in the formula to calculate plasma osmolality (NaCl potentially contributes two osmotically active particles × 0.93 = 1.86). Ethanol has an osmotic coefficient of 0.83. The total osmolality or osmotic pressure of a solution is equal to the sum of the osmotic pressures or osmolalities of all solute species present. The electrolytes Na^+, Cl^-, and HCO_3^-, which are present in relatively high concentrations, make the greatest contributions to serum osmolality. Nonelectrolytes such as glucose and urea, which are present normally at lower molal concentrations, contribute less, and serum proteins contribute less than 0.5% of the total serum osmolality.

Determination of Plasma and Urine Osmolality

Determination of plasma and urine osmolality is useful in the assessment of electrolyte and acid-base disorders. The major osmotic substances in normal plasma are Na^+, Cl^-, glucose, and urea; thus expected plasma osmolality is calculated from the following empirical equation:

$$\begin{aligned}\text{mOsmol/kg} = {} & 1.86\,[Na^+\ (\text{mmol/L})] \\ & + \text{glucose [mmol/L]} \\ & + \text{urea [mmol/L]} \\ & + 9\end{aligned}$$

or

$$\begin{aligned}\text{mOsmol/kg} = {} & 1.86\,[Na^+\ (\text{mmol/L})] \\ & + \text{glucose [mg/dL]}/18 \\ & + \text{urea N[mg/dL]}/2.8 \\ & + 9\end{aligned}$$

The 9 mOsmol/kg added to the previous equation represents the contributions of other osmotically active substances in plasma, such as (1) K^+, (2) Ca^{2+}, and (3) proteins, and 1.86 is 2 × the osmotic coefficient of Na^+, reflecting the contributions of both Na^+ and Cl^-. The reference interval for plasma osmolality is 275 to 300 mOsmol/kg. Comparison of measured osmolality versus calculated osmolality reveals the presence of an **osmolal gap**, which is used to detect the presence of exogenous osmotic substances.

Theoretically, any of the four colligative properties discussed previously—(1) vapor pressure, (2) boiling point, (3) freezing point, and (4) osmotic pressure—could serve as a basis for the measurement of osmolality. However, freezing point depression is most commonly used in clinical laboratories because of its simplicity. Furthermore, freezing point depression, unlike vapor pressure, is independent of changes in ambient temperature.

Freezing Point Depression Osmometer

The components of a freezing point depression osmometer include the following:

1. A thermostatically controlled cooling bath or block maintained at −7 °C.
2. A rapid stir mechanism to initiate ("seed") freezing of the sample.
3. A thermistor probe connected to a circuit to measure the temperature of the sample.
4. A light-emitting diode (LED) display that indicates the time course of the freezing curve and the final result.

During analysis, the following steps occur. The sample, in which the thermistor probe and the stirring wire are centered, is lowered into the bath and, with gentle stirring, is supercooled to a temperature several degrees below its freezing point (−7 °C). When the LED display indicates that sufficient super-cooling has occurred, the sample is raised to a point above the liquid in the cooling bath, and the wire stirrer is changed from a gentle rate of stir to a momentary vigorous amplitude, which initiates freezing of the super-cooled solution. This is freezing occurs only to the slush stage, with about 2% to 3% of the solvent solidifying. The released heat of fusion initially warms the solution, and then the temperature plateaus and remains stationary, indicating the equilibrium temperature at which both freezing and thawing of the solution are occurring. An example of the calculation used to obtain osmolality is as follows: If the observed freezing point is −0.53 °C, then

$$\text{Mosmol/kg } H_2O = \frac{-0.53}{-1.86} \times 1000 = 2.85$$

where −1.86 °C is the molal freezing point depression of pure water.

Vapor Pressure Osmometer

Another type of osmometer is the vapor pressure osmometer. However, osmolality measurement with these instruments is related directly not to a change in vapor pressure (in millimeters of mercury) but to the decrease in dew point temperature of the pure solvent (water) caused by the decrease in vapor pressure of the solvent by the solutes.

An important clinical difference between the vapor pressure technique and the freezing point depression osmometer is the failure of the former to include in its measurement of total osmolality any volatile solutes present in the serum. Substances such as (1) ethanol, (2) methanol, and (3) isopropanol are volatile and thus escape from the solution and increase the vapor pressure instead of lowering the vapor pressure of the solvent (water). This is makes the use of vapor pressure osmometers impractical for identifying osmolal gaps in acid-base disturbances (see Chapter 36), and use of this type of osmometer is not recommended for most clinical laboratories.

Blood Gases and pH

Clinical management of respiratory and metabolic disorders often depends on rapid, accurate measurements of oxygen and carbon dioxide gas in blood. Determination of blood gases also plays an important part in the detection of acid-base imbalances. Details of the pathophysiology of blood gases in relation to respiration and acid-base disorders are discussed in detail in Chapter 36. Nomenclature for this area of analysis has been recommended by the CLSI,[6] but alternative nomenclatures exist and are in common use; these are summarized in Box 24-1.

Behavior of Gases

Determination of gas pressures in expired air or blood depends on the application of certain physical principles (Table 24-3). The **partial pressure** (tension) of a gas dissolved in blood is by definition equal to the partial pressure of the gas in an imaginary ideal gas phase in equilibrium with the blood. At equilibrium, the partial pressure of a gas is the same in erythrocytes and plasma, so that the partial pressure of a gas is the same in whole blood and plasma. The partial pressure of a gas in a gas mixture is defined as the substance fraction of gas (mole fraction) times the total pressure.

Various spaces where gases are present include the ambient environment (room air), the bronchial tree and alveoli of the patient, and the measuring chamber of a laboratory instrument. In all these spaces, atmospheric (barometric) pressure, P(Amb), is the prevailing pressure, and partial pressures of each of the gases present in these spaces must add up to the value of P(Amb), which will vary with altitude and barometric pressure. Scientific convention reduces measurements of gas volume made at P(Amb) to Standard Temperature (0 °C, or 273.16 K) and Pressure (760 mm Hg, or 101.325 kPa) for Dry gas (STPD) to make experimental data transferable. However, in blood gas work, the standard is that measurements of partial pressure are always made at Body Temperature (usually 37 °C), at P(Amb), and in the presence of Saturated water vapor (SVP) the PH_2O = 47 mm Hg.

BOX 24-1 Conversion Factors, Prefixes, Symbols, and Descriptors Used in Discussions of Gases Measured in Blood and Expired Air*

Conversion Factors

1 mm Hg = 0.133 kPa

1 kPa = 7.5 mm Hg

kPa: 1 kilopascal = 1000 pascal. The pascal is the SI derived unit of pressure; it equals 1 Newton/m^2.

General Prefixes

P: partial pressure or tension

Usage: PO_2, PCO_2, PH_2O

Alternative: pO_2

S: saturation fraction

Usage: SO_2

Alternative: sO_2

c: substance concentration

Usage: ctO_2 for concentration of total O_2

Usage: $ctCO_2$ for concentration of total CO_2

Usage: $cHCO_3^-$ for concentration of bicarbonate

d: dissolved gas, used with substance concentration (c)

t: total, used with substance concentration (c), thus

$$ctCO_2 = HCO_3^- + cdCO_2$$

Specimen origin is indicated by lowercase letters. Whole blood and plasma are distinguished by capital letters.

a: arterial B: blood

v: venous P: plasma

c: capillary

Usage: $PO_2(aB)$, for partial pressure of O_2 in arterial blood

Prefixes Associated With External Respiration

V: volume of air or blood (unit, L)

$\dot{V}$: volume rate (unit, L/min)

F: substance fraction, also called mole fraction

E: expired air

I: inspired air

A: alveolar air

Usage: $\dot{V}(A)$ means alveolar ventilation; $\dot{V}(B)$ cardiac output; $FO_2(I)$ fraction of O_2 in inspired air; $PO_2(A)$ partial pressure of O_2 in alveolar air; and $PCO_2(E)$ partial pressure of CO_2 in expired air.

Other Descriptors

BTPS: Body Temperature (37 °C or 310.16 K) and ambient Pressure, fully Saturated (PH_2O = 47 mm Hg or 6.25 kPa)

STPD: Standard Temperature (0 °C or 273.16 K) and standard Pressure (760 mm Hg or 101.08 kPa) of Dry gas

Amb: ambient atmosphere (unit is atm, atmosphere)

B: barometric (atmospheric)

BTPS: usage: P(amb), P(Amb)

SVP: Saturated Vapor Pressure, the vapor pressure of water. SVPT means SVP at a specified temperature (e.g., $SVP_{37\,°C}$ = 47 mm Hg; PH_2O[saturated])

ATPS: Ambient Temperature and Pressure, Saturated with water vapor

From Maas AH. IFCC reference methods for measurement of pH, gases and electrolytes in blood: reference materials. Eur J Clin Chem Clin Biochem 1991;29:253-61.

*This list is not complete but is presented to facilitate interpretation of terms used in the text and to illustrate various forms that may be encountered in the literature.

TABLE 24-3 Physical Principles Applied in Blood Gas Measurements

Boyle's law: The volume of an ideal gas at a constant temperature varies inversely with the pressure exerted to contain it.	$V \propto 1/P$
Charles' (Gay-Lussac's) law: The volume of an ideal gas at a constant pressure varies directly with its absolute temperature.	$V \propto T$
Avogadro's hypothesis: Equal volumes of different ideal gases at the same temperature and pressure contain the same number of molecules.	$n_i/V_i = n_j/V_j$
Dalton's law: The total pressure exerted by a mixture of ideal gases is the sum of the partial pressure of each of the gases in the mixture.	$P = \Sigma P_i$
Henry's law: The amount of a sparingly soluble gas dissolved in a liquid is proportional to the partial pressure of the gas over the liquid.	$c = \alpha \times P$

Boyle's and Charles' laws and Avogadro's hypothesis are combined in what is called the general gas equation:

$$P = \frac{nRT}{V}$$

where

P = pressure in units of millimeters of mercury (mm Hg) or kilopascals (kPa)

V = volume in liters in which an ideal gas is contained

T = temperature in degrees kelvin (0 °C = 273.16 K)

n = number of moles of gas, and

R = gas constant.

The SI unit of P is the pascal (Pa). Pressure, P (or p), may mean total pressure, as in the expression P(Amb) for the mixture of gases in ambient air, or partial pressure in arterial blood, as in $PO_2(aB)$.

Dalton's law (see Table 24-3) may be written for room air as follows:

$$P(Amb) = PO_2 + PCO_2 + PN_2 + PH_2O + PX$$

where PX is that of any other gas in the air sample. However, for gases in solution, Dalton's law does not apply, as the sum of partial pressures of all dissolved gases may be lower than, equal to, or higher than the measured pressure of the solution. Dalton's law of partial pressures remains important, however, for calibration and control of the measuring devices. Consider a calibrator gas certified to contain 15% O_2 (L/L or mol/mol) and 5% CO_2, with the remainder being N_2. This is mixture, after saturation with water vapor at 37 °C (to mimic a patient's blood or alveolar air), is introduced into a blood gas instrument's measuring chamber (held at 37 °C to mimic a patient's body temperature) for the purpose of calibrating the instrument for subsequent measurement of gases in patients' samples. If the local barometric pressure, P(Amb), on this occasion is 747 mm Hg, then humidified calibrator gas is present in the chamber at ambient, barometric pressure, such that

$$P(Amb) = 747 \text{ mm Hg} = PO_2 + PCO_2 + PN_2 + PH_2O$$

To set the instrument to the PO_2 and PCO_2 of the calibrator gas, we first must account for PH_2O at 37 °C, which is equal to the SVP of water, 47 mm Hg. Therefore,

$$P(Amb) - PCO_2 = PO_2 + PCO_2 + PN_2$$
$$747 - 47 = 700 \text{ mm Hg}$$

If P(Amb) corrected for PH_2O represents the sum of partial pressures for the dry gases whose mole fractions we know, it is possible to calculate the exact PO_2 and PCO_2 values for the calibrator gas.

The law of partial pressure is also applied in defining gas mixtures used to determine $PO_2(0.5)$ or P_{50} and other derived quantities, and to control instrumentation with tonometered samples. Henry's law predicts the amount of dissolved gas in a liquid in contact with a gaseous phase (see Table 24-3).

The coefficient for O_2 in blood, αO_2, is 0.00140 (mol/L)/mm Hg (the corresponding coefficient for the volume-volume relationship is 31 μL/L/mm Hg). Therefore when arterial PO_2 is normal (≈100 mm Hg), the concentration of dissolved O_2 in arterial blood, cdO_2, is 0.140 mmol/L, which is a very small proportion of the ctO_2 content in blood (≈9 mmol/L), the bulk of which is O_2 bound by hemoglobin. Increasing the O_2 fraction of inspired air to 100% or increasing the pressure of inspired air, as in a hyperbaric chamber, forces more O_2 into a solution. Prediction of concentrations of cdO_2 in these therapies is useful because tissue oxygenation by dissolved O_2 becomes increasingly important when hemoglobin-mediated O_2 delivery is impaired. The $cdCO_2$ is similarly calculated as αCO_2 at 37 °C in plasma = 0.0306 mmol/L/mm Hg.

Application of the Henderson-Hasselbalch Equation in Blood Gas Measurements

Carbon dioxide and water react to form carbonic acid, which in turn dissociates to hydrogen ions and HCO_3^-.

$$CO_2 + H_2O \underset{}{\overset{K_{hydration}}{\rightleftharpoons}} H_2CO_3 \overset{K_{dissociation}}{\rightleftharpoons} H^{\oplus} + HCO_3^{\ominus}$$

Thus the (1) total concentration of CO_2 ($ctCO_2$), (2) concentration of bicarbonate (HCO_3^-), (3) concentration of dissolved CO_2 ($cdCO_2$), and (4) H^+ ion concentration (cH^+) are interrelated. In the classical 1908 formulation, Henderson, using concentrations for (1) bicarbonate, (2) CO_2, and (3) H^+, and assuming the concentration of water to be constant, incorporated the constant K′ with a value of 4.68×10^{-7}, and thus a pK′ of 6.33 at 37 °C:

$$K' = \frac{cH^+ \times cHCO_3^-}{cdCO_3^-}$$

The concentration of dissolved CO_2 includes the small amount of undissociated (dissolved) carbonic acid. It is expressed as $cdCO_2 = \alpha \times PCO_2$, where α is the solubility coefficient for CO_2. $cHCO_3^-$ then represents $ctCO_2 - cdCO_2$, which includes carbonic acid. The "bicarbonate" concentration by this definition includes undissociated sodium bicarbonate, carbonate ($NaCO_3$), and carbamate (carbamino-CO_2; $RCNHCOO^-$), which are present in exceedingly small amounts in plasma. If the Henderson equation is rearranged and $cdCO_2$ is replaced by $\alpha \times PCO_2$, the following equation results:

$$cH^+ = K' \times \frac{\alpha \times PCO_2}{cHCO_3^-}$$

In 1916, Hasselbalch showed that a logarithmic transformation of the equation was a more useful form and used the symbols pH (= −log cH^+) and pK′ (= −log K′). pH is defined as the negative log of the activity of H+ (aH+), which is the entity actually measured with pH meters. The resulting **Henderson-Hasselbalch equation** becomes

$$pH = pK' + \log \frac{cHCO_3^-}{\alpha \times PCO_2}$$

or

$$pH = pK' + \log \frac{ctCO_2 - \alpha \times PCO_2}{\alpha \times PCO_2}$$

K′ is the apparent overall (combined) dissociation constant for carbonic acid. It is apparent because concentrations are used rather than activities and overall because both the $cdCO_2$ and the concentration of carbonic acid are used. K′ depends not only on the temperature but also on the ionic strength of the solution.

When pK′ and α for normal plasma at 37 °C are inserted, the Henderson-Hasselbalch equation takes the following form:

$$pH = 6.103 + \log \frac{cHCO_3^-}{0.0306 \times PCO_2}$$

where PCO_2 is measured in millimeters.

Therefore, by measuring any two of the four parameters—(1) PCO_2 or $cdCO_2$, (2) pH, (3) $ctCO_2$, and (4) $cHCO_3^-$—and by using the Henderson-Hasselbalch equation with the above values for pK′ and α, the other two parameters may be calculated.

Oxygen in Blood

The total O_2 content (ctO_2) of a blood sample is the sum of the concentrations of hemoglobin-bound O_2 and of dissolved O_2. At a blood ctO_2 of 9 mmol/L, the O_2 associated with hemoglobin as **oxyhemoglobin** (O_2Hb) is 8.86 mmol/L. The O_2Hb is defined as erythrocyte hemoglobin with O_2 reversibly bound to Fe^{2+} of its heme group. Each mole of hemoglobin-Fe^{2+} binds 1 mol of O_2.

Thus 1 g of hemoglobin is capable of binding 1.39 mL (0.062 mmol) of O_2 at STPD (Standard Temperature and Pressure, Dry). This value is referred to as the specific O_2-binding capacity of hemoglobin A (Hb A, the normal adult gene product). Hb A reversibly binds O_2 at its heme moiety. Forms of hemoglobin that are not capable of reversibly binding O_2 include (1) methemoglobin (MetHb), (2) carboxyhemoglobin (COHb), (3) sulfhemoglobin (SulfHb), and (4) cyanmethemoglobin. Because of chemical alterations of their heme moiety (see Chapter 28), these chemically altered hemoglobins are collectively termed dyshemoglobins.

Uptake of O_2 by the blood in the lungs is governed primarily by the PO_2 of alveolar air and by the ability of O_2 to diffuse freely across the alveolar membrane into the blood. At the PO_2 normally present in alveolar air (≈102 mm Hg) and with a normal membrane and normal hemoglobin A, more than 95% of hemoglobin will bind O_2. At a PO_2 >110 mm Hg, more than 98% of normal hemoglobin A binds O_2. When all hemoglobin is saturated with O_2, a further increase in the PO_2 of alveolar air simply increases the concentration of dO_2 in the arterial blood. Delivery of O_2 by the blood to the tissue is governed by the large gradient between PO_2 of the arterial blood and that of the tissue cells and by the dissociation of O_2 from Hb in the erythrocytes at the lower PO_2 of the blood-tissue cell interface.

The following properties of arterial blood are essential to ensure adequate O_2 delivery to the tissue:

1. Arterial PO_2 must be sufficiently high (≈90 mm Hg) to create a diffusion gradient from the arterial blood to the tissue cells. Low arterial PO_2 (hypoxemia) results in tissue O_2 starvation (hypoxia).
2. The O_2-binding capacity of the blood must be normal. Decreased Hb concentration will cause so-called anemic hypoxia.
3. The hemoglobin must be able to bind O_2 in the lungs yet release it at the tissue, as the affinity of hemoglobin for O_2 must be normal. Too great an affinity of hemoglobin for O_2 may cause "affinity-based" tissue hypoxia, in which O_2 is not released at the capillary-tissue interface.

The PO_2 at the venous end of the capillaries should stay around 38 mm Hg; thus the normal arteriovenous difference in PO_2 is 50 to 60 mm Hg.

Hemoglobin Oxygen Saturation

At least three different approaches are known for determining oxygen "saturation," and although each is distinct, they are often used interchangeably. They include (1) hemoglobin oxygen saturation (SO_2), (2) fractional oxyhemoglobin (FO_2Hb), and (3) estimated oxygen saturation (O_2Sat). Each has been defined in a CLSI document.[6]

Before the factors that affect Hb affinity for O_2 are discussed, it is important to first define the concept of hemoglobin **oxygen saturation (SO_2)**:

$$SO_2 = \frac{\text{Oxygen Content}}{\text{Oxygen Capacity}}$$

This is the fraction (percentage) of functional hemoglobin that is saturated with oxygen and is essentially an indirect means of estimating the PO_2. Spectrophotometric methods are used to determine O_2Hb and HHb, and SO_2 is calculated according to

$$SO_2 = \frac{cO_2Hb}{cO_2Hb + cHHb}$$

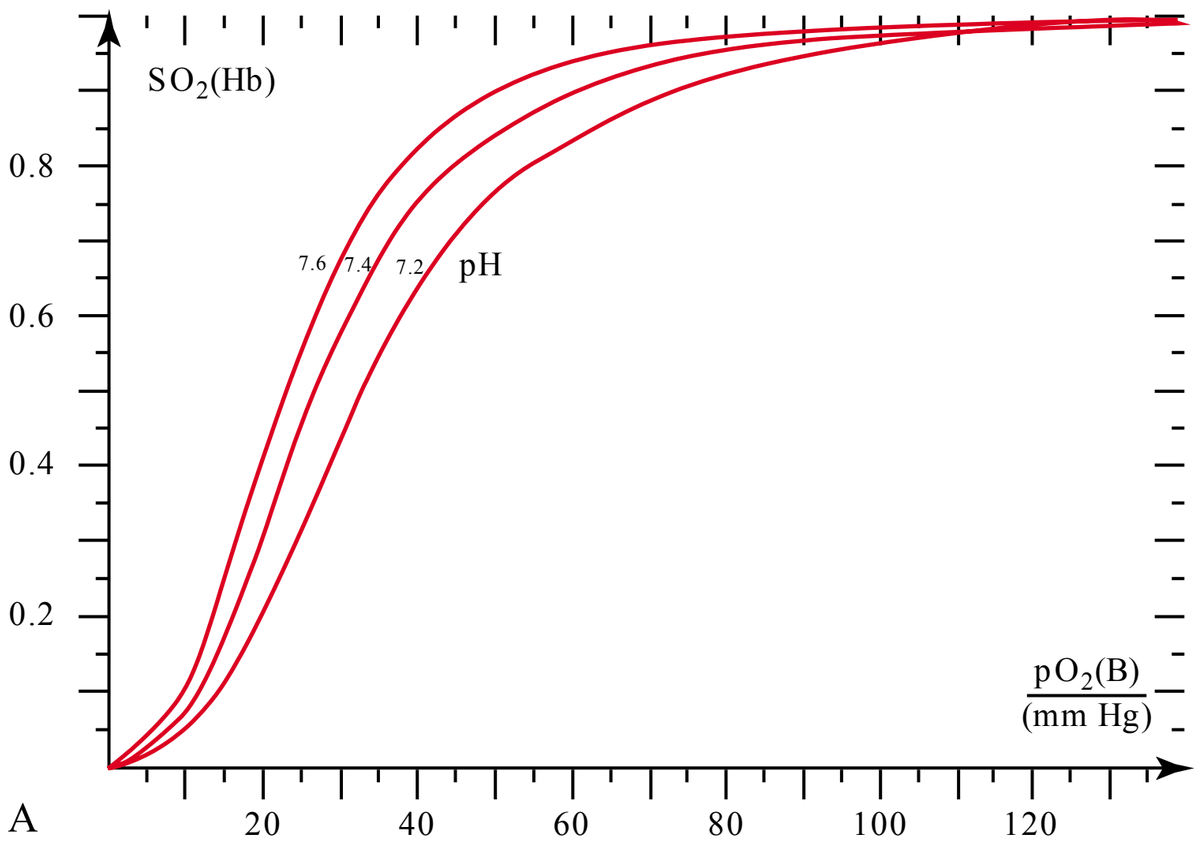
where cO_2Hb is the concentration of oxyhemoglobin, cHHb is the concentration of deoxyhemoglobin, and the sum of oxyhemoglobin and deoxyhemoglobin represents all hemoglobin capable of reversibly binding O_2. SO_2 is usually expressed as a percent.

SO_2 most often is determined by simple pulse **oximetry**, a spectrophotometric approach that determines oxyhemoglobin and reduced hemoglobin (HHb) but not COHb, MetHb, or SulfHb. It should be noted that use of SO_2 in the initial evaluation of a patient with dyshemoglobins or other abnormal hemoglobins can be misleading. For instance, in a comatose patient with 15% COHb, the SO_2 by simple pulse oximetry might read 0.95, whereas the fraction of oxyhemoglobin in reality would be only 0.80. Thus it seems reasonable to assess for the presence of dyshemoglobins before SO_2 is used for clinical purposes. The reference interval for SO_2 from healthy adults is 0.94 to 0.98 (94% to 98%).

Another expression of oxygen "saturation" is fractional oxyhemoglobin (FO_2Hb), which is calculated as

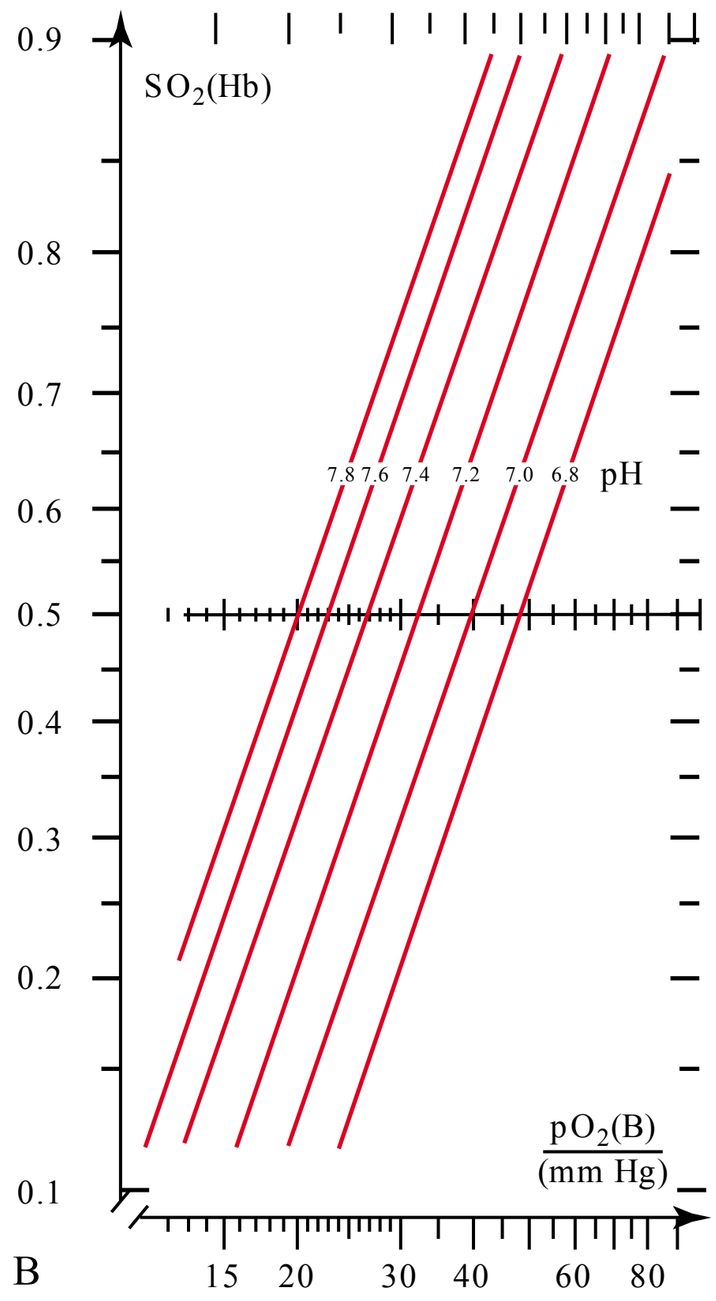
$$FO_2Hb = (cO_2Hb/cHHb + cCOHb + cMethHb + cSulHb)$$

This value requires determination of all hemoglobin species and is performed on a co-oximeter present in many modern blood gas analyzers. These instruments prepare a hemolysate from whole blood by sonication, and by spectrophotometry they determine the total amount of hemoglobin and the percent of each of the aforementioned species. Because each species of hemoglobin has its own absorbance pattern, an onboard microprocessor calculates the percentage of each one. The reference interval for FO_2Hb is 0.90 to 0.95 (90% to 95%).



Finally, the microprocessors of many blood gas instruments are capable of estimating the oxygen saturation from measured (1) pH, (2) PO_2, and (3) hemoglobin with the use of empirical equations. This value should be clearly referred to as estimated oxygen saturation, but it frequently is reported as and referred to as "O_2Sat." Calculated values such as "O_2Sat" should be interpreted with reservation because the algorithm assumes (1) normal O_2, (2) normal affinity of the hemoglobin, (3) normal 2,3-diphosphoglycerol (2,3-DPG) concentrations, and (4) the absence of dyshemoglobins.

Decreases in arterial FO_2Hb may indicate a low arterial PO_2 or an impaired ability of hemoglobin to bind O_2. Decreases in PO_2 indicate a reduced ability of O_2 to diffuse from alveolar air into the blood. Decreases in the concentration of total hemoglobin can result from a decreased number of erythrocytes that contain a normal concentration of hemoglobin (normochromic anemia) or a decreased mean cell concentration of hemoglobin in the erythrocytes (hypochromic anemia). Decreased FO_2Hb hemoglobin also occurs as a result of poisonings that convert part of the hemoglobin into the species COHb, MetHb, SulfHb, or cyanmethemoglobin, which cannot properly bind or exchange O_2.



The oxygen concentration of blood (ctO_2) is the sum of O_2 bound to hemoglobin and cdO_2. Blood gas analyzers determine ctO_2 by the following calculation:

$$ctO_2\ (mL/dL) = FO_2Hb \times bO_2 \times ctHb\ (g/dL) + (\alpha O_2) \times (PO_2)$$

where bO_2 equals 1.39 mL/g Hb and α, the solubility coefficient of O_2 at 37 °C, and STPD = 0.00140 (mmol/L)/mm Hg. Note that this calculation is based on FO_2Hb and ctHb. If SO_2 is used, it is necessary to use the effective hemoglobin concentration by subtracting the concentration of any dyshemoglobins present from the concentration of ctHb.

Figure 24-3 A, Oxygen dissociation curves for human blood with different plasma pH but constant PCO_2 of 40 mm Hg, a 2,3-diphosphoglycerol (2,3-DPG) concentration in erythrocytes of 5.0 mmol/L, and temperature at 37 °C. B, A Hill plot. Conditions are the same as in (A). The coeffcients given in this chart form the basis for the correction of measured PO_2. C, The effect of pH(P) to shift the dissociation curve is called the Bohr effect.

Hemoglobin-Oxygen Dissociation

The degree of association or dissociation of O_2 with hemoglobin is determined by PO_2 and the affinity of hemoglobin for O_2. When the SO_2 of blood is determined over a range of PO_2 and is plotted against PO_2, a sigmoidal curve called the **oxygen dissociation curve** is obtained. The shape of the curve is affected by the increasing efficiency with which HHb molecules bind more O_2 once some O_2 has been bound (cooperativity; see also Chapter 28). The location of the curve relative to the PO_2 required to achieve a particular concentration of SO_2 in the blood is a function of the affinity of hemoglobin for O_2.

The affinity of hemoglobin for O_2 depends on the following five factors: (1) temperature, (2) pH, (3) PCO_2, (4) concentration of 2,3-DPG, and (5) the presence of minor hemoglobins such as COHb and metHb. The graph in Figure 24-3 shows the effect of plasma pH on the O_2 dissociation curve (the Bohr effect). Similar graphs can be constructed for variations in PCO_2, 2,3-DPG, and temperature.

Determination of P_{50}

P_{50} is defined as the PO_2 at which the hemoglobin of the blood is half saturated with O_2. The measured value of P_{50} differs from the standard value of P_{50} by an amount determined by the extent that (1) pH differs from 7.40, (2) PCO_2 differs from 40 mm Hg, (3) temperature differs from 37 °C, and (4) 2,3-DPG differs from 5.0 mmol/L. The value of P_{50} therefore becomes a measure of change in hemoglobin affinity because of the factors that affect it.

Reference Intervals

The P_{50} reference interval for adults, measured at 37 °C and corrected to a pH of 7.4, is 25 to 29 mm Hg. For newborn infants, the interval is 18 to 24 mm Hg because of the presence of Hb F.

Clinical Significance

Increased values for P_{50} indicate displacement of the O_2 dissociation curve to the right because of decreased affinity of the hemoglobin for O_2. The chief causes are (1) hyperthermia, (2) acidemia, (3) hypercapnia, (4) high concentrations of 2,3-DPG, and (5) the presence of a hemoglobin variant with decreased O_2 affinity. Low values for P_{50} signify displacement of the O_2 dissociation curve to the left because of increased affinity of hemoglobin. The main causes are (1) hypothermia, (2) acute alkalemia, (3) hypocapnia, (4) low concentrations of 2,3-DPG, and (5) a hemoglobin variant.

Tonometry

Tonometry is the process of exposing a sample to a gas phase in such a way that each gas in the gaseous phase partitions to an equilibrium between liquid and gas. Equilibration by tonometry uses gases of known fractional composition, humidified at 37 °C, to give a saturated water vapor pressure of 47 mm Hg. The PCO_2 or PO_2 of such gases is calculated according to Dalton's law (see earlier section on behavior of gases). Tonometry is used to treat blood samples for various special studies that are rarely requested in most hospital settings and to prepare quality control material in whole blood. Direct determination of P_{50} and of standard bicarbonate are two applications of tonometry.

Determination of PCO_2, PO_2, and pH

The instruments used for determination of PCO_2, PO_2, and pH are highly automated. Proper specimen collection and handling are critical for accurate determinations.

Specimens

Whole blood is the most likely specimen for a clinical laboratory to receive for gas analysis. Differences in measured blood gas values between arterial and venous blood are most pronounced for PO_2. In fact, PO_2 is the only clinical reason for arterial collections. PO_2 is generally ≈60 mm Hg lower in venous blood after O_2 is released in the capillaries, whereas PCO_2 is 2 to 8 mm Hg higher in venous blood. pH generally is only 0.02 to 0.05 pH units lower in a venous sample.

Arterial and venous specimens are best collected anaerobically with lyophilized heparin anticoagulant in 1- to 3-mL sterile syringes. Although in theory, glass syringes are preferred to prevent gas exchange through the syringe wall, most blood gas syringes today are plastic, and the gas exchange that occurs within 1 hour is trivial. Lyophilized heparin is preferable to liquid heparin because liquid heparin, which has atmospheric PO_2 and PCO_2 values, dilutes the sample, and the effect is greatest when the syringe is not completely filled.

For an anaerobic collection, the blood is not exposed to atmospheric air. The PCO_2 of air is about 0.25 mm Hg; this is much less than that of blood (≈40 mm Hg). Thus the CO_2 content and the PCO_2 of blood exposed to air will decrease, and blood pH, which is a function of PCO_2, will rise. The PO_2 of atmospheric air (≈155 mm Hg) is ≈60 mm Hg higher than that of arterial blood and ≈100 mm Hg higher than that of venous blood. Therefore blood from patients breathing room air that is exposed to atmospheric air gains O_2, and blood with PO_2 >150 mm Hg, as occurs in patients undergoing O_2 therapy, loses O_2. Blood can also be exposed to air simply from the air in the needle and in the syringe hub dead space.

Arterialized capillary blood is sometimes an acceptable alternative to arterial blood when an arterial cannula is not available, or when repeated arterial puncture must be prevented. Freely flowing cutaneous blood originates in the arterioles and corresponds closely to arterial blood in composition. The first blood drop to appear should be wiped away, and subsequent free-forming drops should be taken up in a capillary collection tube containing lyophilized heparin. Only free-flowing blood provides a satisfactory sample, and taking up the drops as soon as they form minimizes aerobic exposure.

Transport and analysis of specimens should be prompt. However, delayed analysis of up to 1 hour will have a minimal effect on reported values from most samples. The pH of freshly drawn blood decreases on standing at a rate of 0.04 to 0.08 pH unit/h at 37 °C, 0.02 to 0.03/h at 22 °C, and <0.01/h at 4 °C. The decrease in pH is accompanied by a corresponding decrease in glucose and an equivalent increase in lactate. PCO_2 increases by ≈5 mm Hg/h at 37 °C, by 1 mm Hg/h at 22 °C, and by only ≈0.5 mm Hg/h at 2 °C to 4 °C. The primary cause of these changes is glycolysis by leukocytes, platelets, and reticulocytes. In freshly drawn blood with a normal PO_2 that is maintained anaerobically, cell respiration causes PO_2 to decrease at a rate of ≈2 mm Hg/h at room temperature and 5 to 10 mm Hg/h at 37 °C. Adverse effects of glycolysis and respiration on pH, $ctCO_2$, PO_2, and PCO_2 of blood are best prevented by analysis within 30 minutes after collection. The small changes in values that are to be expected with delays in analysis are true only when the white blood cell count (WBC) is normal or is only slightly elevated. Glycolysis and the resulting effects on pH, PO_2, and PCO_2 increase dramatically with markedly elevated WBC, as occurs in leukemia.

Instrumentation

A schematic diagram characteristic of a typical instrument is shown in Figure 24-4. Operation of a traditional blood gas instrument begins with the operator presenting a blood specimen at the sample probe. The sample is taken through the probe by a peristaltic pump that loads the chamber with 60 to 150 µL of the sample. The sample then resides in the chamber long

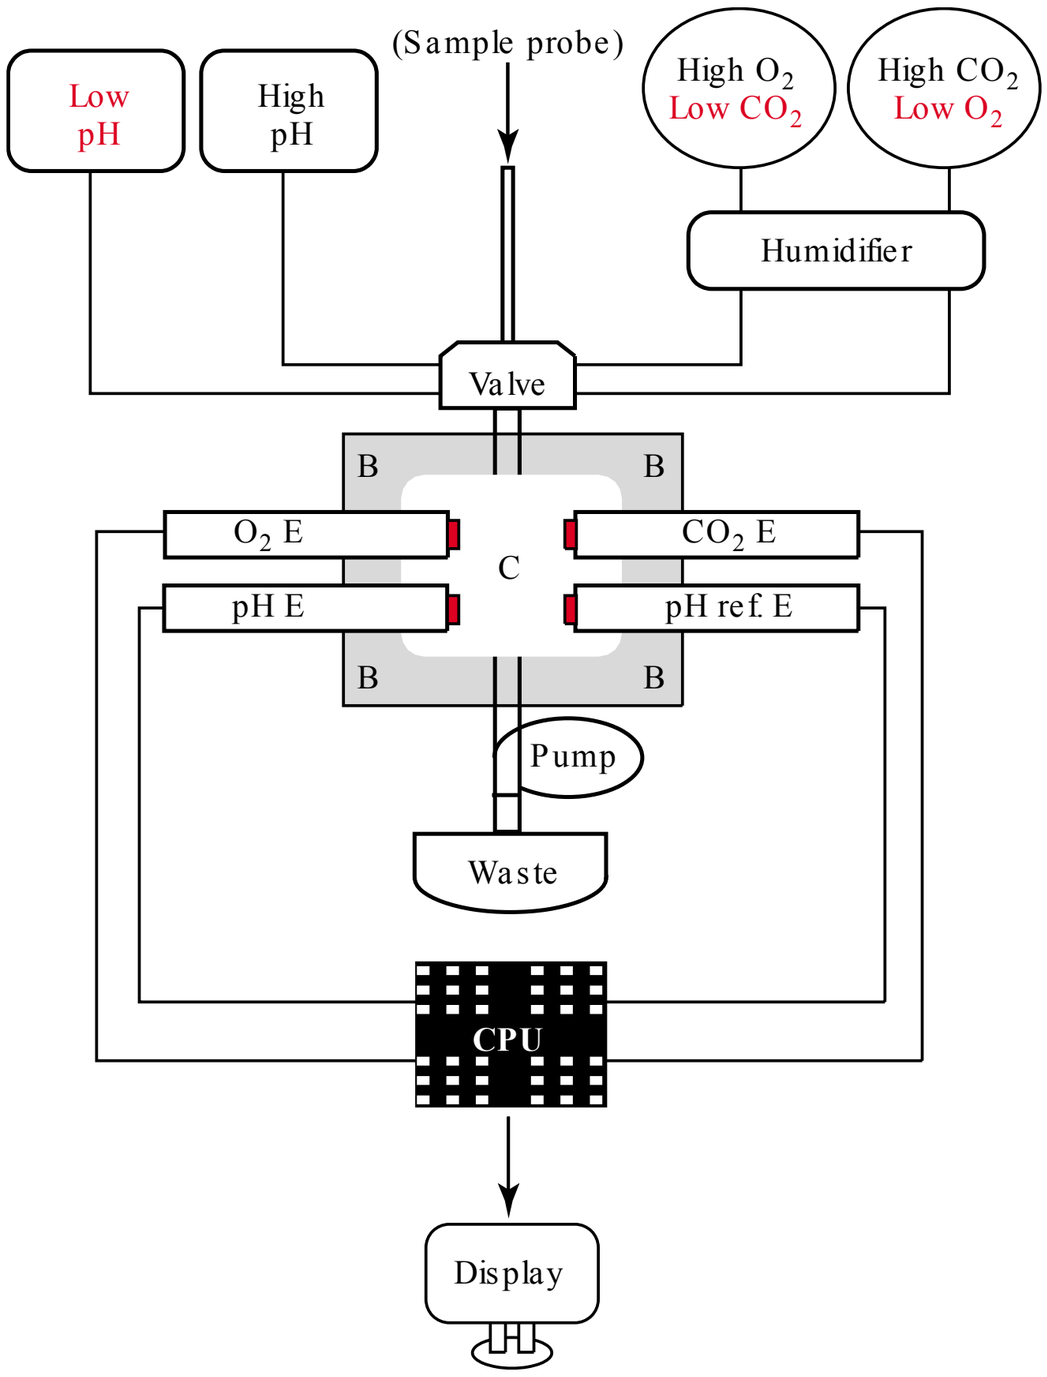

Figure 24-4 Diagram of blood gas instrumentation. B, Constant temperature bath at 37 °C. CPU, computer. E (electrodes), pH, and gas standards are shown at top of diagram.

enough to allow thermal equilibration and completion of measurements. On completion of measurement, the pump pushes the sample to waste, while output is made available on a display, a printed tape, and often a laboratory information system.

Because electrodes are not stable over long periods of time, frequent calibration of pH, PCO_2, and PO_2 is required. Most modern instruments are designed to be self-calibrating with microprocessor-controlled timed intervals of calibration.

Other instruments perform point-of-care or bedside testing. Almost all manufacturers now produce small, portable, stand-alone, easy-to-operate instruments designed for "satellite lab" operations; several handheld devices that use disposable electrodes are also available.

Electrodes

The tip of the pH-measuring electrode typically used in blood gas analyzers is made of H^+-sensitive glass, and, aside from miniaturization, most pH-measuring and reference electrodes differ little from those of free-standing pH meters. The membrane of the PCO_2 electrode usually consists of Teflon or silicone rubber that is approximately 25 μm thick. The electrolyte solution is a thin film containing sodium bicarbonate at 0.005 mol/L and sodium chloride (NaCl) at 0.1 mol/L saturated with AgCl. A spacer of nylon net or cellophane lies between the solution and the H^+-sensitive glass of the measuring element proper. As CO_2 diffuses from the sample into the electrolyte solution, the slight rise in $[H^+]$ from its hydration reaction is measured as ΔpH by an especially sensitive potentiometer and is transformed electronically to Δlog PCO_2. The membrane of a PO_2 electrode in a standard blood gas analyzer is usually ≈20-μm-thick polypropylene. The electrolyte solution is a thin film of phosphate buffer saturated with AgCl but also containing potassium chloride (KCl); it is in contact with the polarized platinum cathode and the Ag/AgCl anode. As O_2 diffuses into the electrolyte, it reacts with the cathode to cause current to flow; the generated current is measured.

Maintenance of Instrumentation

Sophistication of contemporary equipment and availability of high-quality calibrator materials have made reliable and accurate determination of blood pH and gases primarily a matter of (1) meticulous maintenance, (2) adherence to the manufacturer's recommended procedures, (3) control of the equipment and (4) proper collection and handling of specimens. The frequency with which maintenance should be scheduled is in direct proportion to the volume of analyses performed in the laboratory. The manufacturer's suggested schedule should be considered a minimum guideline, with reliance on experience to indicate maintenance frequency.

Quality Assurance and Quality Control

Elements of good quality assurance of blood gas and pH measurements include (1) proper maintenance of the instrument, (2) use of control materials, (3) verification of electrode linearity, (4) checking of barometer accuracy, and (5) accurate measurement of temperature.

External quality assurance (proficiency testing) mandated by federal law in the United States (Clinical Laboratory Improvement Amendments [CLIA] '88) has assumed new importance for quality control of blood gas analysis. These rules became effective in January 1991, and set criteria for satisfactory interlaboratory performance are as follows: (1) pH, target value ± 0.04; (2) PO_2, target value ± 3 SD; and (3) PCO_2, target value ± 8% or ± 5 mm Hg, whichever is greater.

Newer analyzers, particularly the smaller satellite laboratory and point-of-care instruments, frequently have an "auto quality control (QC)" feature or use "electronic QCs." Auto QC consists of onboard QC material that is automatically analyzed by the instrument at designated intervals that fulfill regulatory requirements. Electronic QC, which is most common in devices with disposable electrode cartridges, consists of cartridges that verify the electronic specifications of the instruments.

Blood-Based and Fluorocarbon-Based Control Materials

Commercial blood-based control material usually consists of tanned human erythrocytes suspended in buffered medium and sealed in vials with a gas mixture of known O_2 and CO_2 content. Nonblood fluorocarbon materials with O_2-carrying properties similar to those of blood are also available. Unopened, these types of control materials have a long shelf life in the refrigerator (e.g., 20 to 28 days for tanned erythrocytes and even longer for the others).

Aqueous Fluid Control Materials

T ese materials consist of a buffered medium sealed in vials with gas mixtures; the fluid is equilibrated with the gas by vigorous shaking by hand immediately before the vial is opened, and a sample is admitted to the instrument. Disadvantages of aqueous controls stem from their dissimilarity to blood. Lower viscosity and surface tension confer different washout characteristics and impair their ability to reflect clogging. Greater electrical conductivity reduces their effectiveness in detecting inadequate grounding, and lower thermal coefficients make them slower to detect failures of temperature control. T ese disadvantages are most apparent with respect to PO_2, for which a fluorocarbon-based matrix is superior. Nevertheless, aqueous commercial controls are far and away the most common QC materials used for blood gas analysis.

Reference Intervals

Reference intervals for arterial blood PO_2, SO_2, PCO_2, and pH are listed in Chapter 50. Values for PO_2 and PCO_2 will decrease with increasing altitude, but compensatory mechanisms keep pH values the same. T e P_{50} corrected to pH 7.40 is 18 to 24 mm Hg for newborns and 24 to 29 mm Hg for adults. PCO_2 values decrease with altitude above sea level at a rate of 3 mm Hg/km (5 mm Hg/mile). A physiological change occurs with change in posture; PCO_2 is 2 to 4 mm Hg higher for a sitting or standing person than for one in the supine position. During pregnancy, PCO_2 falls gradually to a mean of about 28 mm Hg just before term.

Temperature Control and Correction

In the Henderson-Hasselbalch equation, pK′ and α are used as constants for a temperature of 37 °C. T e temperature-controlled sample chamber of an instrument is specified to be 37 ± 0.1 °C. T e body temperature of a febrile patient may be elevated to 40 °C to 41 °C, or a patient may be made hypothermic for some surgeries and have a temperature as low as 23 °C. Most blood gas instruments are able to calculate temperature-corrected pH and PCO_2. Correction of pH and PCO_2 to the actual temperature of the patient is usually omitted in states of hyperthermia. However, significant disagreement exists with respect to hypothermic states. Two basic strategies are used by anesthetists in managing hypothermic patients. With the pH-stat method, the measured pH is corrected to the actual body temperature of the patient and then is maintained as close to 7.4 as possible by introducing 3% to 5% CO_2 into the inhaled ventilator gas. Alternatively, with the α-stat strategy, uncorrected values are used to keep pH and PCO_2 close to the 37 °C reference value. In practice, the α-stat method is used, primarily because it is technically easier to perform.

[†]A technique in which arterial carbon dioxide tension and pH are maintained at 5.3 kPa (40 mm Hg) and 7.40 when measured at +37 °C. When a patient is cooled down, the pH value will increase, and if measured at the patient's temperature, the PCO_2 value and the PO_2 value will decrease with lowering of the temperature.

Continuous and Noninvasive Monitoring of Blood Gases

Pulse oximeters that continuously monitor SO_2Hb are common and are generally reliable. Transcutaneous monitoring of PCO_2 and PO_2 is a noninvasive continuous monitoring approach that has particular value and general success in neonatal and pediatric care. Transcutaneous monitoring of PO_2 will sometimes vary widely depending on whether the site of application reflects arterial, capillary, or venous blood flow. However, because little difference is noted between arterial and venous PCO_2, transcutaneous monitoring of PCO_2 is less problematic, and pulse oximeters often serve as a surrogate for PO_2.

Review Questions

1. Hemolysis of a plasma sample will most likely affect which of the following, and why?
   a. Sodium; it is present in equal amounts both intracellularly and extracellularly
   b. Glucose; it moves out of cells into plasma
   c. Insulin; it is the major intracellular anion and is present in high amounts in RBCs
   d. Potassium; it is localized mainly within cells, particularly RBCs
2. Which of the following equations is the correct Henderson-Hasselbalch equation?
   a. $pK' = pH + \log [cHCO_3]/[cH_2CO_3]$
   b. $pK' = pH + \log [cH_2CO_3]/[cHCO_3]$
   c. $pH = pK' + \log [cHCO_3]/[c\,H_2CO_3]$
   d. $pH = pK' + \log [c\,H_2CO_3]/[cHCO_3]$
3. Oxygen is transported in blood in two forms. Which of the following is the most prevalent method of transport?
   a. As carboxyhemoglobin
   b. Dissolved in body fluid
   c. Attached to carbon dioxide
   d. As oxyhemoglobin
4. T e major extracellular anion is
   a. sodium
   b. potassium.
   c. chloride.
   d. carbon dioxide.
5. Circulating levels of sodium are ultimately regulated by which of the following?
   a. Kidneys
   b. Diet
   c. Gastrointestinal tract
   d. Hemoglobin saturation
6. T e correct formula for calculating the SO_2% (oxygen saturation) of arterial blood is which of the following?
   a. ([oxyhemoglobin + deoxyhemoglobin]/oxyhemoglobin) × 100
   b. (oxyhemoglobin/[oxyhemoglobin + deoxyhemoglobin]) × 100
   c. (deoxyhemoglobin/[oxyhemoglobin + deoxyhemoglobin]) × 100
   d. (oxyhemoglobin/deoxyhemoglobin) × 100

7. Which of the following are causes of decreased PO_2?
   a. Elevated RBC count
   b. Defective alveoli in the lungs
   c. Increased hemoglobin concentration
   d. All of the above are correct
8. The oxygen dissociation curve is a graphic plot of
   a. the number of circulating erythrocytes.
   b. the normality of the hemoglobin structure.
   c. oxygen saturation of hemoglobin at a specific PO_2.
   d. the pressure of O_2 at 50 g/dL of hemoglobin.
9. If solute is added to pure solvent, the colligative properties of that solution are altered. The freezing point of a solution is beyond that of pure solvent when solute is added to solvent.
   a. lowered
   b. raised
   c. not changed
10. In the body, total CO_2, hydrogen ion, and HCO_3^- concentrations are interrelated. This is can be illustrated by a formula. Fill in the blanks (a, b, and c) to correctly complete this formula:

$$a + H_2O \rightleftharpoons b \rightleftharpoons HCO_3 + c$$

   a. a = CO_2; b = H; c = H_2CO_3
   b. a = H_2CO_3; b = CO_2; c = H
   c. a = H; b = H_2CO_3; c = CO_2
   d. a = CO_2; b = H_2CO_3; c = H

CHAPTER

25 Hormones*

Michael Kleerekoper, M.D., F.A.C.B., F.A.C.P., M.A.C.E.

Objectives

1. Define the following:

Amino acid–related hormone	Hormone
Autocrine system	Incretin
Calcitriol	Paracrine system
Endocrine system	Protein hormone
Endocrinology	Steroid hormone

2. Describe the three classifications of hormones; include examples of each, chemical structures, characteristics, half-life, and tissues of origin.
3. List and describe three physiological functions of hormones; include the role of hormones in each category and give examples of hormones in each category.
4. Compare the two types of receptor-hormone interactions; include examples of each type, postreceptor actions, and the specific effects that each type of interaction produces in a cell.
5. Provide examples of feedback mechanisms in the endocrine system.
6. List and describe four techniques used to assess hormones; include basic principles, specimen requirements, and an advantage of each technique.

Key Words and Definitions

Adenohypophysis The anterior glandular lobe of the pituitary gland.

Adenylate cyclase An enzyme of the lyase class that catalyzes the formation of 3′,5′-cyclic adenosine monophosphate (cAMP) from ATP.

Autocrine A mode of hormone action in which a cell secretes a hormone that binds to autocrine receptors on that same cell, leading to changes in the cell.

Circadian rhythms Rhythmic repetition of certain phenomena in living organisms at about the same time each day.

Cyclic adenosine monophosphate (cAMP) A cyclic nucleotide that serves as an intracellular and, in some cases, extracellular "second messenger" mediating the action of many peptide or amine hormones.

Endocrine system The system of glands that release their secretions (hormones) directly into the circulatory system. In addition to the endocrine glands, included are the chromaffin and the neurosecretory systems.

Endocrinology The scientific study of the function and pathology of the endocrine glands.

First messenger A factor or hormone that binds to a receptor on the external surface of a cell and sets off a series of reactions that eventually convert a precursor into a second messenger.

Gonadotropin Any hormone that stimulates the gonads.

G-proteins Guanine nucleotide-binding proteins (G-proteins) are a family of proteins involved in transmitting chemical signals outside the cell, and causing changes inside the cell. They communicate signals from many hormones, neurotransmitters, and other signaling factors.

G-protein–coupled receptors (GPCR) A large superfamily of membrane receptors whose intracellular effects are mediated by G proteins.

Half-life In endocrinology, the time required for a hormone to fall to half its original concentration in the specified fluid or blood.

Homeostasis The maintenance of equilibrium of internal body functions in response to external changes.

Hormone A chemical substance that has a specific regulatory effect on the activity of a certain organ or organs on cell types.

Incretin Any of various gastrointestinal hormones and factors that act as potent stimulators of insulin secretion, such as gastric inhibitory polypeptide.

Neurohypophysis The posterior lobe of the pituitary gland, making up the neural portion that secretes various hormones.

Paracrine A type of hormone function in which hormone synthesized in and released from endocrine cells binds to its receptor in nearby cells of a different type and affects their function.

*The author gratefully acknowledges the original contribution by Dr. Ronald J. Whitley on which portions of this chapter are based.

Key Words and Definitions—cont'd

Phospholipase C Any esterase that catalyzes the hydrolysis of the phosphoric ester bond of a membrane phospholipid, generating a phosphorylated alcohol and diacylglycerol.

Pituitary gland A small oval gland attached to the base of the vertebrate brain and consisting of an anterior and a posterior lobe (also known as the hypophysis and the pituitary body).

Receptor A molecular structure within a cell or on the surface characterized by (1) selective binding of a specific substance and (2) a specific physiological effect that accompanies the binding; examples include (1) cell surface receptors for peptide hormones, neurotransmitters, antigens, complement fragments and immunoglobulins, and (2) cytoplasmic receptors for steroid hormones.

Second messenger Any of several classes of intracellular signals that translate electrical or chemical messages from the environment (first messengers) into cellular responses.

Zinc finger protein Any of a class of nucleic acid–binding proteins that also contain one or more zinc-binding domains (tandemly repeated, highly conserved stretches of 28 nucleotides).

A **hormone** is a chemical substance produced in the body by (1) an organ, (2) cells of an organ, or (3) scattered cells that has a specific regulatory effect on the activity of an organ or organs.[15] Hormones are produced at one site in the body (Figure 25-1) and exert their action(s) at distant sites through what is called the (1) **endocrine system**. It is increasingly recognized that many hormones exert actions locally on nearby cells through what is termed (2) **paracrine** action. Finally, some hormones exert their action on the cells of origin, through (3) **autocrine** action. Examples of the classic endocrine hormones include (1) insulin, (2) thyroxine, and (3) cortisol. Neurotransmitters and neurohormones are examples of the paracrine system, and certain growth factors that stimulate synthesis and secretion of true hormones from the same cell are examples of an autocrine system.

Table 25-1 lists hormones that are commonly measured in clinical practice plus a few others to illustrate concepts. Biochemical, clinical, and analytical information for specific hormones are presented in Chapters 33 and 40 through 44.

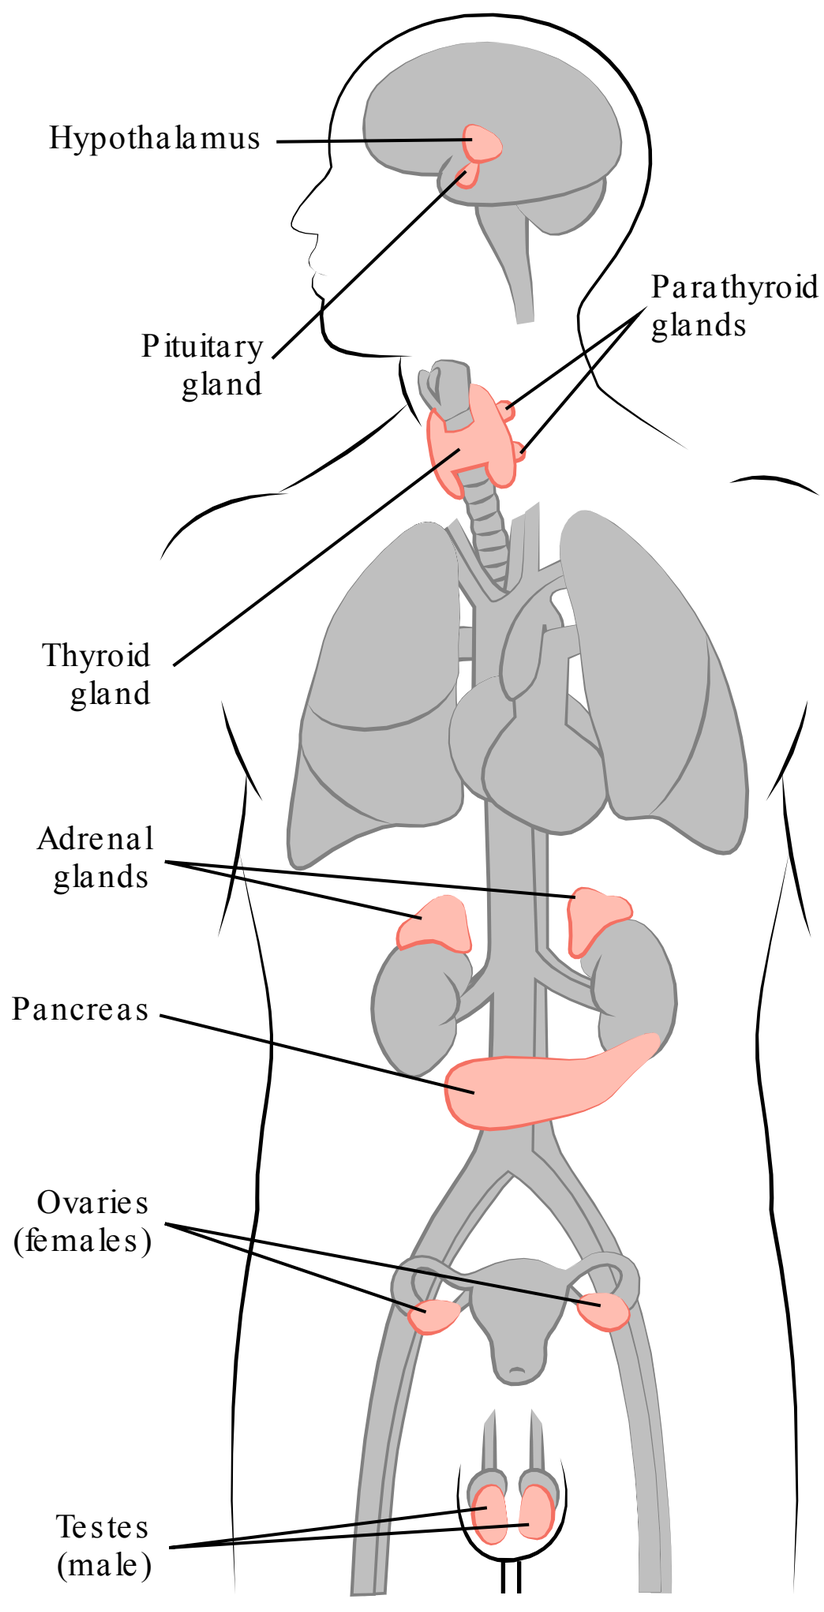

Figure 25-1 Location of the endocrine glands in humans.

Classification

Hormones are classified chemically as (1) polypeptides or proteins, (2) steroids, or (3) derivatives of amino acids.

Polypeptide or Protein Hormones

Examples of polypeptide or protein hormones include (1) adrenocorticotropic hormone (ACTH), (2) insulin, and (3) parathyroid hormone (PTH). They are generally water soluble and circulate freely in plasma as the whole molecule or as active or inactive fragments. The **half-life** of these hormones in plasma is short (≤10 to 30 minutes), and wide fluctuations in their concentration may be seen in several physiological and pathological circumstances. These hormones initiate their response by binding to cell membrane **receptors** (on or in the membrane) and exciting a "**second messenger**" system, which continues the specific actions of these hormones.

Steroid Hormones

Steroid hormones such as cortisol and estrogen are hydrophobic and insoluble in water. These hormones circulate in plasma, reversibly bound to transport proteins with only a small fraction free, or unbound, and available to exert physiological action.[5,8,17] The half-life of steroid hormones is 30 to 90 minutes. Free steroid hormones, being hydrophobic, enter the cell by passive diffusion and bind with intracellular receptors in the cytoplasm or the nucleus.[3]

Amino Acid–Related Hormones

Thyroxine and catecholamine are examples of hormones that are derived from amino acids; they are water soluble and

TABLE 25-1 Major Hormones and Frequently Measured Hormone Precursors and Cytokines

Endocrine Organ and Hormone	Chemical Nature of Hormone	Major Sites of Action	Principal Actions
Hypothalamus			
Thyrotropin-releasing hormone (TRH)	Peptide (3aa,* Glu-His-Pro)	Anterior pituitary	Release of TSH and prolactin (PRL)
Gonadotropin-releasing hormone (GnRH) or luteinizing hormone-releasing hormone (LH-RH)	Peptide (10aa)	Anterior pituitary	Release of LH and FSH
Corticotropin-releasing hormone (CRH)	Peptide (41aa)	Anterior pituitary	Release of ACTH and β-lipotropic hormone (LPH)
Growth hormone-releasing hormone (GH-RH)	Peptides (40, 44aa)	Anterior pituitary	Release of growth hormone (GH)
Somatostatin† (SS) or growth hormone-inhibiting hormone (GH-IH)	Peptides (14, 28aa)	Anterior pituitary	Suppression of secretion of many hormones (e.g., GH, TSH, gastrin, vasoactive intestinal polypeptide [VIP], gastric inhibitory polypeptide [GIP], secretin, motilin, glucagon, and insulin)
Prolactin-releasing peptide	Peptide (20aa)	Anterior pituitary	Release of PRL
Prolactin-releasing/inhibiting factor	Dopamine	Anterior pituitary	Suppression of synthesis and secretion of PRL
Anterior Pituitary Lobe			
Thyrotropin or thyroid-stimulating hormone (TSH)	Glycoprotein, heterodimer‡ (α, 92aa; β, 112aa)	Thyroid gland	Stimulation of thyroid hormone formation and secretion
Follicle-stimulating hormone (FSH)	Glycoprotein, heterodimer‡ (α, 92aa; β, 117aa)	Ovary	Growth of follicles with LH, secretion of estrogens, and ovulation
		Testis	Development of seminiferous tubules; spermatogenesis
Luteinizing hormone (LH)	Glycoprotein, heterodimer‡ (α, 92aa; β, 121aa)	Ovary	Ovulation; formation of corpora lutea; secretion of progesterone
		Testis	Stimulation of interstitial tissue; secretion of androgens
PRL	Peptide (199aa)	Mammary gland	Proliferation of mammary gland; initiation of milk secretion; antagonist of insulin action
Growth hormone (GH) or somatotropin	Peptide (191aa)	Liver	Production of IGF-1 (promoting growth)
		Liver and peripheral tissues	Anti-insulin and anabolic effects
Corticotropin or adrenocorticotropin (ACTH)	Peptide (39aa)	Adrenal cortex	Stimulation of adrenocortical steroid formation and secretion
β-Endorphin (β-END)‡§	Peptide (31aa)	Brain	Endogenous opiate; raising of pain threshold and influence on extrapyramidal motor activity
Chorionic gonadotropin (CG) or choriogonadotropin	Glycoprotein, heterodimer‡ (α, 92aa; β, 145aa)		
α-Melanocyte-stimulating hormone (α-MSH)	Peptide (13aa)	Skin	Dispersion of pigment granules, darkening of skin
Leu-enkephalin (LEK)†§ and met-enkephalin (MEK)†§	Peptide (5aa)	Brain	Same as β-endorphin
Posterior Pituitary Lobe			
Vasopressin or ADH	Peptide (9aa)	Arterioles renal tubules	Elevation of blood pressure; water reabsorption
Oxytocin	Peptide (9aa)	Smooth muscles (uterus, mammary gland)	Contraction; action in parturition and in sperm transport; ejection of milk
Pineal Gland			
Serotonin or 5-hydroxytryptamine (5-HT)	Indoleamine	Cardiovascular, respiratory, and gastrointestinal systems; brain	Neurotransmitter; stimulation or inhibition of various smooth muscles and nerves
Melatonin	Indoleamine	Hypothalamus	Suppression of gonadotropin and GH secretion; induction of sleep
Thyroid Gland			
Thyroxine (T_4) and triiodothyronine (T_3)	Iodoamino acids	General body tissue	Stimulation of oxygen consumption and metabolic rate of tissue
Calcitonin or thyrocalcitonin	Peptide (32aa)	Skeleton	Uncertain in humans

TABLE 25-1 Major Hormones and Frequently Measured Hormone Precursors and Cytokines—cont'd

Endocrine Organ and Hormone	Chemical Nature of Hormone	Major Sites of Action	Principal Actions
Parathyroid Gland			
Parathyroid hormone (PTH) or parathyrin	Peptide (84aa)	Kidney	Increased calcium reabsorption, inhibited phosphate reabsorption; increased production of 1,25-dihydroxycholecalciferol
		Skeleton	Increased bone resorption
Adrenal Cortex			
Aldosterone	Steroid	Kidney	Salt and water balance
Androstenedione¶¶	Steroid	Hormone precursor	Conversion to estrogens and testosterone
Cortisol	Steroid	Many	Metabolism of carbohydrates, proteins, and fats; anti-inflammatory effects; others
Dehydroepiandrosterone (DHEA) and dehydroepiandrostenedione sulfate (DHEAS)	Steroids	Hormone precursors	Conversion to estrogens and testosterone
17-Hydroxyprogesterone	Steroid	Hormone precursor	Conversion to cortisol
Adrenal Medulla			
Norepinephrine and epinephrine	Aromatic amines	Sympathetic receptors	Stimulation of sympathetic nervous system
Epinephrine		Liver and muscle, adipose tissue	Glycogenolysis Lipolysis
Ovary			
Activin A	Peptides¶ 2 β_A-subunits	Pituitary, ovarian follicle	Stimulation of release of FSH; enhanced FSH action; inhibition of androgen production by theca cells
Activin B	Peptides¶ 2 β_B-subunits beta	See activin A above	See activin A above
DHEA and DHEAS	Steroids	Hormone precursors	Conversion to androstenedione
Estrogens	Phenolic steroids	Female accessory sex organs	Development of secondary sex characteristics
		Bone	Control of skeletal maturation, etc.
Follistatin	Peptides (288aa, 315aa)	Pituitary, ovarian follicles	Inhibition of FSH synthesis and secretion by binding of activin
Inhibin A	Peptide (α-subunit and β_A-subunit)	Hypothalamus, ovarian follicle	Inhibition of FSH secretion; stimulation of theca cell androgen production
Inhibin B	Peptide (α-subunit and β_B-subunit)	See inhibin A above	See inhibin A above
Progesterone	Steroid	Female accessory reproductive structure	Preparation of the uterus for ovum implantation, maintenance of pregnancy
Relaxin	Peptide**	Uterus	Inhibition of myometrial contraction
Testis			
Inhibin B	See above	Anterior pituitary, hypothalamus	Control of LH and FSH secretion
Testosterone	Steroid	Male accessory sex organs	Development of secondary sex characteristics, maturation, and normal function
Placenta			
Estrogens	See above	See above	See above
Progesterone	See above	See above	See above
Relaxin	See above	See above	See above
Chorionic gonadotropin (CG) or choriogonadotropin	Glycoprotein, heterodimer‡ (α, 92aa; β, 145aa)	Same as LH	Same as LH; prolongation of corpus luteal function
Placental growth hormone (GH-V)	Peptides (22 and 26 kDa)	Same as GH	Same as GH
Chorionic somatomammotropin (CS) or placental lactogen (PL)	Peptide (191aa)	Same as PRL	Same as PRL
Pancreas			
Amylin	Peptide (37aa)	Pancreas	Inhibition of glucagon and insulin secretion
Glucagon	Peptide (29aa)	Liver	Glycogenolysis
Insulin	Peptide††	Liver, fat, muscle	Regulation of carbohydrate metabolism; lipogenesis

Continued

TABLE 25-1 Major Hormones and Frequently Measured Hormone Precursors and Cytokines—cont'd

Endocrine Organ and Hormone	Chemical Nature of Hormone	Major Sites of Action	Principal Actions
Pancreas—cont'd			
Pancreatic polypeptide (PP)	Peptide (36aa)	Gastrointestinal tract	Increased gut motility and gastric emptying; inhibition of gallbladder contraction
Somatostatin (SS)§	Peptide (14aa)	Pancreas	Inhibition of secretion of insulin, glucagon
Gastrointestinal Tract			
Gastrin§	Peptide (17aa)	Stomach	Secretion of gastric acid, gastric mucosal growth
Ghrelin§ (GHRP)	Peptide (28aa)	Anterior pituitary	Secretion of GH
Secretin	Peptide (27aa)	Pancreas	Secretion of pancreatic bicarbonate and digestive enzymes
Cholecystokinin-pancreozymin (CCK-PZ)§	Peptide (33aa)	Gallbladder and pancreas	Stimulation of gallbladder contraction and secretion of pancreatic enzymes
Motilin	Peptide (22aa)	Gastrointestinal tract	Stimulation of gastrointestinal motility
VIP§	Peptide (28aa)	Gastrointestinal tract	Neurotransmitter; relaxation of smooth muscles of gut and of circulation; increased release of hormones and secretion of water and electrolytes from pancreas and gut
Gastric inhibitory peptide (GIP)	Peptide (42aa)	Gastrointestinal tract	Inhibition of gastric secretion and motility; increase in insulin secretion
Glucagon-like peptide-1	Peptide (30-31aa)	Gastrointestinal tract	Increased insulin and decreased glucagon secretion; inhibition of gastric emptying
Bombesin§	Peptide (14aa)	Gastrointestinal tract	Stimulation of release of various hormones and pancreatic enzymes, smooth muscle contractions and hypothermia, changes in cardiovascular and renal function
Neurotensin§	Peptide (13aa)	Gastrointestinal tract and hypothalamus	Uncertain
Substance P (SP)§	Peptide (11aa)	Gastrointestinal tract and brain	Sensory neurotransmitter, analgesic; increase in contraction of gastrointestinal smooth muscle; potent vasoactive hormone; promotion of salivation, increased release of histamine
Kidney			
1,25-$(OH)_2$ cholecalciferol	Sterol	Intestine Bone	Facilitation of absorption of calcium and phosphorus; increase in bone resorption in conjunction with PTH
		Kidney	Increase in reabsorption of filtered calcium
Erythropoietin	Peptide (165aa)	Bone marrow	Stimulation of red cell formation
Renin-angiotensin-aldosterone system	Peptides (renin, 297aa; Ang I, 10aa; Ang II, 8aa, produced from Ang I by angiotensin-converting enzyme)	Renin (from kidney) catalyzes hydrolysis of angiotensinogen (from liver, 485aa) to Ang I in the intravascular space	Increased blood pressure and stimulation of secretion of aldosterone (see adrenal) by Ang II
Liver			
IGF-1, formerly called somatomedin	Peptide (70aa)	Most cells	Stimulation of cellular and linear growth
IGF-2	Peptide (67aa)	Most cells	Insulin-like activity
Thymus			
Thymosin and thymopoietin	Peptides (28, 49aa)	Lymphocytes	Maturation of T lymphocytes
Heart			
Atrial natriuretic peptide (ANP, atriopeptin)	Peptide with an intrachain disulfide bond (28aa)	Vascular, renal, and adrenal tissues	Regulation of blood volume and blood pressure
B-type natriuretic peptide (BNP)	Peptide with an intrachain disulfide bond (32aa)	Vascular, renal, and adrenal tissues	Regulation of blood volume and blood pressure

TABLE 25-1 Major Hormones and Frequently Measured Hormone Precursors and Cytokines—cont'd

Endocrine Organ and Hormone	Chemical Nature of Hormone	Major Sites of Action	Principal Actions
Adipose Tissue			
Adiponectin	Peptide oligomers of 30-kDa subunits	Muscle Liver	Increased fatty acid oxidation Suppression of glucose formation
Leptin	Peptide (167aa)	Hypothalamus	Inhibition of appetite, stimulation of metabolism
Resistin	Peptide (94aa)	Liver	Insulin resistance
Multiple Cell Types			
Estrogens	See above	See above	See above
Galanin	Peptide (30aa)	Brain, pancreas, GI tract	Regulation of food intake, memory, and cognition; inhibition of endocrine and exocrine secretions of pancreas; delayed gastric emptying; prolonged colonic transport times
Parathyroid hormone-related peptide (PTH-RP)	Peptides (139, 141, 173aa)	Kidney, bone	Physiological function conjectural; PTH-like actions; tumor marker
Growth factors (e.g., epidermal growth factor, fibroblast growth factor, transforming growth factor family, platelet-derived growth factor, nerve growth factors)	Peptides	Many	Stimulation of cellular growth
Monocytes/Lymphocytes/Macrophages			
Cytokines (e.g., interleukins 1 to 18, tumor necrosis factor, interferons)	Peptides	Many	Stimulation or inhibition of cellular growth; other

*aa, Amino acid residues.
†Also produced by gastrointestinal tract and pancreas.
‡Glycoprotein hormones composed of two dissimilar peptides. The α-chains are similar in structure or identical; the β-chains differ among hormones and confer specificity.
§Androstenedione is also produced in the ovary and testis.
¶Two chains linked by two disulfide bonds: α, 24aa; β, 29aa.
**Also produced in the brain.
††Two chains linked by two disulfide bonds: α, 21aa; β, 30aa.
¶¶Each activin and inhibin is found in multiple forms.

circulate in plasma bound to proteins (thyroxine) or free (catecholamines). Thyroxine binds avidly to three binding proteins and has a half-life of about 7 to 10 days in the circulation; free and unbound catecholamines such as epinephrine have a very short half-life of a minute or less. Like the water-soluble peptide and protein hormones, these hormones interact with membrane-associated receptors and use a second messenger system.

Release and Action of Hormones

The physiological functions of hormones have been broadly categorized into those that (1) affect growth and development, (2) exert homeostatic control of metabolic pathways, and (3) regulate the production, use, and storage of energy. The descriptions that follow illustrate examples of these functions and mechanisms of control of hormone secretion.

Growth and Development

Normal growth and development of the whole human organism are dependent on the complex integrative function of many hormones, including (1) gonadal steroids (estrogenic and androgenic), (2) growth hormone, (3) cortisol, and (4) thyroxine. Also, several **pituitary** hormones are responsible specifically for the growth and development of endocrine glands themselves, and thus are responsible for control of synthesis and secretion of other hormones. Those other hormones provide negative feedback on secretion of the pituitary hormones. Other regulators of secretion of the pituitary hormones include **circadian rhythms** and a hypothalamic pulse generator that controls the pulsatile secretion of gonadotropins. Examples of hormones of the anterior pituitary gland (**adenohypophysis**) include the following:

- **Gonadotropins** (such as luteinizing hormone [LH] and follicle-stimulating hormone [FSH]) regulate the (1) development, (2) growth, and (3) function of the ovary and testis (see Chapter 43). Ovarian and testicular hormones in turn regulate (1) pubertal growth, (2) development and maintenance of secondary sex characteristics, (3) growth, (4) development, (5) maintenance of the skeleton and muscles, and (6) distribution of body fat
- ACTH regulates growth of the adrenal glands and synthesis and secretion of adrenal gland hormones (see Chapters 40 and 41)
- Thyroid-stimulating hormone (TSH) regulates growth of the thyroid gland and iodination of amino acids to produce the thyroid hormones triiodothyronine and thyroxine (see Chapter 42)[1]

Homeostatic Control of Metabolic Pathways

Homeostasis is defined as the ability or tendency of an organism or cell to maintain internal equilibrium by adjusting its

physiological processes. Hormones are key to this maintainance, and the metabolic pathways under hormonal control are diverse and complex. The following important examples illustrate the feedback control of hormone secretion, which is critical for homeostasis:

- Regulation of blood glucose: In response to a glucose load (as with feeding), insulin is promptly released from the pancreas, which regulates the dispersal of glucose into cells (fat, muscle, liver, and brain) for the metabolism necessary to produce energy from glucose (see Chapter 33). As circulating glucose concentrations return to preload concentrations, insulin secretion slows. Several counter-regulatory hormones come into play to further regulate this process to ensure that blood glucose concentrations do not become too low. These include (1) glucagon, (2) cortisol, (3) epinephrine, and (4) growth hormone. In addition, attention has focused on a group of gastrointestinal hormones termed **incretins** (see Chapter 33) that are released during eating and stimulate insulin secretion from the pancreas in advance of any measurable increase in blood glucose. Incretins also affect the rate of absorption of nutrients from the gut by slowing down the rate of gastric emptying. Another mechanism by which incretins have a role in the regulation of blood glucose is by delaying release of the counter-regulatory hormone glucagon from the α-cells of the pancreatic islets. The most studied incretins are glucagon-like peptide-1 (GLP-1) and gastric inhibitory peptide (GIP).
- Regulation of serum calcium (see Chapter 39): The calcium-sensing receptor (CaSR) on the parathyroid gland recognizes the circulating concentration of ionized calcium, which, in turn, regulates the synthesis and secretion of PTH. For example, when ionized calcium concentrations fall, PTH synthesis and secretion are stimulated. T is additional PTH will attempt to return the serum ionized calcium concentration to the previous level. PTH acts by enhancing renal tubular reabsorption of calcium and calcium efflux from the skeleton. PTH also catalyzes the synthesis of the renal hormone calcitriol (1,25-dihydroxyvitamin D), which acts on the gut to increase intestinal absorption of calcium. These very rapid responses of PTH and calcitriol quickly restore ionized calcium to concentrations at which the CaSR is no longer activated, and PTH and calcitriol synthesis and secretion return to basal rates.
- Water and electrolyte metabolism: The metabolism of water and electrolytes is regulated by (1) aldosterone from the adrenal gland, (2) renin from the kidney, and (3) vasopressin (antidiuretic hormone [ADH]) from the posterior pituitary gland (**neurohypophysis**; see Chapters 35, 40, and 41).

Regulation of the Production, Use, and Storage of Energy

Under normal conditions, regulation of energy (1) production, (2) use, and (3) storage is under tight hormonal control. More energy is required under several conditions such as (1) exercise, (2) starvation, (3) infection, (4) trauma, or (5) emotional stress. In such conditions, many hormones act to control not only circulating levels of nutrients but also the metabolism of these nutrients into necessary energy. This is very complex activity, which involves hormones from different organs, as already alluded to in the preceding section, is under neurological control, with numerous neuroendocrine hormones participating actively in this integrative metabolic process. This affects most organs in the body and modulates, for example, (1) heart rate, (2) sweating, (3) fertility, and (4) reproduction.

Role of Hormone Receptors

The "unique" or specific action of a hormone on its target tissue is a function of the interaction between the hormone and its receptor. As discussed previously, several types of hormone-receptor interactions occur.[3,5,8,17] The hormone-receptor complex provides the very high specificity of the action of the hormone, allowing the target tissue to accumulate the hormone from among all the molecules to which it is exposed. This is essential because hormones generally circulate in picomolar or nanomolar concentrations (10^{-9} to 10^{-12} mol/L).

Hormone receptors may be on the cell surface or may be intracellular within the cytoplasm or nucleus.

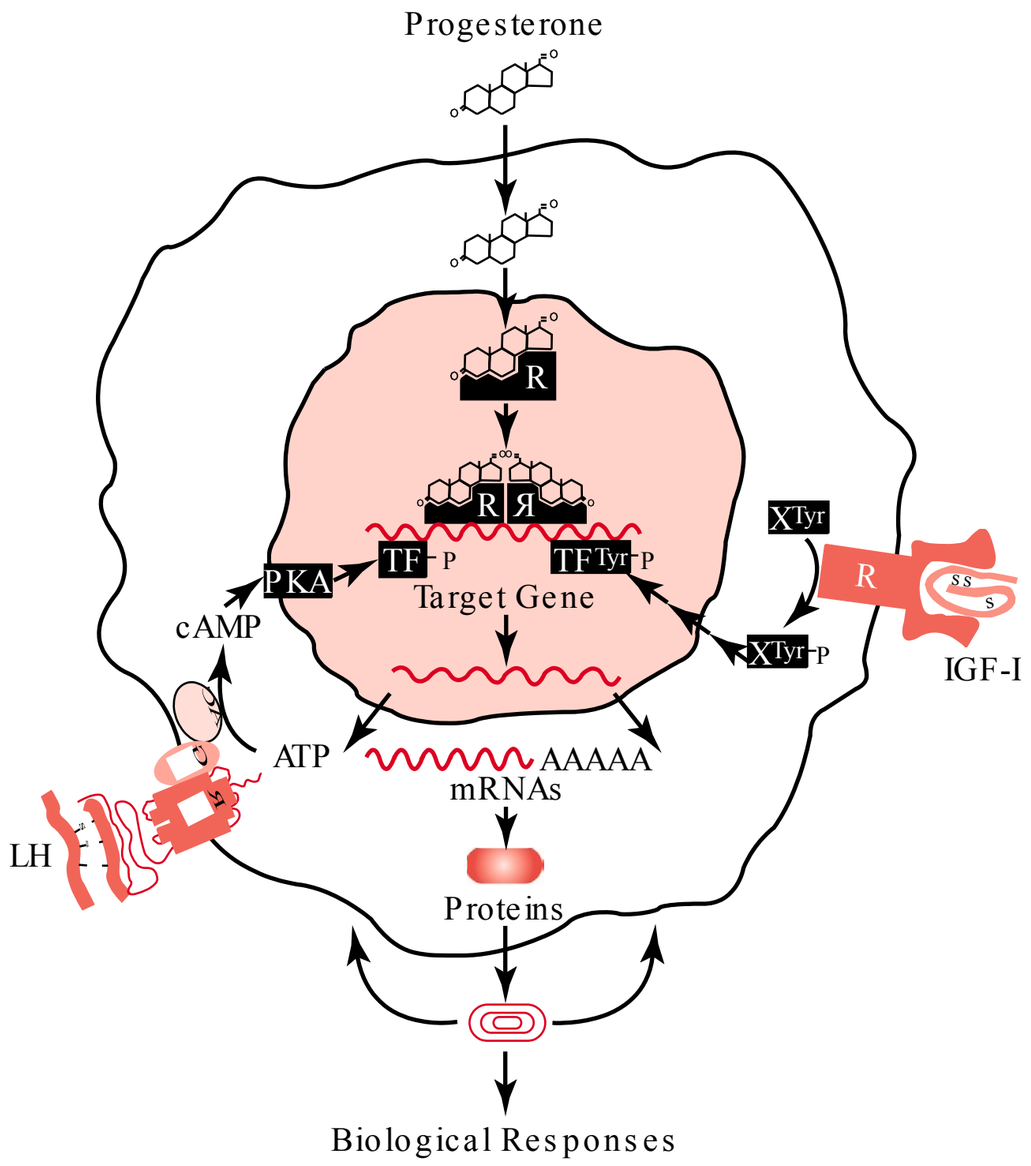

Figure 25-2 Hormonal signaling by cell surface and intracellular receptors. Receptors for the water-soluble polypeptide hormones, luteinizing hormone (LH), and insulin-like growth factor (IGF)-1, are integral membrane proteins located at the cell surface. They bind the hormone using extracellular sequences and transduce a signal through the generation of second messengers—cyclic adenosine monophosphate (cAMP) for the LH receptor and tyrosine-phosphorylated substrates for the IGF-1 receptor. Although effects on gene expression are indicated, direct effects on cellular proteins (e.g., ion channels) are also observed. In contrast, the receptor for the lipophilic steroid hormone progesterone resides in the cell nucleus. It binds the hormone and becomes activated and capable of directly modulating target gene transcription. R, Receptor molecule; Tf, transcription factor. (From Conn PM, Melmed S. Textbook of endocrinology. Towanta NJ: Humana Press, 1997.)

Cell Surface Receptors

Peptide hormones bind to cell surface receptors, and the conformational change resulting from this binding activates an effector system, which, in turn, is responsible for the downstream actions of the hormone (Figure 25-2).[11,12] For most peptide hormones, the intracellular effector that is activated by the hormone-receptor interaction is a specific **G-protein** (guanyl-nucleotide–binding protein),[4,10,13,18] and such receptors are called **G-protein–coupled receptors** (GPCRs; Figure 25-3). The major structural classes of GPCRs have been identified, each containing receptors for specific subsets of hormones. Group I, the largest group, contains receptors for many peptide hormones and catecholamines. Group II contains receptors for gastrointestinal hormones such as (1) secretin, (2) glucagons, and (3) vasoactive intestinal polypeptide. Group III contains the CaSR and the glutamate receptor. Stimulation of a G-protein initiates the intracellular processes of signal transduction that characterize the specific action of the hormone. G-proteins are composed of α-, β-, and γ-subunits and are classified according to the α-subunits, of which 20 have been identified to date. Some G-proteins (G_S type) stimulate the enzyme adenylate cyclase to produce the second messenger cAMP; other G proteins (G_i type) inhibit adenylate cyclase.

The classes of GPCRs and G-proteins briefly described in this section provide some insight into the mechanisms responsible for the specificity of hormone action. Some nonpeptide hormones also use cell surface receptors.

Intracellular Receptors

Lipid-soluble hormones such as progesterone (see Figure 25-2) are transported in plasma bound to carrier proteins, with only a small fraction of the hormone present in the free or unbound state. The free hormone enters the cell via passive diffusion and binds to intracellular receptors. The receptors may be in the cytoplasm or, more often, the nucleus, and may move between subcellular compartments (see Figure 25-2). These receptors are characterized by (1) a hormone-binding domain, (2) a deoxyribonucleic acid (DNA)-binding domain, and (3) an amino-terminal variable domain. Just as the interaction of protein or polypeptide hormones with cell surface receptors changes the conformation of the receptor protein, the binding of a lipid-soluble hormone with its specific hormone-binding domain on the intracellular receptor changes the molecular conformation of the intracellular receptor. This conformational change, or activation of the receptor, enables the hormone-receptor complex to bind to specific regulatory DNA sequences of a target gene or genes, permitting control of specific gene expression (see Figure 25-2).[7]

Postreceptor Actions of Hormones

Cell surface and intracellular receptors have different mechanisms of action within cells.

Cell Surface Receptors

Once GPCRs are occupied by a hormone, G-protein subunits begin a cascade of activation of specific enzymes that

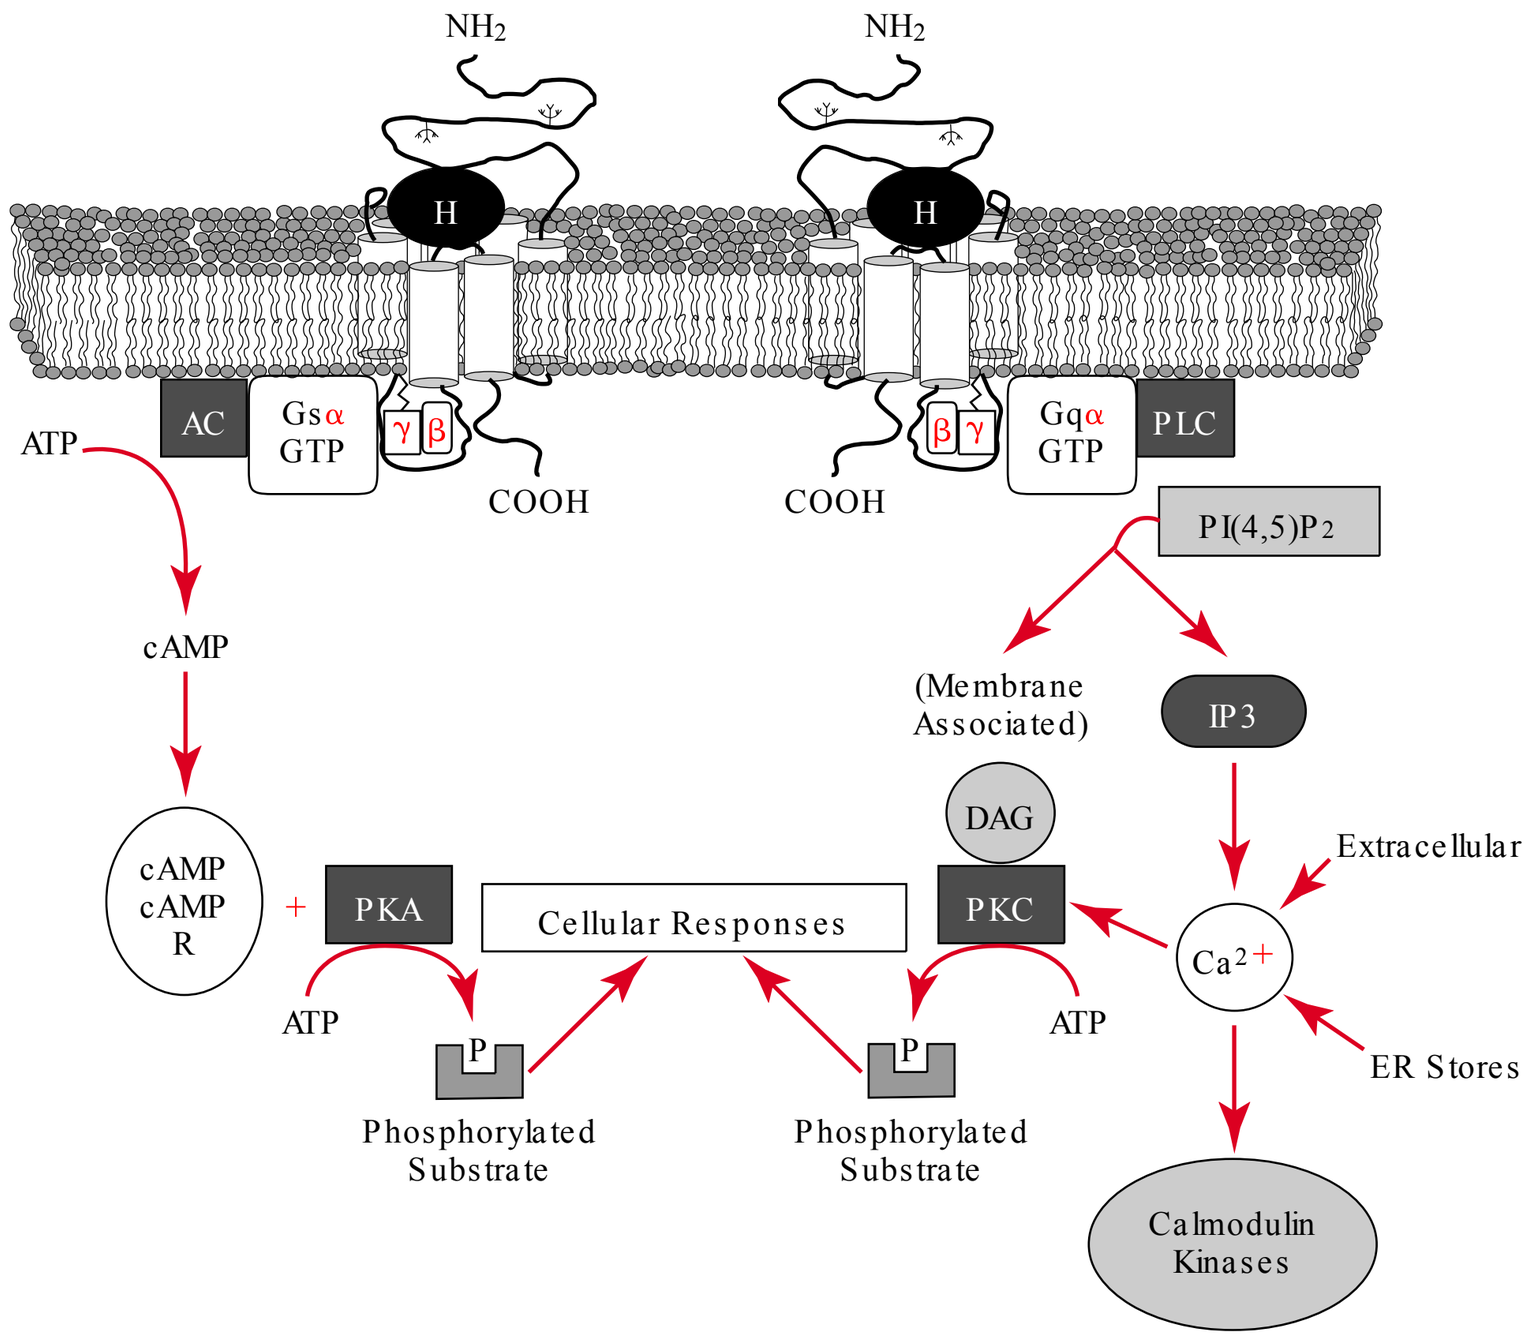

Figure 25-3 Signal transduction by cell surface receptors that are coupled to G-proteins. Two seven-transmembrane domains, coupled to different G-proteins (G_S and G_q), are shown. Activation of G_S leads to stimulation of the effector enzyme adenylate cyclase and production of a cyclic adenosine monophosphate (cAMP) second messenger, causing activation of protein kinase A (PKA) and the initiation of potential phosphorylation cascades. Activation of G_q leads to stimulation of the effector enzyme phospholipase C-β and the production of inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) second messengers, one effect of which is to activate protein kinase C (PKC) and initiate a potential phosphorylation cascade. (From Conn PM, Melmed S, eds. Textbook of endocrinology. Towanta NJ: Humana Press, 1997.)

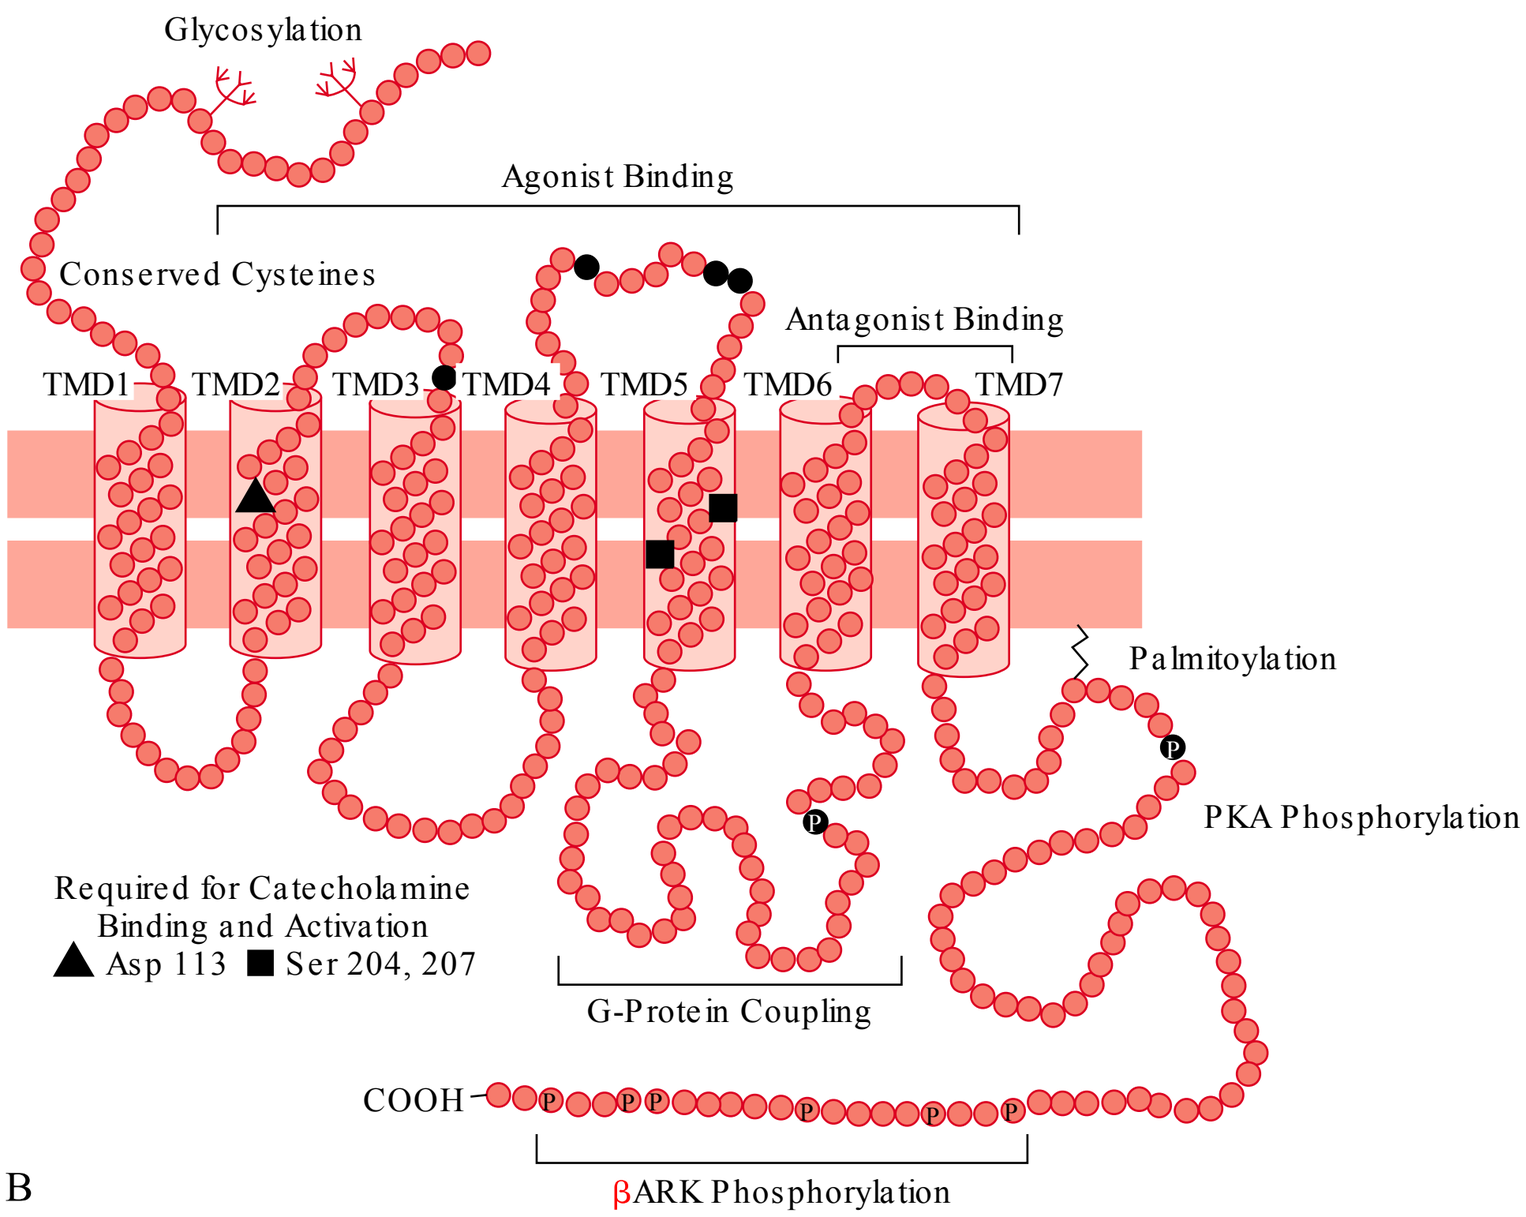
G-Protein–Coupled Receptor (GPCR) Superfamily

Family A:	Receptors Related to Rhodopsin and the β-Adrenergic Receptor
Group I:	Olfactory, Adenosine, Melanocortin Rs
Group II:	Adrenergic, Muscarinic, Serotonin, DA Rs
Group III:	Neuropeptide Rs and Vertebrate Opsins
Group IV:	Bradykinin R and Invertebrate Opsins
Group V:	Peptide and GP Hormone, Chemokine Rs
Group VI:	Melatonin and Orphan Rs

Family B:	Receptors Related to the Calcitonin and Parathyroid Hormone Receptors
Group I:	Calcitonin, Calcitonin-like, CRF Rs
Group II:	PTH and PTHrP Rs
Group III:	Glucagon, Secretin, VIP, GHRH Rs



Family C:	Receptors Related to the Metabotropic Glutamate Receptors
Group I:	Metabotropic Glutamate Rs
Group II:	Extracellular Calcium Ion Sensor Rs

Family D:	Receptors Related to the STE2 Pheromone Receptor
Group I:	Alpha Factor Pheromone Rs

Family E:	Receptors Related to the STE3 Pheromone Receptor
Group I:	A Factor Pheromone Rs

Family F:	Receptors Related to the cAMP Receptor
Group I:	Dictyostelium cAR1-4 Rs

A

B

Figure 25-4 **A,** G protein–doubled receptor super family. **B,** Signaling by G_S. The α-, β-, and γ-subunits of G_s are shown. The α-subunit, when bound to guanosine triphosphate (GTP), activates adenylyl cyclase, which catalyzes the formation of cAMP from ATP. Then cAMP binds to the regulatory subunit (R) of protein kinase A (PKA, cAMP-dependent protein kinase), releasing the PKA catalytic subunit (C), thus leading to phosphorylation of target proteins.

generate molecules that serve as second messengers to affect the hormone response. The best known of these are (1) **adenylyl cyclase**, which generates **cyclic adenosine monophosphate (cAMP)**, and (2) **phospholipase C**, which generates both inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (see Figure 25-3). The production of second messengers and the subsequent magnitude of the effect of the hormone are functions of the amount of hormone bound to the GPCR. The binding of a small number of hormone molecules on the cell surface leads to the production of many molecules of the

second messenger, thus amplifying the signal sent by the hormone (which is considered the **first messenger**).

cAMP-dependent protein kinases (PKAs) are a family of enzymes that, in the presence of cAMP, phosphorylate a number of intracellular enzymes and other proteins to activate or inactivate the function of these enzymes and proteins. This process regulates their function. As a further means of regulating hormone action, these cAMP-dependent kinases consist of two catalytic and two regulatory subunits (C and R, respectively, in Figure 25-4). The regulatory subunits exist as a dimer (pair of subunits) that binds two molecules of cAMP. This binding releases the catalytic subunits, which then are active as phosphorylating enzymes, acting on serine and threonine residues in target proteins.

Phospholipase C (see Figure 25-3) acts on inositol phospholipids within the cell membrane to produce IP_3, which opens up ion channels to facilitate entry of (1) calcium into the cytoplasm, where it acts as a messenger, and (2) diacylglycerol, which modulates protein kinase C activity.

The insulin receptor represents a somewhat different class of cell surface receptors that contain intrinsic hormone-activated tyrosine kinase activity, that is, an activity to add phosphates to tyrosine residues in specific proteins. They do not otherwise involve a second messenger.[16] The insulin receptor, the prototype of this type of receptor, consists of two α- and two β-subunits joined by disulfide bridges. The extracellular hormone-binding domains are the α-subunits, and the β-subunits are intracellular. They contain an ATP-binding site and a catalytic kinase domain through which tyrosine kinase is activated immediately upon binding of insulin to the receptor.

Because hormones largely serve a regulatory function, of necessity many self-limiting steps are included in the previous processes. Without these self-limiting processes, hormone action would continue unabated. Cessation of hormone action of cAMP involves the inactivation of G-protein stimulation of adenylate cyclase by guanosine triphosphatase (GTPase) (Figure 25-5). In the absence of hormone interaction with the GPCR (basal or unstimulated state), G_s is bound to guanosine diphosphate (GDP). Once the hormone is bound to the receptor, GDP is released from G_s and is replaced by GTP, and the G_s-GTP complex activates adenylate cyclase. The G_s-GTP complex is inactivated by GTPase, restoring the G_s-GDP state, which cannot stimulate formation of cAMP until further hormone binding to the GPCR takes place. Within a few minutes (or less) of hormone-GPCR interaction and initiation of hormone action, the receptor is phosphorylated by protein kinase A and protein kinase C. This phosphorylation of the hormone receptor permits internalization of the complex from the cell surface into the cytoplasm. There, dephosphorylation occurs, permitting degradation of the hormone and recycling of the GPCR to its original transmembrane location, awaiting coupling with more hormone. In addition, one of the proteins that is phosphorylated and activated by PKA is an enzyme that breaks down cAMP, thus removing the key activator of PKA.

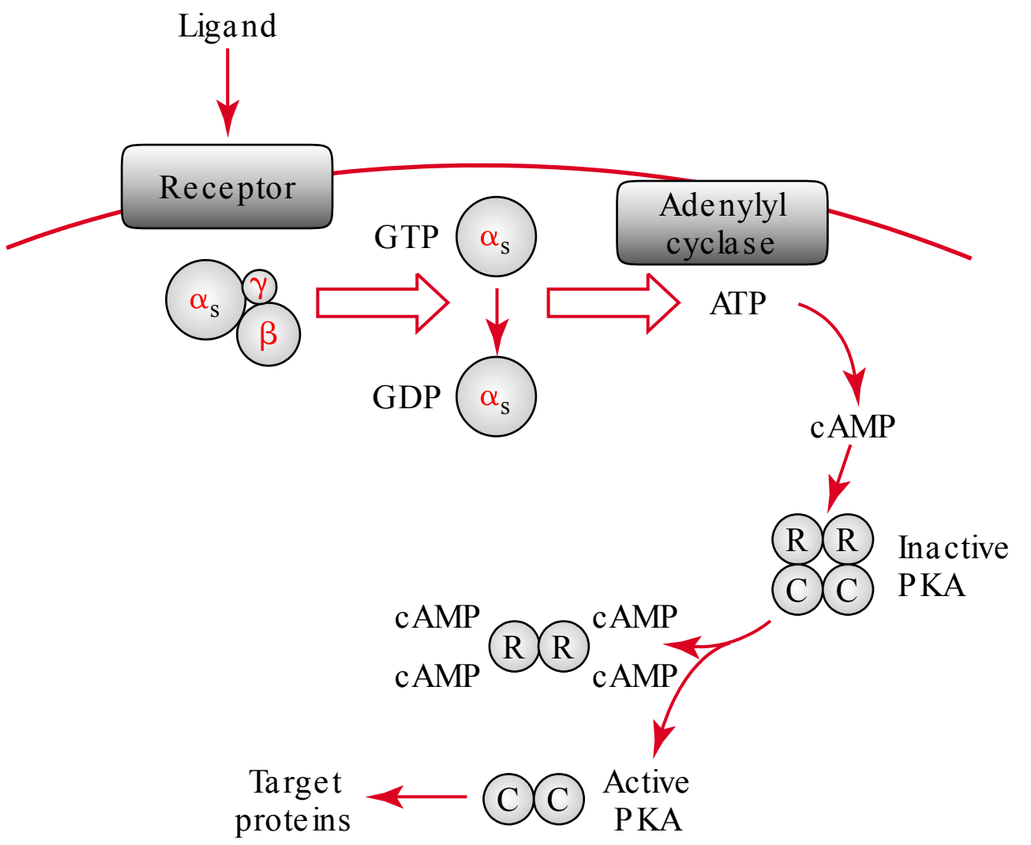


Figure 25-5 The G-protein cycle. The α-, β-, and γ-subunits of G_s are shown. The α-subunit, when bound to GTP, activates the effector molecule (such as adenylyl cyclase). GTP then is hydrolyzed to GDP, stopping activation of the effector molecule and leading to re-formation of the GDP-bound state of the G-protein.

Intracellular Receptors

As previously noted, lipid-soluble hormones bind to the hormone-binding domain of cytosolic or nuclear receptors.[11,12] This results in a conformational change that enables the hormone-receptor complex to bind to specific regulatory DNA sequences in the 5′ end of the target gene.[7] The binding specificity of the (hormone-bound) receptor for specific regions of DNA of the target gene is determined by **zinc finger protein** structures in the receptor's DNA-binding domain. It is the binding of the hormone-receptor complex to DNA regulatory elements that enhances or represses gene transcription. The messenger ribonucleic acid (RNA) that is enhanced or diminished by hormone-receptor binding to the target gene regulates the synthesis of specific proteins that mediate the hormone's physiological actions. The system is further regulated by the presence or absence of co-activators or co-repressors of gene expression. In addition, many actions of hormones that bind to intracellular receptors are rapid and do not depend on synthesis of protein, suggesting that these hormone-receptor complexes exert actions by mechanisms different from binding to DNA.

From these descriptions, it is possible for one to deduce both the complexity and the specificity of hormone action, in terms of an "on and/or off" concept and in terms of an "effect size" concept.

Measurements of Hormones and Related Analytes

Hormones are measured by a variety of analytical techniques, including (1) bioassay, (2) receptor assay, (3) immunoassay, and (4) instrumental techniques such as mass spectrometry interfaced with liquid or gas chromatography. A general overview of these techniques is given here with more detailed discussions found in Chapters 9 to 15. Also, analytical details for

individual hormones using such techniques are found in the discussion of individual hormones in Chapters 40 through 43.

Bioassay Techniques

Bioassays are based on observations of physiological responses specific for the hormone being measured. In vivo bioassays usually involve the injection of test materials (such as blood or urine from a patient) into suitably prepared animals. Target gland responses such as growth or steroidogenesis are then measured. In vitro bioassays involve the incubation of (1) tissue, (2) membranes, (3) dispersed cells, or (4) permanent cell lines in a defined culture medium, with subsequent measurement of an appropriate hormone response. Most in vitro bioassays measure responses proximal or distal to a second messenger such as stimulation of cAMP formation. Bioassays, however, tend to be imprecise and are rarely necessary in clinical medicine.

Receptor-Based Assays

Receptor assays depend on the in vitro interaction of a hormone with its biological receptor. In this type of assay, unlabeled hormone displaces trace amounts of labeled hormone from receptor sites. A second approach is to measure a response, such as production of cAMP, when a test sample is added to a preparation that includes the receptor and necessary cofactors. In general, receptor assays are simpler to perform and are more sensitive than bioassays. Receptor assays also provide an advantage over immunoassays in that they reflect the biological function of a hormone, namely, the capacity to combine with specific receptor sites. By contrast, immunoassays may measure (1) active hormone, (2) inactive prohormone, (3) hormone polymer, and (4) metabolites when all share a common antigenic determinant or set of determinants. In general, receptor assays are not as sensitive as immunoassays, and enzymes in the biological specimen may degrade the receptor or destroy the labeled tracer. T e added complexity and lability of receptor preparations also contribute to the limited application of these assays in the routine clinical laboratory.

Immunoassay Techniques

Immunoassays employing antibodies are widely used to quantify hormones (see Chapter 15). Currently labeled antibody (immunometric) assays with nonisotopic labels are the method of choice for measuring most hormones, especially peptides and proteins. Immunometric assays use saturating concentrations of two or more antibodies (often monoclonal) that are prepared against different epitopes of the protein molecule. One of the two antibodies is usually attached to a solid-phase separation system and extracts the hormone from the serum specimen. T e second ("detection") antibody is linked to a signal molecule or "label". When the second antibody binds to the hormone, a "sandwich" is formed in which the hormone is in the middle, with an antibody on each side. At this point the whole sandwich is attached to the solid phase (such as plastic). When more hormone is present, more labeled antibody is able to be bound. After washing away unbound labeled antibody, the label or signal that remains attached to the solid phase is then measured to quantify the bound hormone.

Instrumental Techniques

Mass spectrometers (see Chapter 13) coupled with gas and liquid chromatographs (see Chapter 12) are powerful qualitative and quantitative analytical tools that are widely used to measure hormones.[2,6,9,14] Technical advancements in mass spectrometry have resulted in the development of matrix-assisted laser desorption/ionization (MALDI) and electrospray ionization techniques that allow sequencing of peptides and mass determination of picomole quantities of analytes.

Compared with older methods, mass spectrometry offers greater analytical (1) sensitivity, (2) accuracy, and (3) speed, and allows simultaneous determination of multiple hormones related to a clinical condition.[14] Mass spectrometric methods are widely available to measure small molecules such as cortisol and, increasingly are used to measure even large peptide hormones and hormone precursors such as thyroglobulin.

Specimen Requirements

As seen from the brief descriptions of hormone action given previously and amplified in the hormone-specific chapters, particular attention must be paid to the clinical material sent to the laboratory for assay. Some hormones (such as insulin) are directly affected by intake of nutrients and others (such as cortisol) are affected by time of day. In many clinical circumstances, the metabolic environment plays a crucial role in hormone production, and it is essential to obtain a simultaneous sample for measurements of both the hormone and the molecule(s) regulated by that hormone. An isolated measurement of plasma insulin without concurrent knowledge of the plasma glucose, or measurement of parathyroid hormone independent of serum calcium, is of little value. For example, PTH concentrations in plasma should be very low when plasma calcium is high; failure of PTH to be suppressed is a sign of an overactive parathyroid gland.

When a patient is evaluated for possible hormone deficiency or hormone excess, it is often necessary to perform a stimulation or suppression test. Most hormone assays are performed on plasma or serum, and many are performed on urine samples, usually a 24-hour collection. Increasingly, saliva has become a convenient body fluid for hormone analysis, particularly for hormones secreted in a diurnal rhythm such as cortisol. Unlike blood sampling, patients are provided with salivary collection material such that they are able to provide to the laboratory specimens collected at multiple times during the day or at unusual (but biologically very relevant) times such as 21:00 (11:00 pm)—a commonly used time for obtaining a specimen for measurement of cortisol.

Review Questions

1. Steroid hormones, by binding specific nuclear receptors, have a direct effect on:
   a. enzyme phosphorylation.
   b. gene expression.
   c. cAMP formation.
   d DNA replication.
2. When a protein hormone binds a cell membrane receptor, the classical result is:
   a. phosphorylation of intracellular enzymes.
   b. inhibition of mRNA within the cell nucleus.
   c. replication of DNA and division of the cell.
   d. glycosylation of intracellular proteins.
3. An example of an amino acid–related hormone would be:
   a. testosterone.
   b. thyroid hormone.
   c. growth hormone.
   d. prostaglandin.
4. Which of the following hormones is classified as a polypeptide?
   a. Cortisol
   b. Estrogen
   c. Adrenocorticotropic hormone
   d. T yroid hormone
5. T e type of hormone assay that best reflects hormone functionality as opposed to quantification of the hormone itself is the:
   a. receptor-based assay.
   b. mass spectrometry–based assays.
   c. bioassay technique.
   d. liquid chromatography.
6. A hormone released from the pancreas in response to a glucose load that is involved in cellular energy production is considered to be involved in:
   a. modification of the response to stress.
   b. synthesis of milk proteins.
   c. promotion of bone development and growth
   d. homeostatic control of metabolism.
7. Which of the following is a characteristic of steroid hormones?
   a. Account for the majority of hormones
   b. Circulate freely
   c. Water soluble
   d. Long half-life in the circulation

CHAPTER

26 Catecholamines and Serotonin

Graeme Eisenhofer, Ph.D., Thomas G. Rosano, Ph.D., D.A.B.F.T., D.A.B.C.C., and Ronald J. Whitley, Ph.D., F.A.C.B., D.A.B.C.C

Objectives

1. Define the following terms:
   - 5-HIAA
   - Carcinoid
   - Carcinoid syndrome
   - Catecholamine
   - Gastroenteropancreatic neuroendocrine tumor
   - Homovanillic acid
   - Metanephrine
   - Neuroblastoma
   - Normetanephrine
   - Paraganglioma
   - Pheochromocytoma
   - Serotonin
2. Discuss the following biogenic amines, including function and clinical relevance, synthesis, metabolism, and storage and release:
   - Norepinephrine
   - Epinephrine
   - Dopamine
   - Serotonin
   - Melatonin
3. List the clinically relevant metabolites of the biogenic amines listed in Objective 2 above.
4. State the clinical significance and function of the catecholamines and serotonin in each of the following systems:
   - Central nervous system
   - Sympathetic nervous system
   - Adrenal medullary system
   - Peripheral dopaminergic system
   - Enteric nervous system
5. Compare pheochromocytoma and neuroblastoma, including causes, symptoms, organ(s) and/or cell type involved, and laboratory evaluation of each; describe the clonidine suppression test and the results obtained when pheochromocytoma is present.
6. Explain the laboratory values obtained for serotonin and 5-HIAA in the assessment of a gastroenteropancreatic tumor and the carcinoid syndrome.
7. Describe the collection techniques used to obtain specimens for catecholamine, metanephrine, and serotonin analysis.
8. Describe how diet interferes with serotonin analysis; state how tricyclic antidepressants interfere in the measurement of catecholamines.
9. List the laboratory methods used to analyze metanephrines, catecholamines, serotonin, and 5-HIAA.
10. Analyze and solve case studies related to catecholamine and serotonin disorders using descriptions of symptoms and results of laboratory analyses.

Key Words and Definitions

Carcinoid syndrome A syndrome due to carcinoid tumors and characterized by attacks of severe cyanotic flushing of the skin—lasting from minutes to days—and by diarrheal watery stools, bronchoconstrictive attacks, sudden drops in blood pressure, edema, and ascites. Symptoms are caused by secretion from the tumor of serotonin, prostaglandins, and other biologically active substances.

Carcinoid tumor A yellow circumscribed tumor arising from enterochromaffin cells, usually in the small intestine, appendix, stomach, or colon, and less commonly in the bronchus; sometimes used alone to refer to the gastrointestinal tumor (called also argentaffinoma).

Catecholamine One of a group of biogenic amines having a sympathomimetic action, the aromatic portion of whose molecule is catechol, and the aliphatic portion an amine; examples include dopamine, norepinephrine, and epinephrine.

Catecholamine metabolites Products of catecholamine metabolism, such as dihydroxyphenylacetic acid, methoxytyramine, homovanillic acid, dihydroxyphenylglycol, methoxyhydroxyphenylglycol, normetanephrine, metanephrine, and vanillylmandelic acid.

Catechol-O-methyltransferase (COMT) An enzyme that degrades catecholamines.

Chromaffin cell Neuroendocrine cell derived from embryonic neural crest found in the medulla of the adrenal gland and in other ganglia of the sympathetic nervous system; so-named because of the presence of cytoplasmic granules that give a brownish reaction with chromium salts.

Key Words and Definitions—cont'd

3,4-Dihydroxyphenylglycol (DHPG) The metabolite produced within the peripheral sympathetic or central nervous system noradrenergic nerves by deamination of norepinephrine (can also be formed from epinephrine); O-methylated to methoxyhydroxyphenylglycol in extraneuronal tissues.

l-Dopa An amino acid—3,4-dihydroxyphenylalanine—produced by oxidation of tyrosine by tyrosine hydroxylase; the precursor of dopamine and an intermediate product in the biosynthesis of norepinephrine, epinephrine. Can also be formed in melanocytes by the actions of tyrosinase as part of the production of melanin.

Dopamine A catecholamine formed in the body by the decarboxylation of l-dopa; an intermediate product in the synthesis of norepinephrine; acts as a neurotransmitter in the central nervous system, produced peripherally and acts on peripheral receptors.

Enteric nervous system (ENS) An independent and integrated system of neurons and supporting cells.

Epinephrine (adrenaline) A catecholamine hormone secreted by the adrenal medulla.

Gastroenteropancreatic neuroendocrine tumor (GEP-NET) Encompasses neuroendocrine tumors of the digestive system and pancreas but also covers neuroendocrine pulmonary tumors and includes carcinoid tumorss.

Homovanillic acid (HVA) A product of dopamine metabolism; elevated urinary concentrations are used to diagnose neuroblastoma.

5-Hydroxyindoleacetic acid (5-HIAA) A metabolite of serotonin (5-hydroxytryptamine) that is excreted in large amounts by patients with carcinoid tumors.

Melatonin A hormone synthesized by the pineal gland in many species of animals; its secretion increases during exposure to light.

(MEN) Multiple endocrine neoplasia A group of rare genetic disorders characterized by hyperplasia and hyperfunction of two or more components of the endocrine system.

Metanephrine A catecholamine metabolite resulting from O-methylation of epinephrine; formed mainly within adrenal chromaffin cells; excreted mainly in the urine as a sulfate-conjugated metabolite; measurements of the free and conjugated metabolites provide useful tests for diagnosis of pheochromocytoma.

Methoxyhydroxyphenylglycol (MHPG) A metabolite of epinephrine and norepinephrine formed primarily from O-methylation of dihydroxyphenylglycol and in smaller amounts from deamination of normetanephrine and metanephrine; found in brain, blood, CSF, and urine, where its concentrations can be used to measure catecholamine turnover.

Neuroblastoma A sarcoma consisting of malignant neuroblasts, usually arising in the autonomic nervous system (sympathicoblastoma) or in the adrenal medulla; considered a type of neuroepithelial tumor that affects mostly infants and children up to 10 years of age.

Neuroendocrine tumors (NET) Neoplasms that arise from cells of the endocrine and peripheral nervous systems, most commonly in the digestive tract, but also found in the lung, pancreas, pituitary, thyroid, and other tissues.

Neurofibromatosis 1 (NF1) An autosomal dominant disorder due to mutation in the NF1 gene.

Norepinephrine (noradrenaline) A major neurotransmitter produced by some brain neurons and peripheral sympathetic nerves that acts on α- and β_1-adrenergic receptors; produced in the adrenal chromaffin cells as a precursor for epinephrine.

Normetanephrine An O-methylated metabolite of norepinephrine produced in extraneuronal cells and the adrenal medulla; excreted in the urine largely as a sulfate-conjugated metabolite; measurements of free and conjugated metabolites provide useful tests for diagnosis of pheochromocytoma.

Paraganglioma A tumor of the tissue composing the paraganglia.

Parkinson disease A slowly progressive disorder affecting the basal ganglia, usually occurring in late life, with an average age of onset of 60 years.

Pheochromocytoma A usually benign, well-encapsulated, lobular, vascular tumor of chromaffin tissue of the adrenal medulla or sympathetic paraganglia.

Serotonin (5-hydroxytryptamine) A monoamine vasoconstrictor synthesized in the intestinal enterochromaffin cells or in central or peripheral neurons; found in high concentrations in many body tissues, including intestinal mucosa, pineal body, and central nervous system.

Vanillylmandelic acid (VMA) The main end-product of norepinephrine and epinephrine metabolism excreted in the urine; formed primarily in the liver from oxidation of methoxyhydroxyphenylglycol.

Catecholamines and serotonin are biogenic amines that facilitate neuronal or hormonal signaling for a wide range of physiological processes. T e naturally occurring catecholamines, **dopamine** and **norepinephrine (noradrenaline)**, function as neurotransmitters in the brain and peripheral sympathetic nerves, whereas **epinephrine (adrenaline)** functions as a hormone released by the adrenal medulla. Catecholamines are critical in maintaining the body's homeostasis and in responding to acute and chronic stress through orchestration of (1) cardiovascular, (2) metabolic, (3) glandular, and (4) visceral organ activities.[4] **Serotonin (5-hydroxytryptamine)** also serves as a neurotransmitter in the brain and as a modulator of vascular and gastrointestinal functions in the periphery. Abnormal production of catecholamines or serotonin may occur in a number of neuroendocrine tumors, where clinical signs and symptoms reflect the pharmacological properties of the secreted amines. Clinical measurement of the biogenic amines or of their metabolites aids in tumor detection and monitoring, and analytical advances have produced sensitive and specific laboratory methods for clinical practice.[13,14]

Chemistry, Biosynthesis, Release, and Metabolism

Chemistry

The catecholamines—dopamine, norepinephrine (noradrenaline), and epinephrine (adrenaline)—are phenylethylamines with hydroxyl groups on positions three and four of the benzene ring and an ethylamine sidechain on position one (Figure 26-1). Hydroxyl and methyl substitutions on the ethylamine sidechain distinguish the individual catecholamines in terms of both structure and function. The catecholamines demonstrate varying degrees of alkaline instability in biological fluids, and their dihydroxybenzene or catechol structure is sensitive to oxidative formation of quinones in the presence of air and light. Serotonin with its indoleamine structure is distinct from the catecholamines but is an important naturally occurring biogenic amine. **Melatonin** is the principal indoleamine produced from serotonin by the pineal gland.

Biosynthesis

The rate-limiting step in catecholamine biosynthesis involves conversion of tyrosine to **3,4-dihydroxyphenylalanine (l-dopa)** by the enzyme tyrosine hydroxylase (Figure 26-2).[4] A related enzyme, tryptophan hydroxylase, catalyzes conversion of tryptophan to 5-hydroxytryptophan in the first step of serotonin synthesis. Tissue sources of catecholamines are principally dependent on the presence of tyrosine hydroxylase, which is largely confined to dopaminergic and noradrenergic neurons of the central nervous system and to the sympathetic and adrenal medullary systems in peripheral tissues.[4] Similarly, sources of serotonin are largely dependent on the presence of tryptophan hydroxylase in central nervous system serotonergic neurons, the pineal gland, and some peripheral endocrine tissue, particularly enterochromaffin cells of the digestive tract.[7] Platelets also contain large amounts of serotonin synthesized in enterochromaffin cells of the gastrointestinal tract.

Conversion of l-dopa to dopamine and 5-hydroxytryptophan to serotonin is catalyzed by aromatic-l–amino acid decarboxylase (see Figure 26-2), an enzyme with a wide tissue distribution and broad substrate specificity for aromatic amino acids. The dopamine and serotonin formed in the cytoplasm by aromatic-l–amino acid decarboxylase are transported into vesicular secretory granules, where the amines are concentrated and stored ready for exocytotic release as the principal neurotransmitters of central nervous system dopaminergic and serotonergic neurons. The dopamine formed in noradrenergic neurons and **chromaffin cells** is further converted to norepinephrine by dopamine β-hydroxylase, an enzyme specifically located in secretory granules. The additional presence of phenylethanolamine N-methyltransferase in adrenal medullary chromaffin cells leads to further conversion of norepinephrine to epinephrine.

Melatonin is synthesized from serotonin in the pineal gland by two highly specific enzymes; the first step is catalyzed by serotonin-N-acetyltransferase and the second by hydroxyindole-O-methyltransferase.

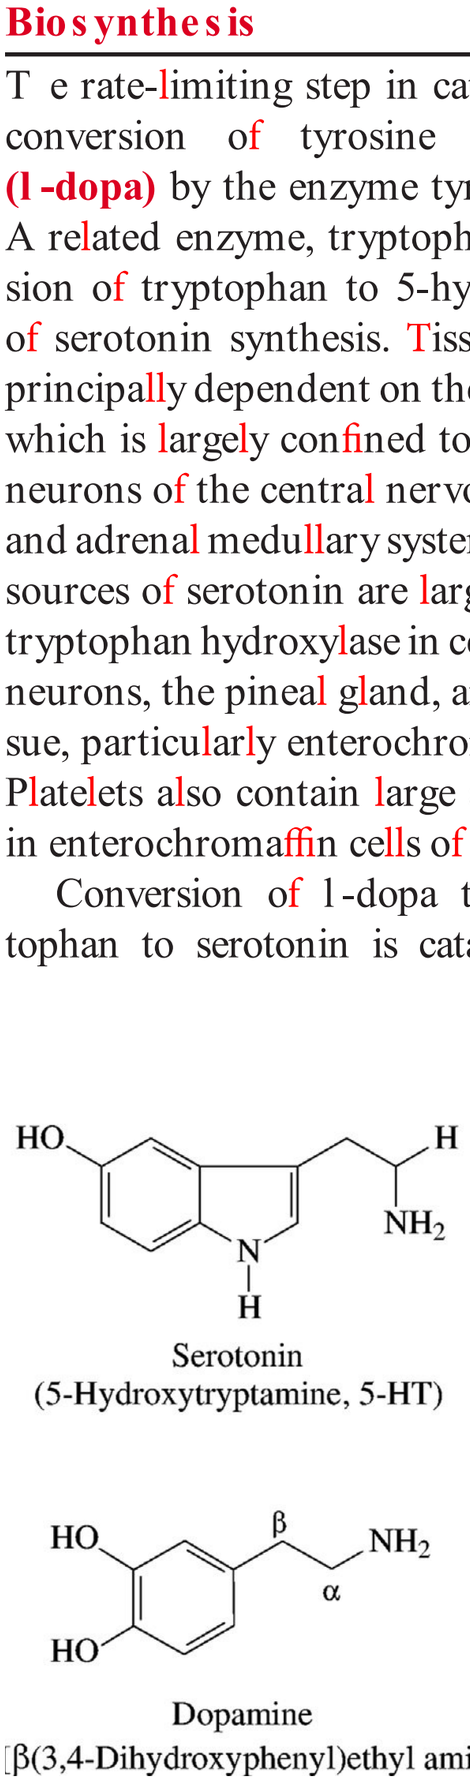

Figure 26-1 Chemical structures of the catecholamines and serotonin.

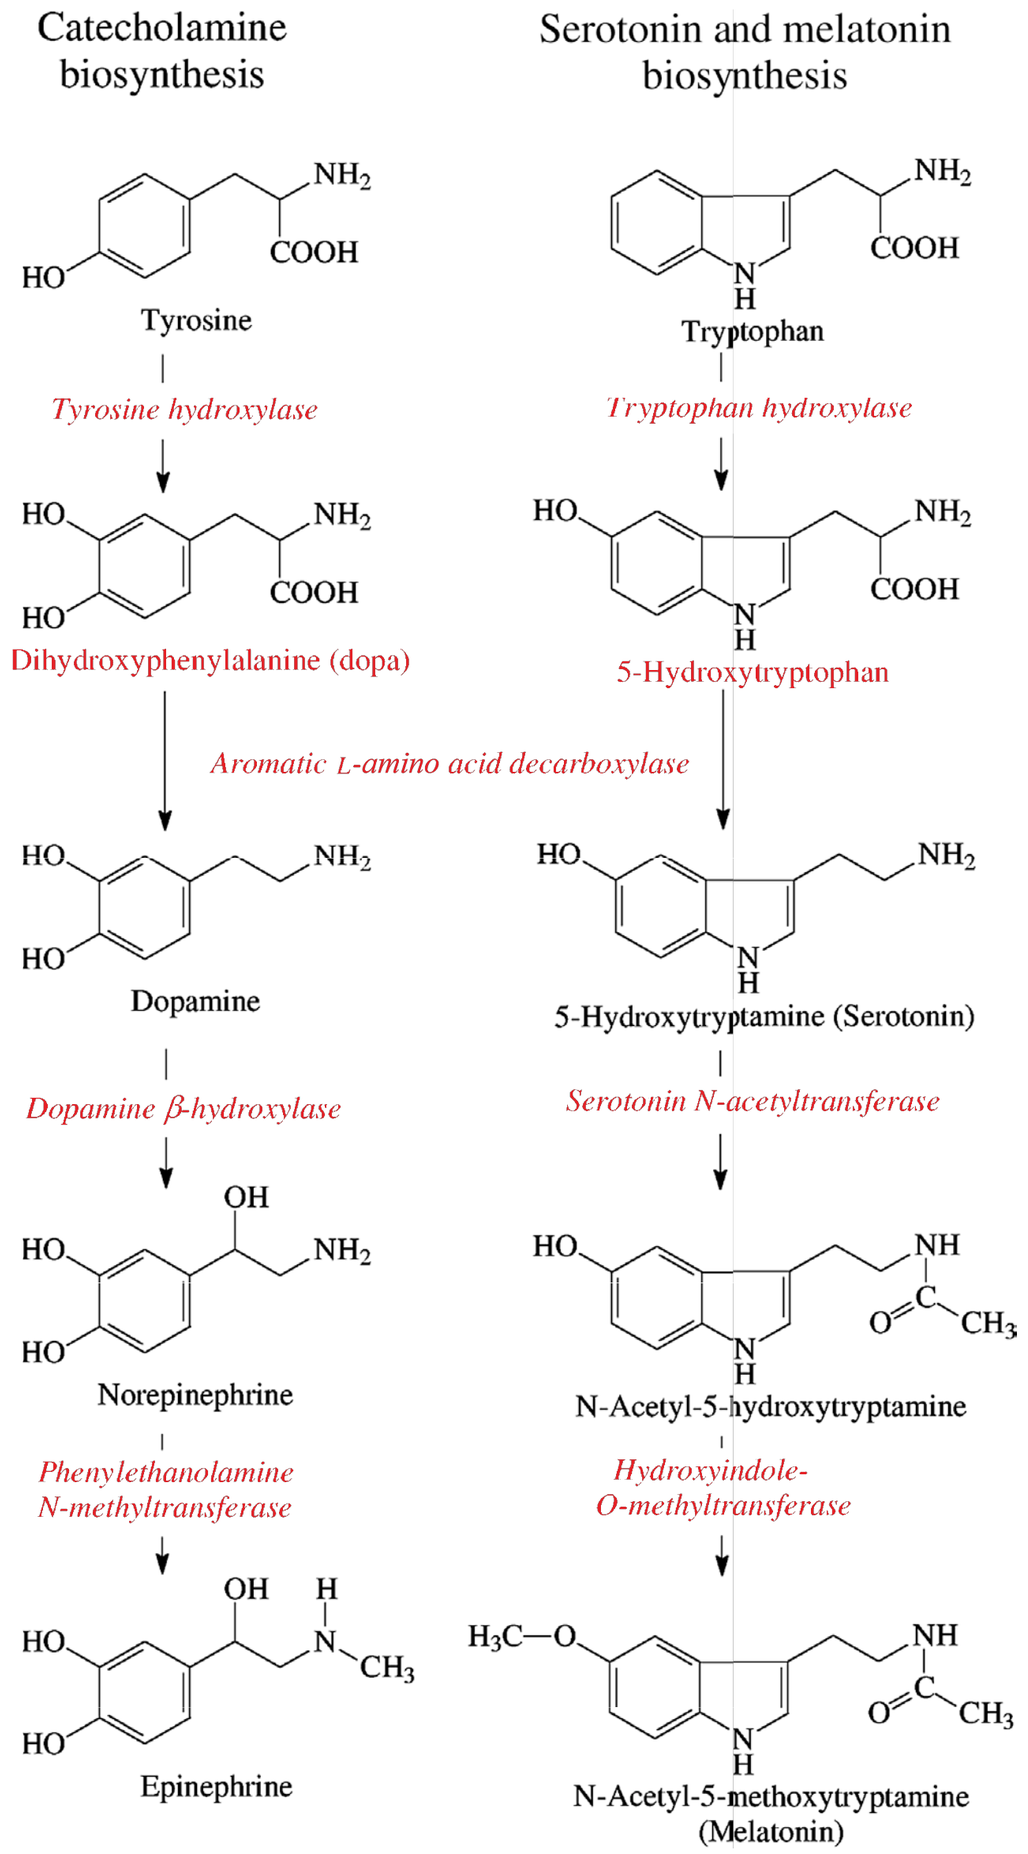

Figure 26-2 Biosynthesis of catecholamines and serotonin, and metabolism of serotonin to melatonin.

Storage and Release

Monoamines stored in secretory granules exist in a highly dynamic equilibrium with the surrounding cytoplasm, with passive outward leakage of monoamines into the cytoplasm counterbalanced by inward active transport under the control of vesicular monoamine transporters (Figure 26-3).[2] Monoamines share the acid environment of the secretory granule matrix with ATP, peptides, and proteins, the best known of which are the chromogranins. The chromogranins are common components of monoamine-containing secretory granules. Their widespread presence among endocrine tissues has led to their measurement in plasma as useful, albeit relatively nonspecific, markers of neuroendocrine tumors (see Chapter 20).

Monoamines are released from secretory vesicles into the extracellular space through the process of exocytosis. This is stimulated by an influx of calcium, primarily controlled in neurons by nerve impulse–mediated membrane depolarization, and in adrenal medullary cells by acetylcholine released from innervating splanchnic nerves. Neuronal release may also occur by calcium-independent nonexocytotic processes involving increased loss of monoamines from storage vesicles into the cytoplasm and reversal of normal inward carrier-mediated transport to outward transport of monoamines into the extracellular environment. Examples of this process include the release of catecholamines induced by tyramine and amphetamine.

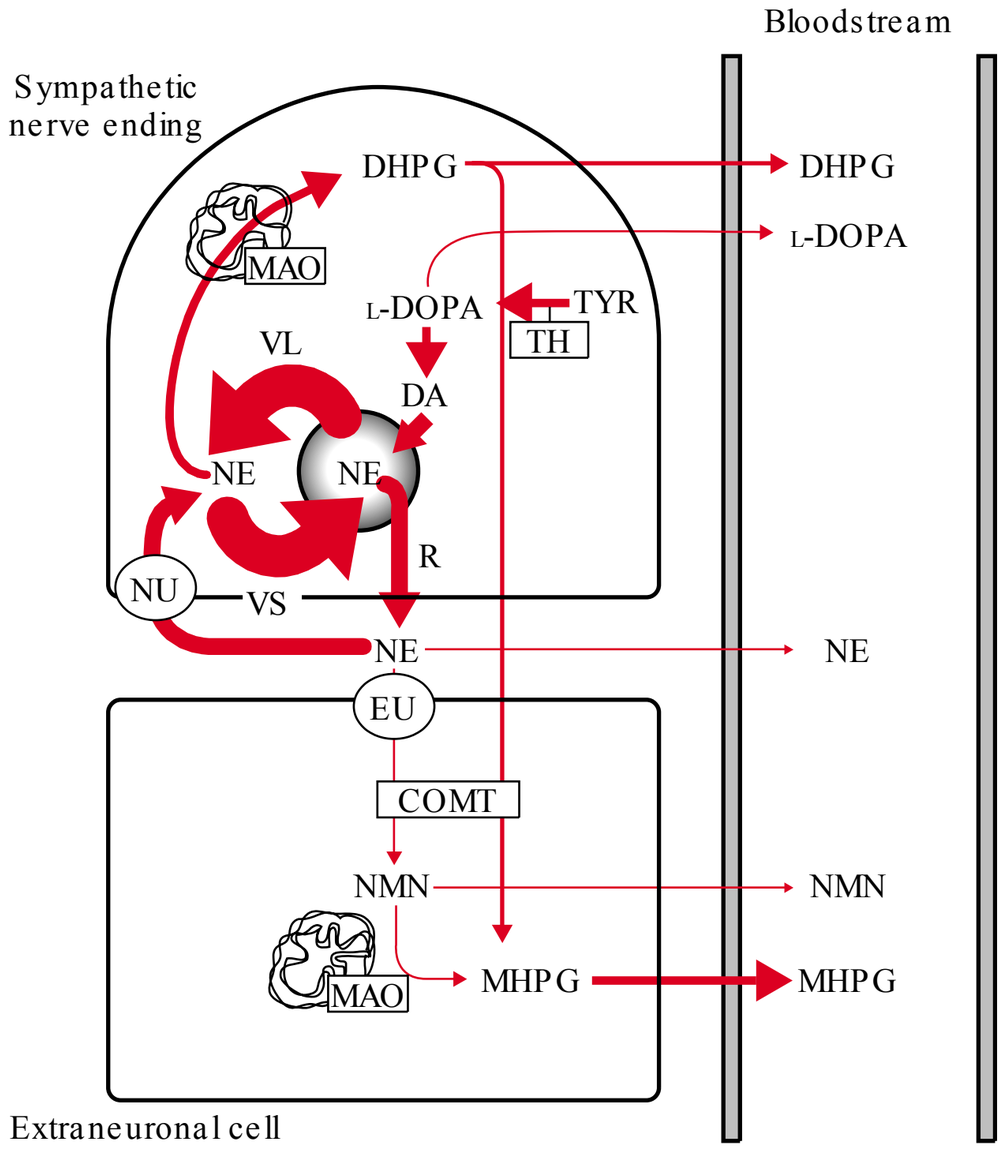

Figure 26-3 Schematic diagram illustrating the dynamics of synthesis, exocytotic release (R), neuronal reuptake (NU), extraneuronal uptake (EU), vesicular leakage (VL), vesicular sequestration (VS), and metabolism of norepinephrine (NE) in sympathetic nerve endings in relation to extraneuronal tissue and the bloodstream. Relative magnitudes of the various processes are reflected by the relative sizes of arrows. COMT, Catechol-O-methyltransferase; DA, dopamine; DHPG, 3,4-dihydroxyphenylglycol; L-dopa, 3,4-dihydroxyphenylalanine; MAO, monoamine oxidase; MHPG, 3-methoxy-4-hydroxyphenylglycol; NMN, normetanephrine; TH, tyrosine hydroxylase; TYR, tyrosine.

Uptake and Metabolism

Because the enzymes responsible for metabolism of catecholamines have intracellular locations, the primary mechanism limiting the duration of action of catecholamines in the extracellular space is uptake by active transport (see Figure 26-3).[2] Uptake is facilitated by transporters that belong to two families of proteins with mainly neuronal or extraneuronal locations. Neuronal monoamine transporters provide the principal mechanism for rapid termination of the signal in neuronal transmission, whereas transporters at extraneuronal locations are more important for limiting the spread of the signal and for clearance of catecholamines from the bloodstream. Of the norepinephrine released by sympathetic nerves, about 90% is removed back into nerves by neuronal uptake, 5% is removed by extraneuronal uptake, and 5% escapes these processes to enter the bloodstream. In contrast, of epinephrine released directly into the bloodstream from the adrenals, about 90% is removed by extraneuronal monoamine uptake.

In addition to terminating the actions of released monoamines, plasma membrane monoamine transporters function in sequence with vesicular monoamine transporters to recycle catecholamines for rerelease (see Figure 26-3).[2,4] Thus, most of the norepinephrine released and recaptured by sympathetic nerves is sequestered back into secretory granules by vesicular monoamine transporters, thereby reducing the requirements for synthesis of new transmitter. Plasma membrane monoamine transporters also function as part of metabolizing systems, requiring the additional actions of enzymes for irreversible inactivation of the released amines.

Catecholamines undergo metabolism by multiple pathways involving differing series of several enzymes with differing expression in various cells and tissues (Figure 26-4).[2] Most metabolism occurs within the same cells in which catecholamines are synthesized and is dependent on leakage of amines from secretory granules into the cytoplasm. In sympathetic nerves, the presence of monoamine oxidase (MAO) leads to conversion of norepinephrine to **3,4-dihydroxyphenylglycol (DHPG)**. This is then largely metabolized by **catechol-O-methyltransferase (COMT)** in extraneuronal tissues to **3-methoxy-4-hydroxyphenylglycol (MHPG)**. **Vanillylmandelic acid (VMA)**, the primary end-product of norepinephrine and epinephrine metabolism, is produced almost exclusively in the liver. This process is dependent on the hepatic localization of alcohol dehydrogenase, an enzyme required for conversion of MHPG to VMA.

In adrenal chromaffin cells, the additional presence of COMT leads to metabolism of norepinephrine to **normetanephrine** and of epinephrine to **metanephrine** (see Figure 26-4).[2] Because the intraneuronal deamination pathway far predominates over the extraneuronal O-methylation pathway, normetanephrine and metanephrine represent relatively minor products of catecholamine metabolism. As a consequence, the

adrenal medulla represents the single largest tissue source of normetanephrine and metanephrine, accounting for 24% to 40% of the former and more than 90% of the latter. The metanephrine and normetanephrine produced in the adrenal medulla or in extraneuronal tissues—the former from catecholamines leaking from secretory granules and the latter from catecholamines released from sympathoadrenal sources—may be deaminated to MHPG and then converted to VMA in the liver or may be sulfate-conjugated by a sulfotransferase enzyme expressed mainly in the gastrointestinal tissues.

Serotonin is not a substrate for COMT; it follows simpler pathways of metabolism than those for catecholamines. Serotonin is deaminated to **5-hydroxyindoleacetic acid (5-HIAA)**, the major urinary excretion product of serotonin metabolism.

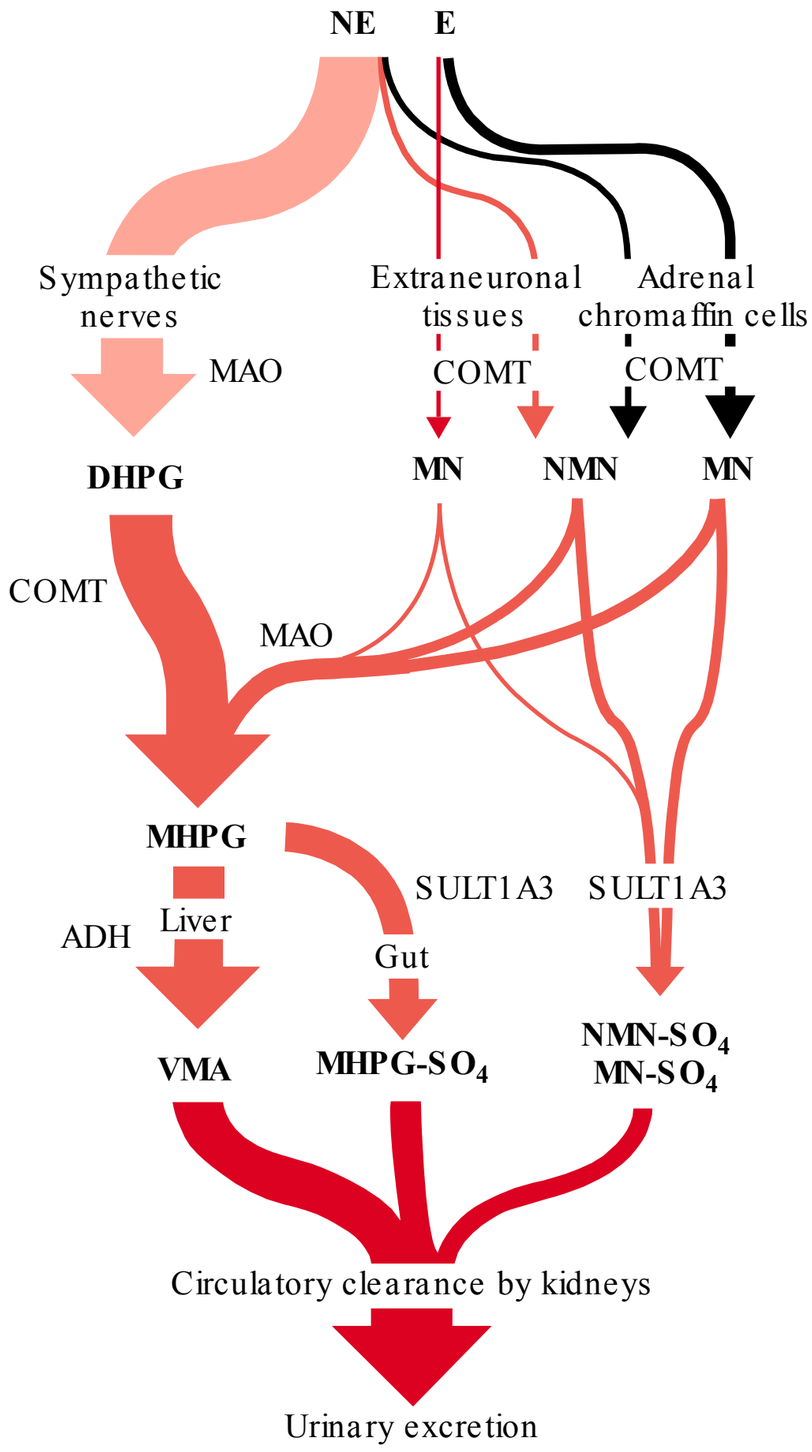

Figure 26-4 Schematic diagram showing the main pathways for metabolism of the norepinephrine and epinephrine derived from sympathoneuronal or adrenal medullary sources. Deamination in sympathetic nerves (pink) is the major pathway of catecholamine metabolism and involves intraneuronal deamination of norepinephrine leaking from storage granules, or of norepinephrine recaptured after release by sympathetic nerves. Metabolism in adrenal chromaffin cells (black) involves O-methylation of catecholamines leaking from storage granules into the cytoplasm of adrenal medullary cells. The extraneuronal pathway (light red) is a relatively minor pathway of metabolism of catecholamines released from sympathetic nerves or the adrenal medulla, but it is important for further processing of metabolites produced in sympathetic nerves and adrenal chromaffin cells. The free metanephrines produced in extraneuronal tissues or adrenal chromaffin cells are further metabolized by deamination or sulfate conjugation. ADH, Alcohol dehydrogenase; COMT, catechol-O-methyltransferase; DHPG, 3,4-dihydroxyphenylglycol; E, epinephrine; MAO, monoamine oxidase; MHPG, 3-methoxy-4-hydroxyphenylglycol; MHPG-SO_4, 3-methoxy-4-hydroxyphenylglycol sulfate; MN, metanephrine; MN-SO_4, metanephrine-sulfate; NE, norepinephrine; NMN, normetanephrine; NMN-SO_4, normetanephrine-sulfate; SULT1A3, phenolsulfotransferase type 1A3; VMA, vanillylmandelic acid.

Physiology of Catecholamine and Serotonin Systems

Catecholamines and serotonin regulate physiological events at the cellular level through interaction with families of cell surface receptors.[4,6,16] Norepinephrine and epinephrine act on two broad classes of adrenergic receptors: α- and β-adrenoceptor families. Dopamine transmits signals primarily by interaction with a large family of dopamine receptors. An even larger family of serotonergic receptor subtypes has been identified by histological and molecular techniques. The major physiological effects of catecholamines and serotonin are explained in part by these diverse receptor interactions that occur in function-specific locations throughout the vasculature and organ systems of the body.

Central Nervous System

Norepinephrine, dopamine, and serotonin are produced primarily in regions of the brainstem by neurons with projections to other areas of the brain or spinal cord.[16] About half of the norepinephrine in the brain is produced in norepinephrine-producing neurons in the lower brainstem that send diffuse axonal projections throughout the brain as high as the cerebral cortex. They also send descending fibers to the spinal cord, where they synapse with preganglionic sympathetic neurons that communicate with the peripheral sympathetic nervous system. The norepinephrine-producing neurons of the brainstem participate in regulating the activity of the sympathetic nervous system and the overall state of attention and vigilance.

Dopamine produced in dopaminergic neurons has functions and shows distributions that are notably different from those of norepinephrine. Dopamine in the brain influences reward-seeking behavior and is important for initiation and maintenance of movement. Disturbances in dopamine production and release in the brain are therefore involved in drug-dependency states and are central to the movement disorder that characterizes **Parkinson disease**.[4] Dopamine neurotransmission is also involved in processing sensory signals and in regulating hormonal release. Dopaminergic neurons in the retina and olfactory bulb have ultrashort projections that transmit signals within these neuronal centers for vision and smell. Dopamine neurons in the hypothalamus have regulatory influences on release of several hormones of the pituitary gland.

Serotonin, like norepinephrine, is produced by small clusters of neurons in the brainstem regions, but it serves a diverse range of behavioral and physiological functions. Physiological and behavioral processes influenced by this

serotonergic system include (1) memory, (2) learning, (3) feeding behavior, (4) sleep patterns, (5) thermoregulation, (6) pain modulation, (7) cardiovascular function, and (8) hypothalamic regulation of pituitary hormones.

Sympathetic Nervous System

Sympathetic nerve transmission operates below the level of consciousness in controlling the physiological function of many organs and tissues of the body (Figure 26-5).[6] The sympathetic nervous system plays a particularly important role in regulating cardiovascular function in response to (1) postural, (2) exertional, (3) thermal, and (4) mental stress. With sympathetic activation, (1) heart rate is increased, (2) peripheral arterioles are constricted, (3) skeletal arterioles are dilated, and (4) blood pressure is elevated. Sympathetic signals work in balance with the parasympathetic portion of the autonomic nervous system to maintain a stable internal environment.

Efferent or outgoing signals from the central nervous system are transmitted by preganglionic, cholinergic, sympathetic neurons that exit the spinal cord and converge on sympathetic ganglia along the spinal column or in visceral ganglia (see Figure 26-5). The terminal branches of the postganglionic

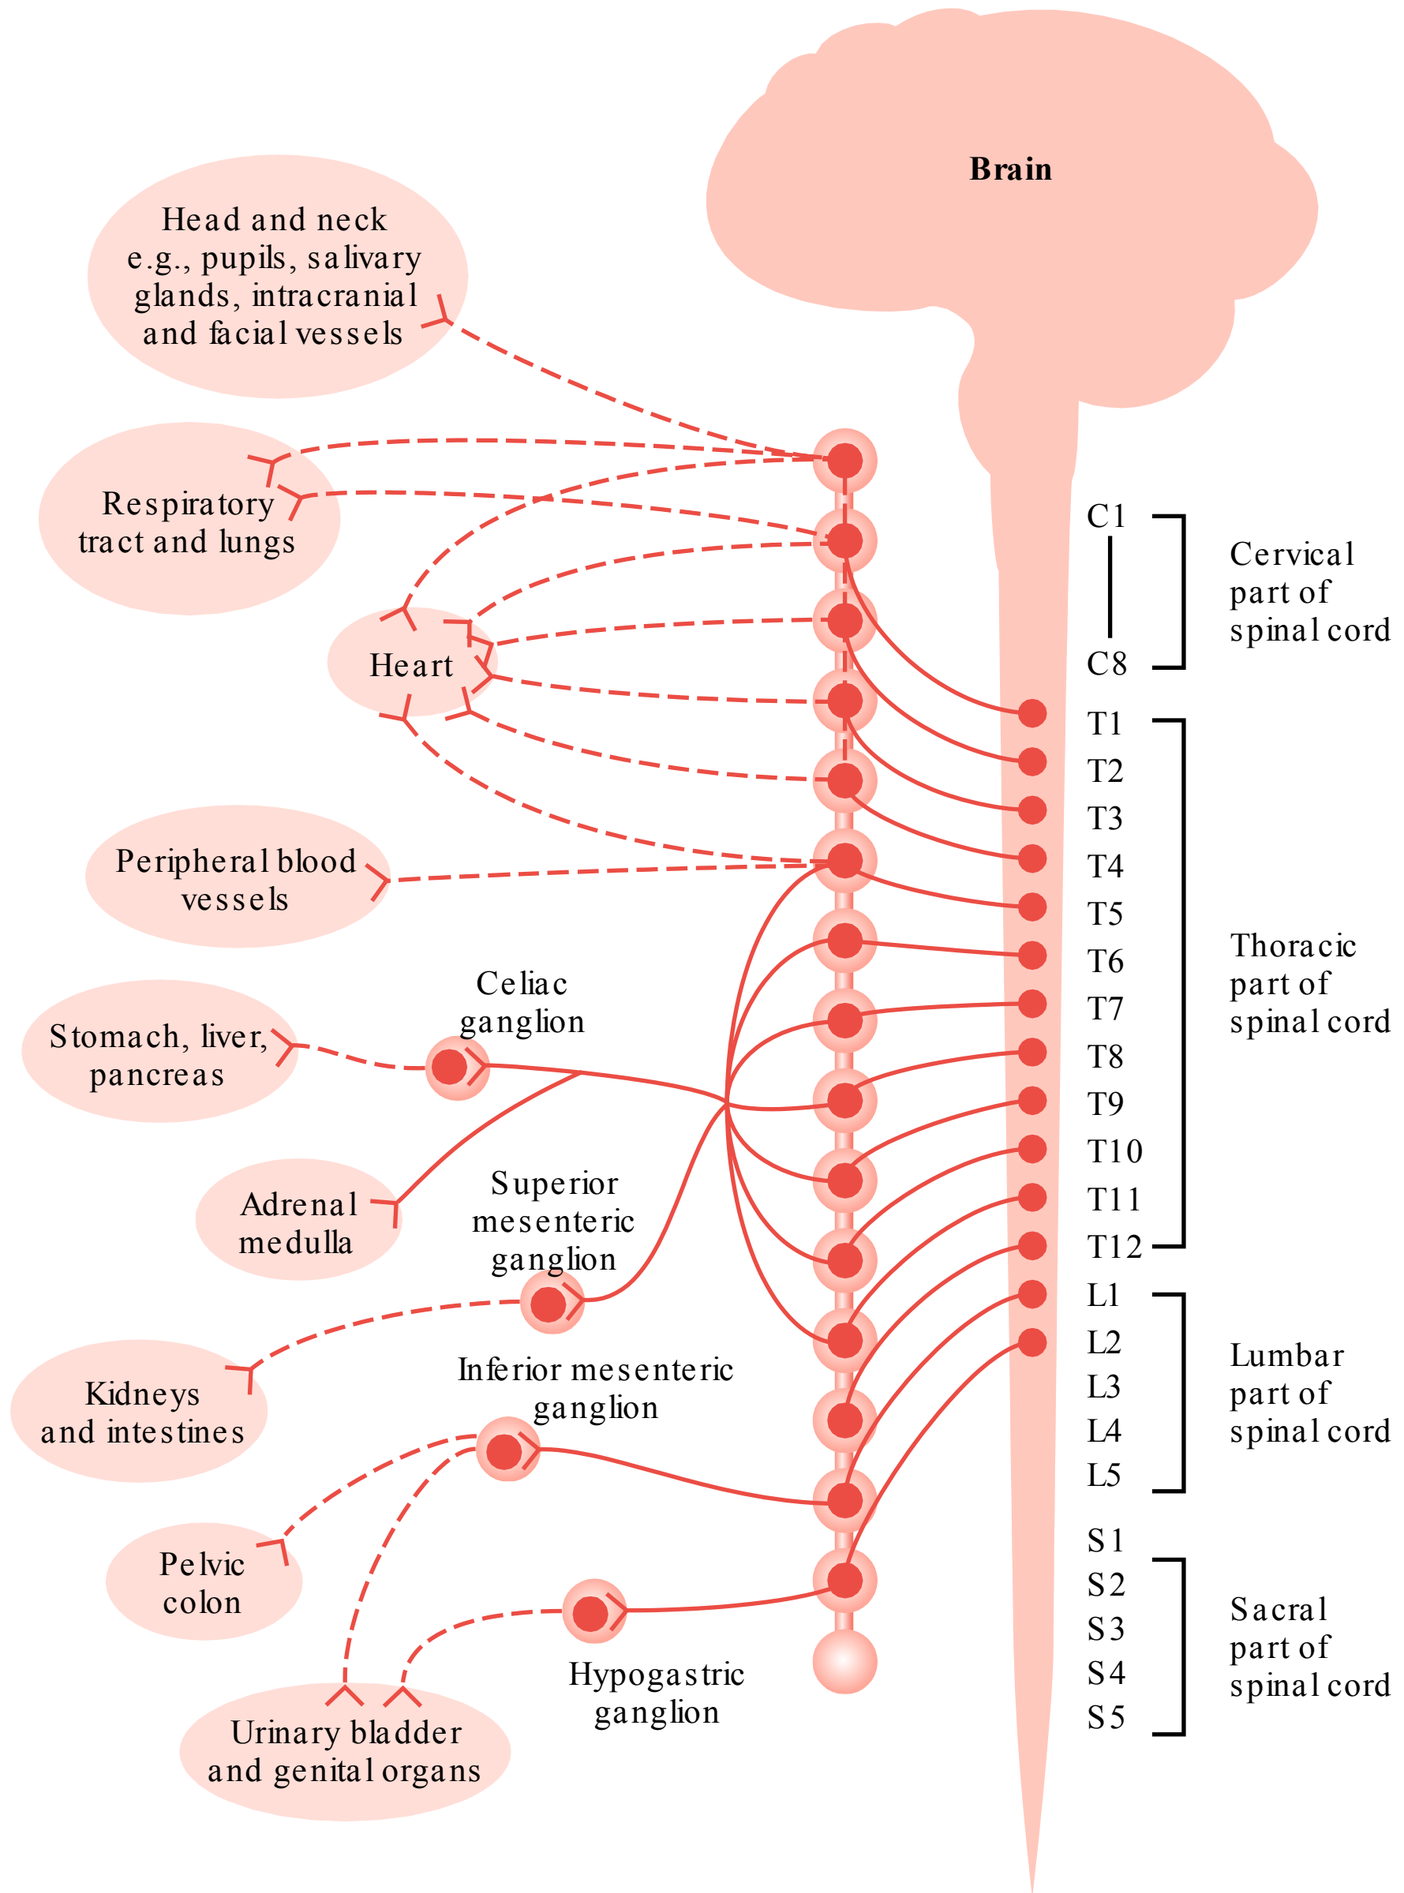

Figure 26-5 Schematic diagram of sympathetic division of the autonomic nervous system. Preganglionic cholinergic fibers (solid lines) from the spinal cord project to the paravertebral sympathetic chain, visceral peripheral ganglia, and the adrenal medulla, whereas postganglionic noradrenergic fibers (dashed lines) project from sympathetic ganglia to sympathetically innervated target organs. About 5% to 10% of the norepinephrine released from sympathetic nerves innervating target organs escapes neuronal and extraneuronal uptake to enter the bloodstream. This contrasts with epinephrine, which functions as a circulating hormone and is released directly from the adrenal medulla into the bloodstream. Most of the catecholamines entering the bloodstream are removed by extraneuronal uptake processes and are metabolized (e.g., in the liver), so that only small proportions are excreted in the urine.

fibers that project from these ganglia into target organs have varicosities that form a rich ground plexus for synaptic contact with a large number of effector cells in glands and muscle fibers. Most sympathetic postganglionic nerves liberate norepinephrine as their neurotransmitter. In limited locations, sympathetic nerve endings release acetylcholine. Sympathetic fibers that release acetylcholine innervate sweat glands and the adrenal medulla, the latter stimulating release of epinephrine from chromaffin cells.

Plasma and urinary norepinephrine are derived primarily from postganglionic sympathetic neurons with little contribution from the central nervous system or from hormonal release by the adrenal medulla.[4] Because of intervening neuronal and extraneuronal removal processes, the amount of norepinephrine that escapes into the bloodstream represents less than 10% of the total norepinephrine released by sympathetic nerves. Alterations in release and plasma concentrations of norepinephrine occur in response to physiological and pathological states, such as (1) exercise, (2) overeating, (3) low salt intake, (4) upright position, (5) mental stress, and (6) aging, all of which increase sympathetic outflow.[4] Increased plasma concentrations of norepinephrine are also found in disorders such as cardiac failure, hypertension, and depression.

Adrenal Medullary System

The human adrenal glands overlie the superior poles of the kidneys (see Chapter 41). Each gland consists of an outer cortex and a thin inner central medulla containing chromaffin cells. A characteristic feature of adrenal medullary chromaffin cells is the presence of numerous catecholamine storage granules. These granules turn brown when exposed to (1) potassium bichromate solutions, (2) ammoniacal silver nitrate, or (3) osmium tetroxide because of the oxidation and polymerization of epinephrine and norepinephrine. This process is known as the chromaffin reaction, hence the terms chromaffin cells and chromaffin granules.

Although often considered a part of the sympathetic nervous system, the adrenal medulla produces and secretes epinephrine with different functions from the norepinephrine secreted by sympathetic nerves.[4] The adrenal medulla and the sympathetic nerves are regulated separately, often in divergent directions in response to different forms of stress. Epinephrine is secreted from adrenal chromaffin cells directly into the bloodstream to act on cells distant from sites of release. Epinephrine and norepinephrine have overlapping but different potencies of effect on α- and β-adrenoceptors. The proximity of sites of norepinephrine and epinephrine release to adrenoceptors determines differences in adrenoceptor-mediated responses to the two catecholamines. Because of the factors mentioned earlier, epinephrine exerts its effects on different populations of adrenoceptors than those affected by norepinephrine. Epinephrine released from the adrenal glands is more important as a metabolic hormone than as a hemodynamic regulatory hormone. In particular, epinephrine stimulates (1) lipolysis, (2) ketogenesis, (3) thermogenesis, and (4) glycolysis. It also raises plasma glucose concentrations by stimulating glycogenolysis and gluconeogenesis. Epinephrine also has potent effects on pulmonary function, causing dilation of airways.

Peripheral Dopaminergic System

Dopamine is usually thought of as a neurotransmitter in the brain or as an intermediate in the production of norepinephrine and epinephrine in peripheral tissues. The contribution of the brain to plasma concentrations and urinary excretion of dopamine metabolites is, however, relatively minor, and dopamine produced in sympathetic nerves and the adrenal medulla is mainly converted to norepinephrine. Most circulating and urinary dopamine and dopamine metabolites are therefore derived from other sources (Figure 26-6).[2]

In the kidneys, dopamine functions as an autocrine or paracrine effector substance contributing to the regulation of sodium excretion.[4] Unlike neuronal catecholamine systems, production of dopamine in the kidneys is largely independent of local synthesis of l-dopa by tyrosine hydroxylase. Production of dopamine in the kidneys depends mainly on uptake of l-dopa from the circulation and conversion to dopamine by aromatic amino acid decarboxylase (see Figure 26-6). Thus most of the free dopamine excreted in urine derives from renal uptake and decarboxylation of circulating l-dopa.

Although the kidneys represent the major source of urinary free dopamine, this source does not account for the much larger quantities of excreted dopamine metabolites, such as **homovanillic acid (HVA)** and dopamine sulfate. Substantial proportions of these metabolites are produced in the gastrointestinal tract, where dopamine appears to function as

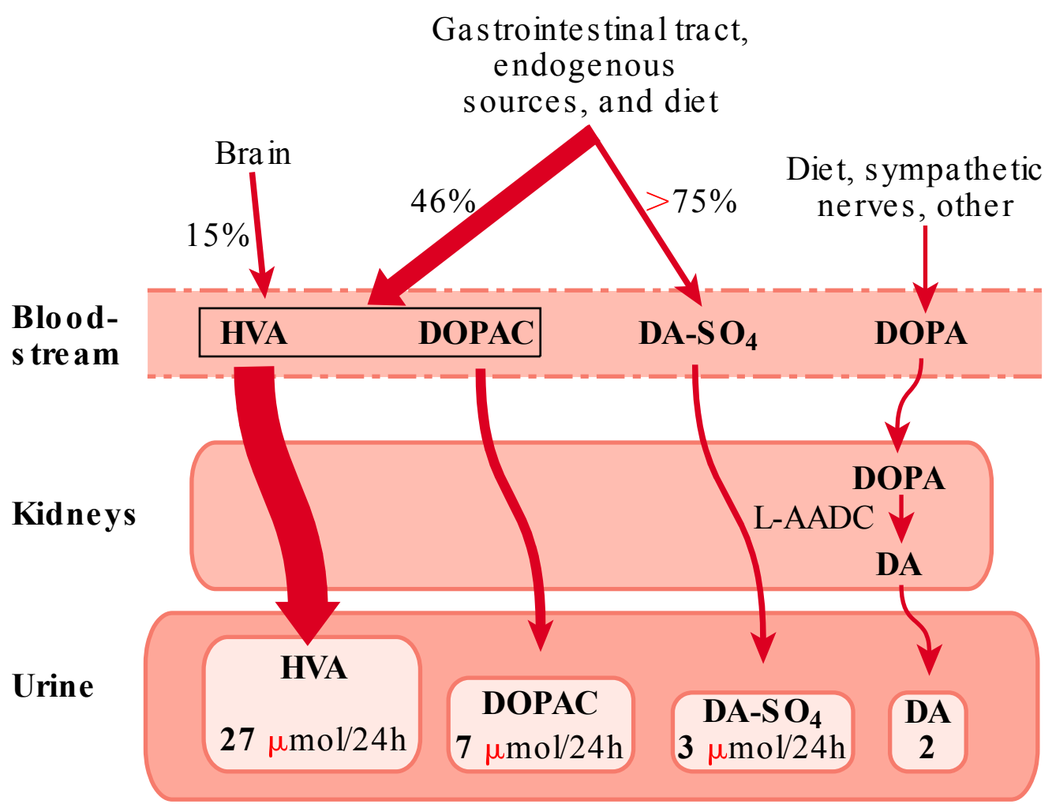

Figure 26-6 Schematic diagram illustrating the main plasma and urinary sources of dopamine (DA) and the principal metabolites of dopamine, homovanillic acid (HVA), dihydroxyphenylacetic acid (DOPAC), and dopamine sulfate (DA-SO_4). The brain makes a relatively minor contribution, whereas dopamine synthesized in the gastrointestinal tract or derived from the diet contributes substantially to dopamine metabolites in the bloodstream and urine. This contrasts with the free dopamine excreted in urine, which is derived almost entirely from renal extraction of circulating dihydroxyphenylalanine (DOPA) and local decarboxylation to dopamine by l-aromatic amino acid decarboxylase (l-AADC).

an enteric neuromodulator or as a paracrine or autocrine substance.[2,4] However, unlike in the kidneys, where dopamine is produced mainly from circulating l-dopa, in the gastrointestinal tract, production of dopamine requires the presence of tyrosine hydroxylase or other sources of l-dopa.

Consumption of food increases plasma concentrations of (1) l-dopa, (2) dopamine, and (3) dopamine metabolites, particularly dopamine sulfate, indicating that dietary constituents may represent an important source of peripheral dopamine (see Figure 26-6).[4] It is now clear that dopamine sulfate is produced mainly in the gastrointestinal tract from both dietary and locally synthesized dopamine. T is is consistent with findings that the gastrointestinal tract contains high concentrations of the specific sulfotransferase enzyme responsible for sulfate conjugation of catecholamines and **catecholamine metabolites**.

Enteric Nervous System

T e **enteric nervous system (ENS)** is defined as an independent and integrated system of neurons and supporting cells located in the (1) gastrointestinal tract, (2) gallbladder, and (3) pancreas.[5] T e ENS is composed of two networks or plexuses of intrinsic neurons: the myenteric plexus and the submucous plexus. Both are embedded in the wall of the gut and extend from the esophagus to the anus. T ese networks contain more than 100 million (1) sensory neurons, (2) interneurons, and (3) motor neurons. T e myenteric plexus lies between the longitudinal and circular layers of intestinal smooth muscle and controls propulsive movements (peristalsis). T e submucous plexus innervates (1) glandular epithelium, (2) intestinal endocrine cells, and (3) submucosal blood vessels. T is network (1) senses the environment within the lumen, (2) regulates local blood flow, and (3) controls epithelial cell secretion.

T e ENS is connected to the central nervous system by extrinsic parasympathetic and sympathetic motor neurons, and by spinal and vagal sensory neurons. T rough these bidirectional connections, the ENS is monitored and modified.[5] Despite the presence of these extrinsic nerve connections, the ENS functions autonomously in some intestinal regions. Neural transmission within the ENS is controlled by a large variety of neurotransmitters and neuromodulatory peptides, such as (1) serotonin, (2) norepinephrine, (3) acetylcholine, (4) ATP, and (5) nitric oxide. Serotonin acts as a local paracrine molecule, participating in mucosal sensory transduction. More than 95% of the body's serotonin is produced within the gastrointestinal tract, and most is synthesized and stored in enterochromaffin cells in the gut mucosa.[7] Intrinsic sensory neurons activated by serotonin stimulate peristaltic reflex and secretion, whereas extrinsic sensory neurons initiate bowel sensations such as (1) nausea, (2) vomiting, (3) abdominal pain, and (4) bloating. T e paracrine actions of serotonin are terminated by uptake into epithelial cells by the same serotonin transporter used in serotonergic neurons.

Clinical Applications

Measurements of (1) catecholamines, (2) serotonin, and (3) their metabolites are used in investigations of a range of pathophysiological processes. Measurements of the amines and their metabolites are directed primarily at the diagnosis of neuroendocrine tumors. Catecholamine-producing neuroendocrine tumors include (1) **pheochromocytomas**, (2) **paragangliomas**, and (3) **neuroblastomas**, whereas serotonin-producing tumors are typically **carcinoid tumors**.

Pheochromocytoma and Paraganglioma

Catecholamine-producing tumors that derive from chromaffin cells may occur within the adrenal glands, where they are referred to as pheochromocytomas, or at extra-adrenal sites, where the tumors are termed paragangliomas.[8] Paragangliomas derived from extra-adrenal sympathetic chromaffin tissue usually produce significant quantities of catecholamines—and are commonly referred to as extra-adrenal pheochromocytomas. Pheochromocytomas are rare, with an annual detection rate of 2 to 5 per million. Autopsy studies, indicating prevalences of 0.05% to 0.1%, suggest that most of the tumors remain undetected and contribute to premature death.

T e presence of a pheochromocytoma is usually suspected because of signs and symptoms that reflect the biological effects of catecholamines released by the tumor.[12] Hypertension, the most common sign, can be sustained or paroxysmal. Symptoms include (1) headache, (2) palpitations, (3) diaphoresis (excessive sweating), (4) pallor, (5) nausea, (6) attacks of anxiety, and (7) generalized weakness. Among patients tested because of such signs and symptoms, the pretest prevalence of tumors is low—usually less than 1%.

Patients with a higher risk for pheochromocytoma include those with (1) a hereditary predisposition to the tumor, (2) a previous history of the tumor, or (3) the incidental finding of an adrenal mass during routine abdominal imaging procedures.[8] In such patients, testing may be carried out independently of the presence of signs and symptoms. See Box 26-1 for a summary of the key points of pheochromocytomas.

Advances in understanding catecholamine metabolism have changed the approach to biochemical diagnosis of pheochromocytoma, concentrating now on measurements of metanephrines rather than their precursor catecholamines.[3,8] T is has followed several observations, including findings that adrenal medullary cells and pheochromocytoma tumor cells contain COMT, the enzyme that converts catecholamines to their O-methylated metabolites.[2]

Normally, most norepinephrine is metabolized by deamination within sympathetic nerves, so that O-methylation represents a minor pathway of catecholamine metabolism. In patients with pheochromocytoma, intratumoral O-methylation becomes a dominant pathway of catecholamine metabolism. Consequently, the presence of the tumor leads to relatively large increases in production of O-methylated metabolites, compared with minor increases in deaminated metabolites. T e metanephrines are produced continuously as a result of ongoing leakage of catecholamines from chromaffin granule stores into the cell cytoplasm; in contrast, catecholamines are of en released episodically or in relatively low quantities compared with metanephrines.

BOX 26-1 Pheochromocytoma and Paraganglioma Key Points

Biology

- Rare tumors of mainly adrenal chromaffin cells that produce, store, metabolize, and secrete catecholamines, usually with a predominance of norepinephrine over epinephrine
- Those developing from extra-adrenal sympathetic chromaffin tissue—termed paragangliomas—usually produce near exclusively norepinephrine and very rarely predominantly dopamine

Presentation

- Tumor usually suspected because of signs and symptoms of catecholamine excess (e.g., hypertension, palpitations, headaches, excessive sweatiness) or the incidental finding of an adrenal mass during routine imaging procedures for unrelated medical conditions
- Most pheochromocytomas are benign; 15% of adrenal tumors and 35% of extra-adrenal tumors are malignant
- At least 30% of pheochromocytomas have a hereditary basis, resulting from mutations of ten genes identified to date
- Less than 1% of patients tested because of signs and symptoms have the tumor (low pretest prevalence), but the prevalence is higher among patients with identified mutations of disease-causing genes or those with an incidental adrenal mass; thus testing in these patients is recommended independently of the presence of signs and symptoms

Biochemical Diagnosis

- Biochemical diagnosis based on evidence of excess production of catecholamines, best determined from measurements of metanephrines in urine or plasma
- Because secretion of catecholamines by tumors is episodic, but metabolism to metanephrines within tumors is continuous, measurements of plasma or urinary fractionated metanephrines provide more reliable diagnostic tests for the tumor than measurements of catecholamines (metanephrines increased in >97% and catecholamines in 69% to 92% of patients with pheochromocytomas)

Numerous independent studies have now confirmed that the measurements of plasma metanephrines are very sensitive. This has led to the recommendation that measurements of either plasma or urinary fractionated metanephrines should always be used during initial work-up of a patient with a suspected pheochromocytoma.[3] Negative results of these tests virtually exclude a pheochromocytoma. Exceptions include small (<1 cm) tumors encountered during routine screening and tumors that do not synthesize norepinephrine and epinephrine. Among the latter, tumors that produce only dopamine may be detected by measurements of plasma or urinary methoxytyramine, the O-methylated metabolite of dopamine.[3] Measurements of plasma dopamine also are useful, whereas urinary dopamine is largely derived from renal extraction and decarboxylation of l-dopa and therefore provides a relatively insensitive and nonspecific test for detection of a dopamine-producing tumor (see Figure 26-6).

Plasma or urinary fractionated metanephrines are usually elevated sufficiently to conclusively establish the presence of most cases of pheochromocytoma.[12] However, in about 20% of patients with the tumor, increases are smaller. Such true-positive results are difficult to distinguish from the larger proportion of false-positive results. Additional biochemical testing is then necessary. Before further biochemical testing is initiated, consideration should be given to eliminating possible causes of false-positive results. These may occur because of (1) inappropriate sampling conditions (e.g., blood sampling without a preceding 30-minute period of supine rest), (2) medications such as tricyclic antidepressants, or (3) clinical conditions that increase sympathetic outflow.

When biochemical testing continues to yield equivocal results, the clonidine suppression test may be useful for further confirming or excluding a pheochromocytoma.[12] As originally introduced, this test was designed to distinguish patients with increases in plasma catecholamines caused by pheochromocytoma from those with increases caused by sympathetic activation. By activating α_2-adrenoceptors in the brain and on sympathetic nerve endings, clonidine suppresses norepinephrine release by sympathetic nerves. Decreases in elevated plasma norepinephrine after clonidine therefore suggest sympathetic activation, whereas lack of decrease suggests a pheochromocytoma. The test has subsequently been shown to be useful for distinguishing increases in plasma normetanephrine due to a pheochromocytoma from those due to sympathetic activation.

Most pheochromocytomas are sporadic, but as many as 30% to 40% have a hereditary basis.[3] Hereditary forms of the tumor result from mutations of ten disease-causing genes identified to date. Pheochromocytomas occur at a relatively low prevalence in about 1% of patients with **neurofibromatosis type 1 (NF1)**. Risk for the other nine currently known hereditary conditions is higher. Pheochromocytomas in multiple endocrine neoplasia type 2 (**MEN** 2) result from mutations of the ret proto-oncogene, which also predisposes to medullary thyroid cancer. In von Hippel-Lindau syndrome (VHL), family-specific mutations of the VHL tumor suppressor gene determine the varied clinical presentation of tumors, which, in addition to pheochromocytomas and paragangliomas, include (1) retinal angiomas, (2) central nervous system hemangioblastomas, and (3) tumors in the kidneys, pancreas, and testis. Familial paragangliomas and pheochromocytomas may occur secondary to mutations of genes for four subunits of succinate dehydrogenase (SDHA, SDHB, SDHC, and SDHD). Mutations of genes encoding the SDH complex assembly factor 2 (SDHAF2), transmembrane protein 127 (TMEM127), and MYC-associated factor X (MAX) represent other recently identified tumor susceptibility genes.

Mutations of the different tumor susceptibility genes have been found to give rise to distinct catecholamine metabolite profiles.[3] Tumors in patients with MEN 2 and NF1 are almost always confined to the adrenals and are characterized by increases in plasma-free metanephrine, indicating epinephrine production. In contrast, tumors in patients with VHL, SDHD, and SDHB mutations, including those at adrenal locations, are characterized by increases in plasma or urinary normetanephrine without increases in metanephrine. Increases in methoxytyramine, the metabolite of dopamine, are additionally present in up to 70% of patients with mutations of SDHD and SDHB genes. In some patients, methoxytyramine represents the only metabolite increased.

The distinct mutation-dependent biochemical profiles are useful for stratifying patients for genetic testing and are important to consider during routine screening of tumors.[3] For mutations that confer a high risk of disease, such screening is generally recommended at yearly intervals and should include biochemical testing for evidence of excess catecholamine production individualized according to the expected biochemical profile of the tumor.

Although most often benign, about 10% of pheochromocytomas and 35% of paragangliomas eventually metastasize.[3,12] The risk of malignancy is particularly high in patients with SDHB mutations. Tumors in such patients typically produce low quantities of catecholamines and are much larger at diagnosis than tumors in other patients. This fact, along with their typically extra-adrenal location, explains their higher predisposition to malignancy.

Diagnosis of malignant pheochromocytoma on the basis of histopathological features is not possible and instead requires evidence of metastatic lesions in (1) liver, (2) lungs, (3) lymphatic nodes, and (4) bones. All patients with a previous history of tumor are at risk for recurrent or malignant disease and should undergo periodic tumor screening. Measurements of plasma methoxytyramine appear to serve as a promising new biomarker for malignant pheochromocytoma and therefore should be considered as part of biochemical testing in patients tested as a result of past history of the disease.[3]

BOX 26-2 Neuroblastoma Key Points

Biology

- Tumors occurring almost exclusively in children that develop from primitive neural crest cells of the sympathoadrenal system, with about 60% derived from extra-adrenal sympathetic tissue and 40% from the adrenals
- Biological behavior of tumors is highly variable, with some tumors spontaneously regressing but most (60%) having an aggressive course with disseminated malignant disease and an unfavorable outcome

Presentation

- Neuroblastomas produce variable amounts of dopamine and norepinephrine but show a poor capacity for storage and release of catecholamines. Consequently, the tumors rarely produce signs and symptoms of catecholamine excess
- Suspicion of disease is usually based on palpation of a mass, space-occupying complications of the tumor, or effects of bone marrow involvement
- Hereditary causes of neuroblastomas are rare; most neuroblastomas occur sporadically

Biochemical Diagnosis

- Biochemical diagnosis based on overproduction of dopamine and norepinephrine, but because the tumors have poorly developed machinery for catecholamine storage and release, diagnosis depends mainly on measurements of catecholamine metabolites
- Measurements of urinary VMA and HVA represent the most widely used tests but in a large prospective screening study were shown to detect only 73% of tumors

Neuroblastoma

Neuroblastomas are neoplasms that derive from primordial neural crest cells of the sympathetic nervous system.[9] Neuroblastomas are almost exclusively a pediatric cancer, accounting for approximately 7% of all childhood neoplasms; they are the most common malignancies in the first year of life. The incidence of neuroblastoma is approximately 10 cases per million children. A vast majority of neuroblastomas develop sporadically. Activating mutations in the tyrosine kinase domain of the anaplastic lymphoma kinase oncogene account for most cases of hereditary neuroblastoma and may occur as somatic mutations in 5% to 15% of sporadic cases. Mutations of paired-like homeobox 2b (PHOX2B), also known as neuroblastoma Phox (NBPhox), account for other cases of hereditary neuroblastoma.

Most neuroblastomas are intra-abdominal, arising in the adrenal gland or in the upper abdomen. Less frequent locations include chest, neck, and pelvis. About 60% are extra-adrenal. Metastases in disseminated neuroblastomas may involve (1) bone marrow, (2) bone, (3) lymph nodes, (4) liver, and, less frequently, (5) skin, (6) testis, and (7) intracranial structures.

The biological behavior of a neuroblastoma varies from regression or maturation to an aggressive course with an unfavorable outcome.[9] Neuroblastomas are most notable for a subset of cases with complete regression or maturation to ganglioneuroma, a benign neoplasm. Most clinically diagnosed tumors, however, are aggressive and have an unfavorable outcome. This highly variable clinical outcome underlies a need for diagnostic markers to stratify patients for therapeutic intervention. Age at diagnosis serves as a primary criterion for stratification; infants younger than 18 months have a more favorable outcome than older children.[9] Beyond this, stratification for therapeutic intervention considers (1) clinical stage of the disease (localized vs. disseminated), (2) histopathological features, and (3) consideration of v-myc myelocytomatosis viral related oncogene (MYCN) expression status.

Somatic mutations of the α-thalassemia/MR, X-linked (ATRX) gene have recently emerged as defining a subset of older children with an indolent, but nevertheless chronic and progressive, course of disease.[1] Unfortunately, the overall incidence of metastatic neuroblastoma at the time of diagnosis is approximately 60%, and the need for earlier detection of children with the progressive disseminating tumor remains a diagnostic challenge. See Box 26-2 for a summary of the key points of neuroblastomas.

Hypertension and signs and symptoms of catecholamine excess are uncommon in neuroblastoma; this appears to reflect inefficient storage of catecholamines, leading to their intracellular metabolism and release as mainly inactive metabolites. Patients commonly present with a tumor mass and clinical signs from compression effects on neighboring structures or hematological abnormalities from bone marrow involvement.

Laboratory evidence of a functional catecholamine-producing tumor is important in the clinical evaluation when a neuroblastoma is suspected.[15] Catecholamine and metabolite secretion patterns, however, may differ markedly among patients with the tumor. Neuroblastoma tumor cells have the capacity to synthesize dopamine and norepinephrine, but lack phenylethanolamine N-methyltransferase and consequently do not produce epinephrine. Because of variability in

catecholamine production and metabolism, no single reliable marker of catecholamine overproduction has been identified. Combinations of catecholamines and metabolites are therefore of en measured in the diagnostic evaluation of neuroblastoma.

HVA and VMA, produced, respectively, from dopamine and norepinephrine, are most widely used for diagnosis of a neuroblastoma. A small diurnal variation in HVA and VMA excretion and a positive correlation between random and 24-hour urine test results allow the convenient use of random urine specimens, with results expressed as the ratio of catecholamine metabolites to creatinine excretion. Clinical sensitivity in the range of 90% has been reported by some centers for urinary HVA and VMA testing. However, others have reported a lower rate of neuroblastoma detection. In a large neuroblastoma screening program, in which the population with negative screening results was tracked for occurrence of neuroblastoma, an elevation in VMA, HVA, or both acid metabolites detected only 73% of the tumors.[15] Diagnostic sensitivity of these measurements in screening programs is therefore limited and in particular appears to miss patients with aggressive disease diagnosed at a later age. Consequently, screening programs have been generally unsuccessful in reducing the rate of metastatic neuroblastoma.

Additional markers of catecholamine overproduction have been employed to improve the detection of neuroblastomas. Plasma measurements of dopamine and l-dopa, the amino acid precursor of dopamine, may have clinical value and allow the alternate use of plasma. Measurement of O-methylated metabolites, especially normetanephrine, has also been studied. When urinary (1) normetanephrine, (2) metanephrine, (3) methoxytyramine, (4) dopamine, (5) norepinephrine, (6) VMA, and (7) HVA concentrations were measured, clinical sensitivity for detection of neuroblastomas was reported at 97% to 100%. Nevertheless, a low incidence of biochemically negative tumors must be considered in the interpretation of negative test results.

Some evidence suggests that the pattern of catecholamine metabolism is associated with important biological and genetic prognostic factors in neuroblastoma. Immature metabolic patterns in neuroblastoma tumor tissue are based on higher excretion of dopamine or HVA relative to norepinephrine or VMA. A high ratio of HVA/VMA, dopamine/VMA, or dopamine/norepinephrine indicates a relative deficiency in β-hydroxylation with a reduction in tumor cell conversion of dopamine to norepinephrine. T e immature metabolic pattern is suggested to be associated with aggressive tumor behavior and other unfavorable prognostic factors, but the clinical application of such metabolic patterns has not been established.

Finally, clinical specificity in detecting neuroblastoma with catecholamine and metabolite measurements may be influenced by the choice of (1) laboratory methods, (2) dietary interference, and (3) other catecholamine overproduction conditions. Significant advances in the analytical specificity of laboratory methods have reduced many of the exogenous sources of interference. Histopathology remains the ultimate diagnostic criterion for distinguishing neuroblastoma from pheochromocytoma or other catecholamine-producing neurogenic tumors, such as ganglioneuroma and ganglioneuroblastoma.

Gastroenteropancreatic Neuroendocrine and Carcinoid Tumors

Gastroenteropancreatic neuroendocrine tumors (GEP-NET), including classical **carcinoid tumors**, are derived from a variety of neuroendocrine cell types, in particular, enterochromaffin cells.[10] T ese tumors are widely distributed in the body and are highly heterogeneous in their clinical presentation. T e usual carcinoid tumor is solid and yellow-tan in appearance. Tumor cells exhibit a monotonous morphology, with pink granular cytoplasm and round nuclei with infrequent mitoses. Most of these neuroendocrine tumors are recognized by their reactions to silver stains and to neuroendocrine cell markers, such as chromogranin and neuron-specific enolase.

T e tumors are traditionally classified according to their presumed origin from the embryonic (1) foregut (bronchus, lung, stomach, duodenum, and pancreas), (2) midgut (ileum, jejunum, appendix, and proximal colon), or (3) hindgut (rectum and distal colon).[10] T e most common sites for these tumors are (1) bronchus or lung—33%, (2) ileum or jejunum—20%, (3) rectum—10%, and (4) appendix—8%. T e annual incidence of clinically significant gastroenteropancreatic tumor is estimated at 2.5 to 5 cases per 100,000 persons. T ese tumors may develop in all age groups but appear most frequently in adults; a mean age of 63 has been reported for tumors of the small intestine and respiratory tract. Clinically, most patients are asymptomatic until metastases are present. Bowel obstruction and abdominal pain are the most frequent presenting symptoms.

Gastroenteropancreatic neuroendocrine tumors show aggressive malignant behavior depending on (1) origin, (2) depth of penetration, and (3) size of the primary tumor. Most rectal carcinomas are found incidentally at endoscopy. T ey are often smaller than 1 cm and have a low rate of metastasis, even though they may show extensive local spread. Carcinoids of the appendix are seen in about 1 in every 300 appendectomies. Almost all measure less than 1 cm, and distant metastasis is rare. By contrast, 90% of intestinal neuroendocrine tumors that penetrate halfway through the muscle wall will have spread to lymph nodes and distant sites at the time of diagnosis. More than 70% of these tumors 1 to 2 cm in diameter metastasize to the liver. Fortunately, most grow slowly, and patients may live for many years. See Box 26-3 for a summary of the key points of carcinoid tumors and gastroenteropancreatic neuroendocrine tumors.

As with normal gut endocrine cells, gastroenteropancreatic neuroendocrine tumors (1) synthesize, (2) store, and (3) release a variety of hormones and biogenic amines.[7,11] One of the best characterized of these substances in **carcinoid syndrome** is serotonin. T ese tumors also produce and secrete other biologically active substances, including (1) histamine, (2) kallikrein, (3) bradykinins, (4) tachykinins, (5) prostaglandins, (6) dopamine, (7) norepinephrine, and (8) peptide hormones. Production of these substances varies in relation to the tissue origin of the tumor. Midgut neuroendocrine tumors

BOX 26-3 Gastroenteropancreatic and Carcinoid Tumor Key Points

Biology
- Neuroendocrine tumors derived from enterochromaffin cells of the gastrointestinal and respiratory tracts
- Usually develop as small tumors (<2 cm) with slow growth but with propensity to metastasize
- Synthesize, store, and release a variety of peptide hormones and biogenic amines, including serotonin

Presentation
- Bowel obstruction and abdominal pain
- Symptoms related to secretion of vasoactive amines and peptides resulting in carcinoid syndrome (flushing, diarrhea, bronchoconstriction, and right-sided heart failure); relatively uncommon and usually occurring only after development of metastases

Biochemical Diagnosis
- Biochemical diagnosis of carcinoids depends mainly on measurements of serotonin, serotonin metabolites (5-HIAA), and the serotonin precursor (5-HTP) in urine, plasma, whole blood, and platelets
- False-positive results are a common problem resulting from dietary influences

release large quantities of serotonin, whereas tumors derived from the foregut secrete primarily 5-hydroxytryptophan (5-HTP) (a serotonin precursor) and histamine, rather than serotonin. Primary hindgut neuroendocrine tumors usually show no secretory activity. Pancreatic neuroendocrine tumors are capable of producing (1) gastrin, (2) insulin, (3) glucagon, and (4) vasoactive intestinal peptide (VIP).

Secretion of vasoactive substances into the systemic circulation plays an important role in development of the carcinoid syndrome. The fully developed syndrome associated with humoral manifestations of these tumors is striking but uncommon, usually occurring only after metastasis to the liver and release of these substances directly into the systemic circulation. The classic clinical presentation of the carcinoid syndrome includes pronounced (1) flushing (especially on the face and neck), (2) diarrhea, (3) bronchoconstriction, and (4) eventual right-sided valvular heart failure. Overproduction of serotonin is found in 90% to 100% of patients with the carcinoid syndrome and is thought to be responsible for diarrhea through its known effects on gut motility and fluid secretion.

Clinical laboratory evaluation of the carcinoid syndrome relies on measurements of serotonin and its metabolites in body fluids and tissue.[7] In patients with the typical carcinoid syndrome, 5-HTP is converted to serotonin and is stored in tumor secretory granules and in platelets. A small amount of serotonin remains in plasma, but most is converted to 5-HIAA, which is excreted in urine. These patients have increased blood and platelet serotonin concentrations and increased urinary 5-HIAA excretion. However, some foregut neuroendocrine tumors lack aromatic l-amino acid decarboxylase and secrete 5-HTP rather than serotonin into the bloodstream. Patients with these tumors have normal serotonin concentrations in blood and in platelets, but urinary amounts are increased because 5-HTP is converted to serotonin in the kidney; urinary 5-HIAA may be slightly elevated.

Patients with serotonin-producing carcinoid tumors usually have striking increases in urinary 5-HIAA excretion (at least tenfold), but occasionally elevations are smaller. False-positive elevations have been known to occur if the patient ingests a wide range of serotonin-rich foods or medications. Conversely, alcohol, aspirin, and other drugs suppress 5-HIAA concentrations. Patients should avoid these agents during 24-hour urine collections. Fasting plasma 5-HIAA has been proposed as a convenient replacement for urine collections.

Most physicians rely on measurement of 5-HIAA to diagnose carcinoid syndrome. But when a patient strongly suspected for carcinoid syndrome shows normal or borderline increases in urinary 5-HIAA, documentation of elevated serotonin concentrations in whole blood or platelets may help establish the diagnosis. Measurement of the concentration of platelet serotonin has been reported to be a more sensitive assay than that for urinary 5-HIAA for detecting carcinoids that produce small or moderate amounts of serotonin, such as foregut and hindgut carcinoids and midgut carcinoids with low tumor volume. Also, platelet serotonin concentrations are not affected by the patient's diet. Platelets can be saturated at high serotonin secretion rates, however, and 5-HIAA is often preferred for monitoring high serotonin production. Measurements of chromogranin A provide an important complement to measurements of serotonin and 5-HIAA and are particularly useful for many gastroenteropancreatic neuroendocrine tumors that do not produce appreciable amounts of serotonin.[11]

Analytical Methodology

In clinical practice, laboratory determinations of (1) catecholamines, (2) serotonin, and (3) their metabolites in biological fluids are performed primarily for diagnosis and follow-up of patients with catecholamine- or serotonin-producing tumors.[3,7,13,14] In accordance with changes in recommended clinical procedures, most laboratories now offer measurements of urinary or plasma metanephrines (normetanephrine and metanephrine) as primary tests for diagnosis of pheochromocytoma and paraganglioma. Liquid chromatography with tandem mass spectrometry (LC-MS/MS) is increasingly becoming the method of choice for these measurements (Figure 26-7). Measurements of catecholamines, usually in urine and less frequently in plasma, are also employed at some medical centers as secondary tests. Measurements of urinary VMA are of declining importance. For detection of neuroblastoma, urinary HVA and VMA remain the most commonly ordered biochemical tests in clinical practice, but other catecholamine metabolites and dopamine are also measured. Diagnostic evaluation of patients with carcinoid tumor routinely involves measurement of 5-HIAA; measurement of serotonin in platelets and urine has also been advocated.

Collection and Storage of Samples

The conditions under which plasma or urine samples are collected is crucial to the reliability and interpretation of test

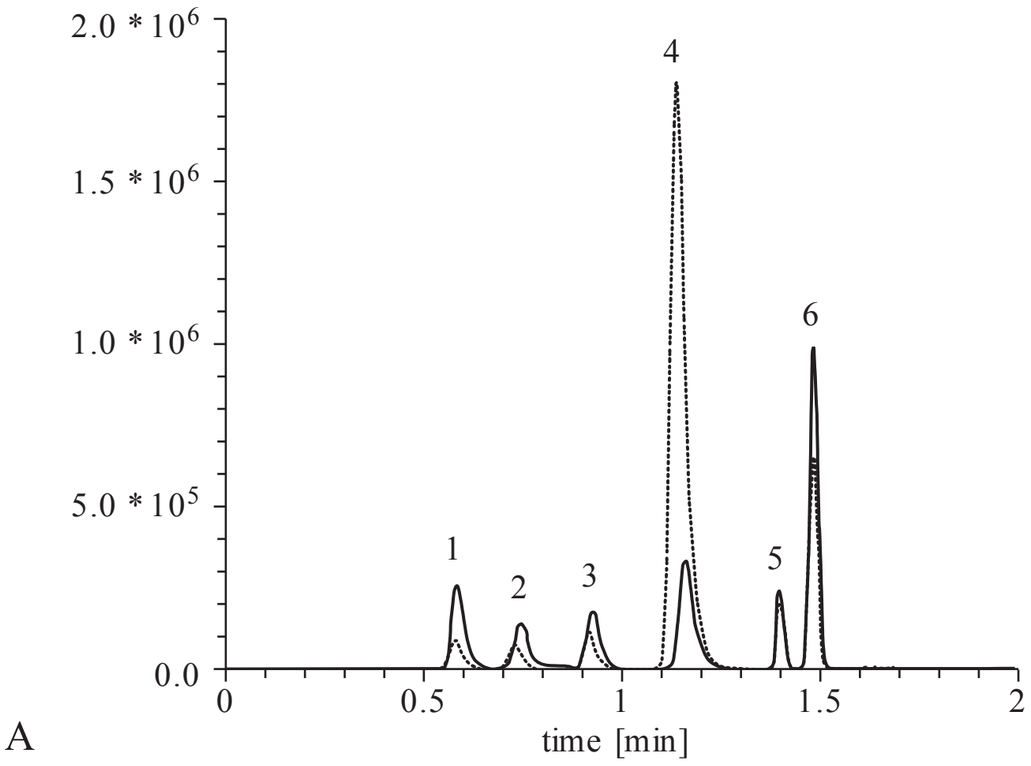

Figure 26-7 Chromatograms obtained by LC-MS/MS for simultaneous measurement of urinary catecholamines and their free O-methylated derivatives for a calibrator (A) and extracted urine samples of two patients (B). Chromatographic peaks are shown for norepinephrine (1), epinephrine (2), normetanephrine (3), dopamine (4), metanephrine (5), and 3-methoxytyramine (6), with respective concentrations in the calibrator (A) of 59.1, 54.6, 54.6, 65.3, 50.7, and 59.8 nmol/L. For the calibrator, internal standards are shown by a dotted line. Patient sample–derived chromatograms (B) represent urinary output of catecholamines and their O-methylated metabolites from a patient with confirmed pheochromocytoma (dashed line) and a patient without pheochromocytoma. Note the much larger signal intensity (peak height) for normetanephrine (3) in the patient with than without pheochromocytoma.

results.[3,12] Some clinicians prefer 24-hour collection of urine to blood sampling because the former avoids the rigid sampling conditions associated with blood catecholamine collection (e.g., samples should be taken after supine rest) and is more convenient for clinical staff to implement. However, 24-hour urine collections are often difficult and inconvenient for patients. The reliability of the collection timing is frequently in doubt. Plasma metanephrines are not as readily influenced by the trauma of phlebotomy as catecholamines, but the conditions of blood sampling still require consideration to minimize false-positive test results. It remains preferable to take blood with patients in the supine position and fasting. For urine collection, the influences of diet and sympathoadrenal activation associated with physical activity or changes in posture are not as easily controlled as they are for blood collections. Spot or overnight urine collection with correction for differences in duration of collection using urinary creatinine excretion provides an alternative to 24-hour urine collection that may overcome some of these problems.

For measurements of urinary metanephrines, no preservatives are required, whereas for catecholamines, samples are best preserved with hydrochloric acid to maintain urine acid. For storage over protracted periods, aliquots are best kept frozen at −80 °C to minimize auto-oxidation and deconjugation. Blood samples for both metanephrines and catecholamines are best collected into tubes containing heparin or ethylenediaminetetraacetic acid (EDTA) as an anticoagulant and stored on ice before centrifugation at 4 °C, with separation of plasma for further storage at −80 °C.

Whole blood measurement of serotonin is popular because time-consuming isolation of platelets is not required. For whole blood serotonin, venous blood is (1) drawn into a tube containing potassium EDTA as an anticoagulant, (2) gently mixed and placed on ice, and (3) transferred to a storage tube. An aliquot of blood is then removed for a platelet count. Blood serotonin samples are stored frozen at −20 °C, preferably within 2 hours after collection.

Platelet-rich plasma samples are prepared from whole blood by low-speed centrifugation. To prevent lowering of serotonin concentration, platelet-rich plasma is prepared within 1 hour after the blood is collected and placed on ice. Plasma and pellets are stored frozen at −20 °C and are analyzed within 1 to 2 weeks after collection.

Twenty-four-hour urine samples for serotonin and 5-HIAA are collected in 2-L brown polypropylene bottles, each of which contains 250 mg of sodium metabisulfite and EDTA as preservatives. Samples are acidified to pH 4 with acetic acid before freezing. Most important, the specimen should be refrigerated during collection.

Interferences from and Influences of Diet and Drugs

Dietary constituents or drugs may cause direct analytical interference in assays or influence the physiological processes that determine plasma and urinary concentrations of monoamines and monoamine metabolites. In the former circumstances, interference is highly variable depending on the particular measurement method used. In the latter circumstances, interference is usually of a more general nature and independent of the measurement method.

Development of new drugs, variations in assay techniques, and continuing improvements in analytical procedures make it difficult to identify which directly interfering medications should be avoided for a given analytical test. For modern mass spectrometric–based detection methods, however, such interferences are rarely a problem compared with electrochemical and spectrophotometric detection methods.

More readily identifiable and generalized sources of interference that are independent of the particular assay method tend to be associated with drugs that have primary actions on monoamine systems. Because these systems serve as important therapeutic targets, such drugs represent a relatively common source of false-positive results. Tricyclic antidepressants are a major source of false-positive results for measurements of norepinephrine and normetanephrine; this is a result of the primary actions of these agents to inhibit monoamine reuptake. Other medications that cause significant interference but are less commonly encountered during testing for pheochromocytoma include (1) l-dopa, (2) Sinemet, (3) α-methyldopa (Aldomet), and (4) MAO inhibitors.

Dietary interference is sometimes particularly troublesome for measurements of serotonin metabolites, requiring detailed dietary instruction for these patients.[7] Dietary sources of 5-hydroxyindoles such as (1) walnuts, (2) bananas, (3) avocados, (4) eggplants, (5) pineapples, (6) plums, and (7) tomatoes should be restricted 3 to 4 days before and during urine collection. If possible, patients should abstain from all known medications that may cause an apparent increase, such as (1) glycerol (2) guaiacolate, (3) mephenesin, (4) phenacetin, and (5) acetaminophen, or decrease in 5-HIAA, including (1) methenamine, (2) phenothiazine tranquilizers, (3) homogentisic acid, (4) acetic acid, and (5) levodopa. Measurements of methoxytyramine are subject to influences of dietary catecholamines.[2] For plasma measurements, an overnight fast is sufficient to avoid such influences.

Reference Intervals

Use of appropriately matched reference populations is important for effective screening for monoamine-producing tumors among different populations of patients. Urinary and plasma catecholamines and metanephrines vary with age and have different intervals in hospitalized patients compared with normotensive healthy volunteers and in males compared with females. Also, quantities of catecholamines and metanephrines in 24-hour urine specimens and plasma are nonnormally distributed, necessitating nonparametric methods to establish reference intervals or logarithmic transformation to normalize before parametric analyses (Figure 26-8). Because of variations in methods of analysis and subsequent analytical test results, any laboratory establishing measurements of monoamines or metabolites for diagnostic purposes should validate its own reference intervals in line with current standards in clinical practice.

Urinary and Plasma Fractionated Metanephrines

T e metanephrines, normetanephrine and metanephrine, and the O-methylated metabolite of dopamine, methoxytyramine, are present in plasma and urine in free and sulfate- or glucuronide-conjugated forms.[3,13] Plasma concentrations of the conjugates are 20- to 30-fold higher than those of the free metabolites, reflecting more rapid circulatory clearance of free than conjugated metabolites. Clearance of free metabolites occurs by active uptake into tissues followed by deamination or conjugation. T e conjugated metabolites so produced are cleared relatively slowly by renal extraction and elimination in the urine. Metanephrines in urine are therefore routinely measured af er acid hydrolysis and represent mainly conjugated metabolites, whereas metanephrines in plasma are usually measured in the free form.

Measurements of metanephrines in urine and plasma are now widely performed in many laboratories by LC-MS/MS (see Figure 26-7).[3] Such methods offer advantages of (1) short chromatographic run times, (2) high sample throughput, and (3) elimination of drug interference that render obsolete earlier methods, which used liquid chromatography with electrochemical detection (LC-EC). A sample preparation step, usually employing ion exchange chromatography, remains a requirement; however, this is accomplished more simply for LC-MS/MS than for LC-EC methods, with some methods allowing on-line sample purification.

Immunoassay measurements of plasma and urine metanephrines are used by some laboratories, particularly when sample throughput is not high enough to justify the expense of LC-MS/MS instrumentation. Nevertheless, immunoassay methods suffer from relatively poor accuracy and precision and are not recommended for routine clinical use.[3]

Urinary and Plasma Catecholamines

LC-EC methods are still commonly used for measurement of plasma catecholamines, whereas mass spectrometric methods are increasingly used for measurement of urinary catecholamines.[13,14] T e most common extraction procedure employed for LC-EC measurement of plasma catecholamines involves alumina extraction (Figure 26-9). For urinary catecholamines, the alumina extraction procedure may be combined with or without a cation exchange step. Boric acid gels provide an alternate approach for selective adsorption of catecholamines. For LC-MS/MS methods, more simple methods of extraction are used, such as 96-well–based ion exchange chromatographic procedures, but with final elution of analytes from extraction columns under acid conditions rather than basic conditions commonly used for metanephrines. When appropriate exchange resins are used, an advantage of these methods over those previously used for preparation of samples for LC-EC is that catecholamines and metanephrines are purified and measured together by LC-MS/MS.

Urinary Vanillylmandelic Acid and Homovanillic Acid

Vanillylmandelic acid (VMA) is the major end-product of norepinephrine and epinephrine metabolism, whereas HVA is the major end-product of dopamine metabolism. Both metabolites are excreted in urine in relatively high amounts, making their analysis relatively simple. VMA in contrast to HVA is not significantly conjugated. Nevertheless, because large amounts of HVA are also present in urine in the free form, both metabolites are commonly measured without a hydrolysis step. Compared with metanephrines and catecholamines, measurements of VMA and HVA have limited value for diagnosis of pheochromocytoma but are commonly used for diagnosis of neuroblastoma.

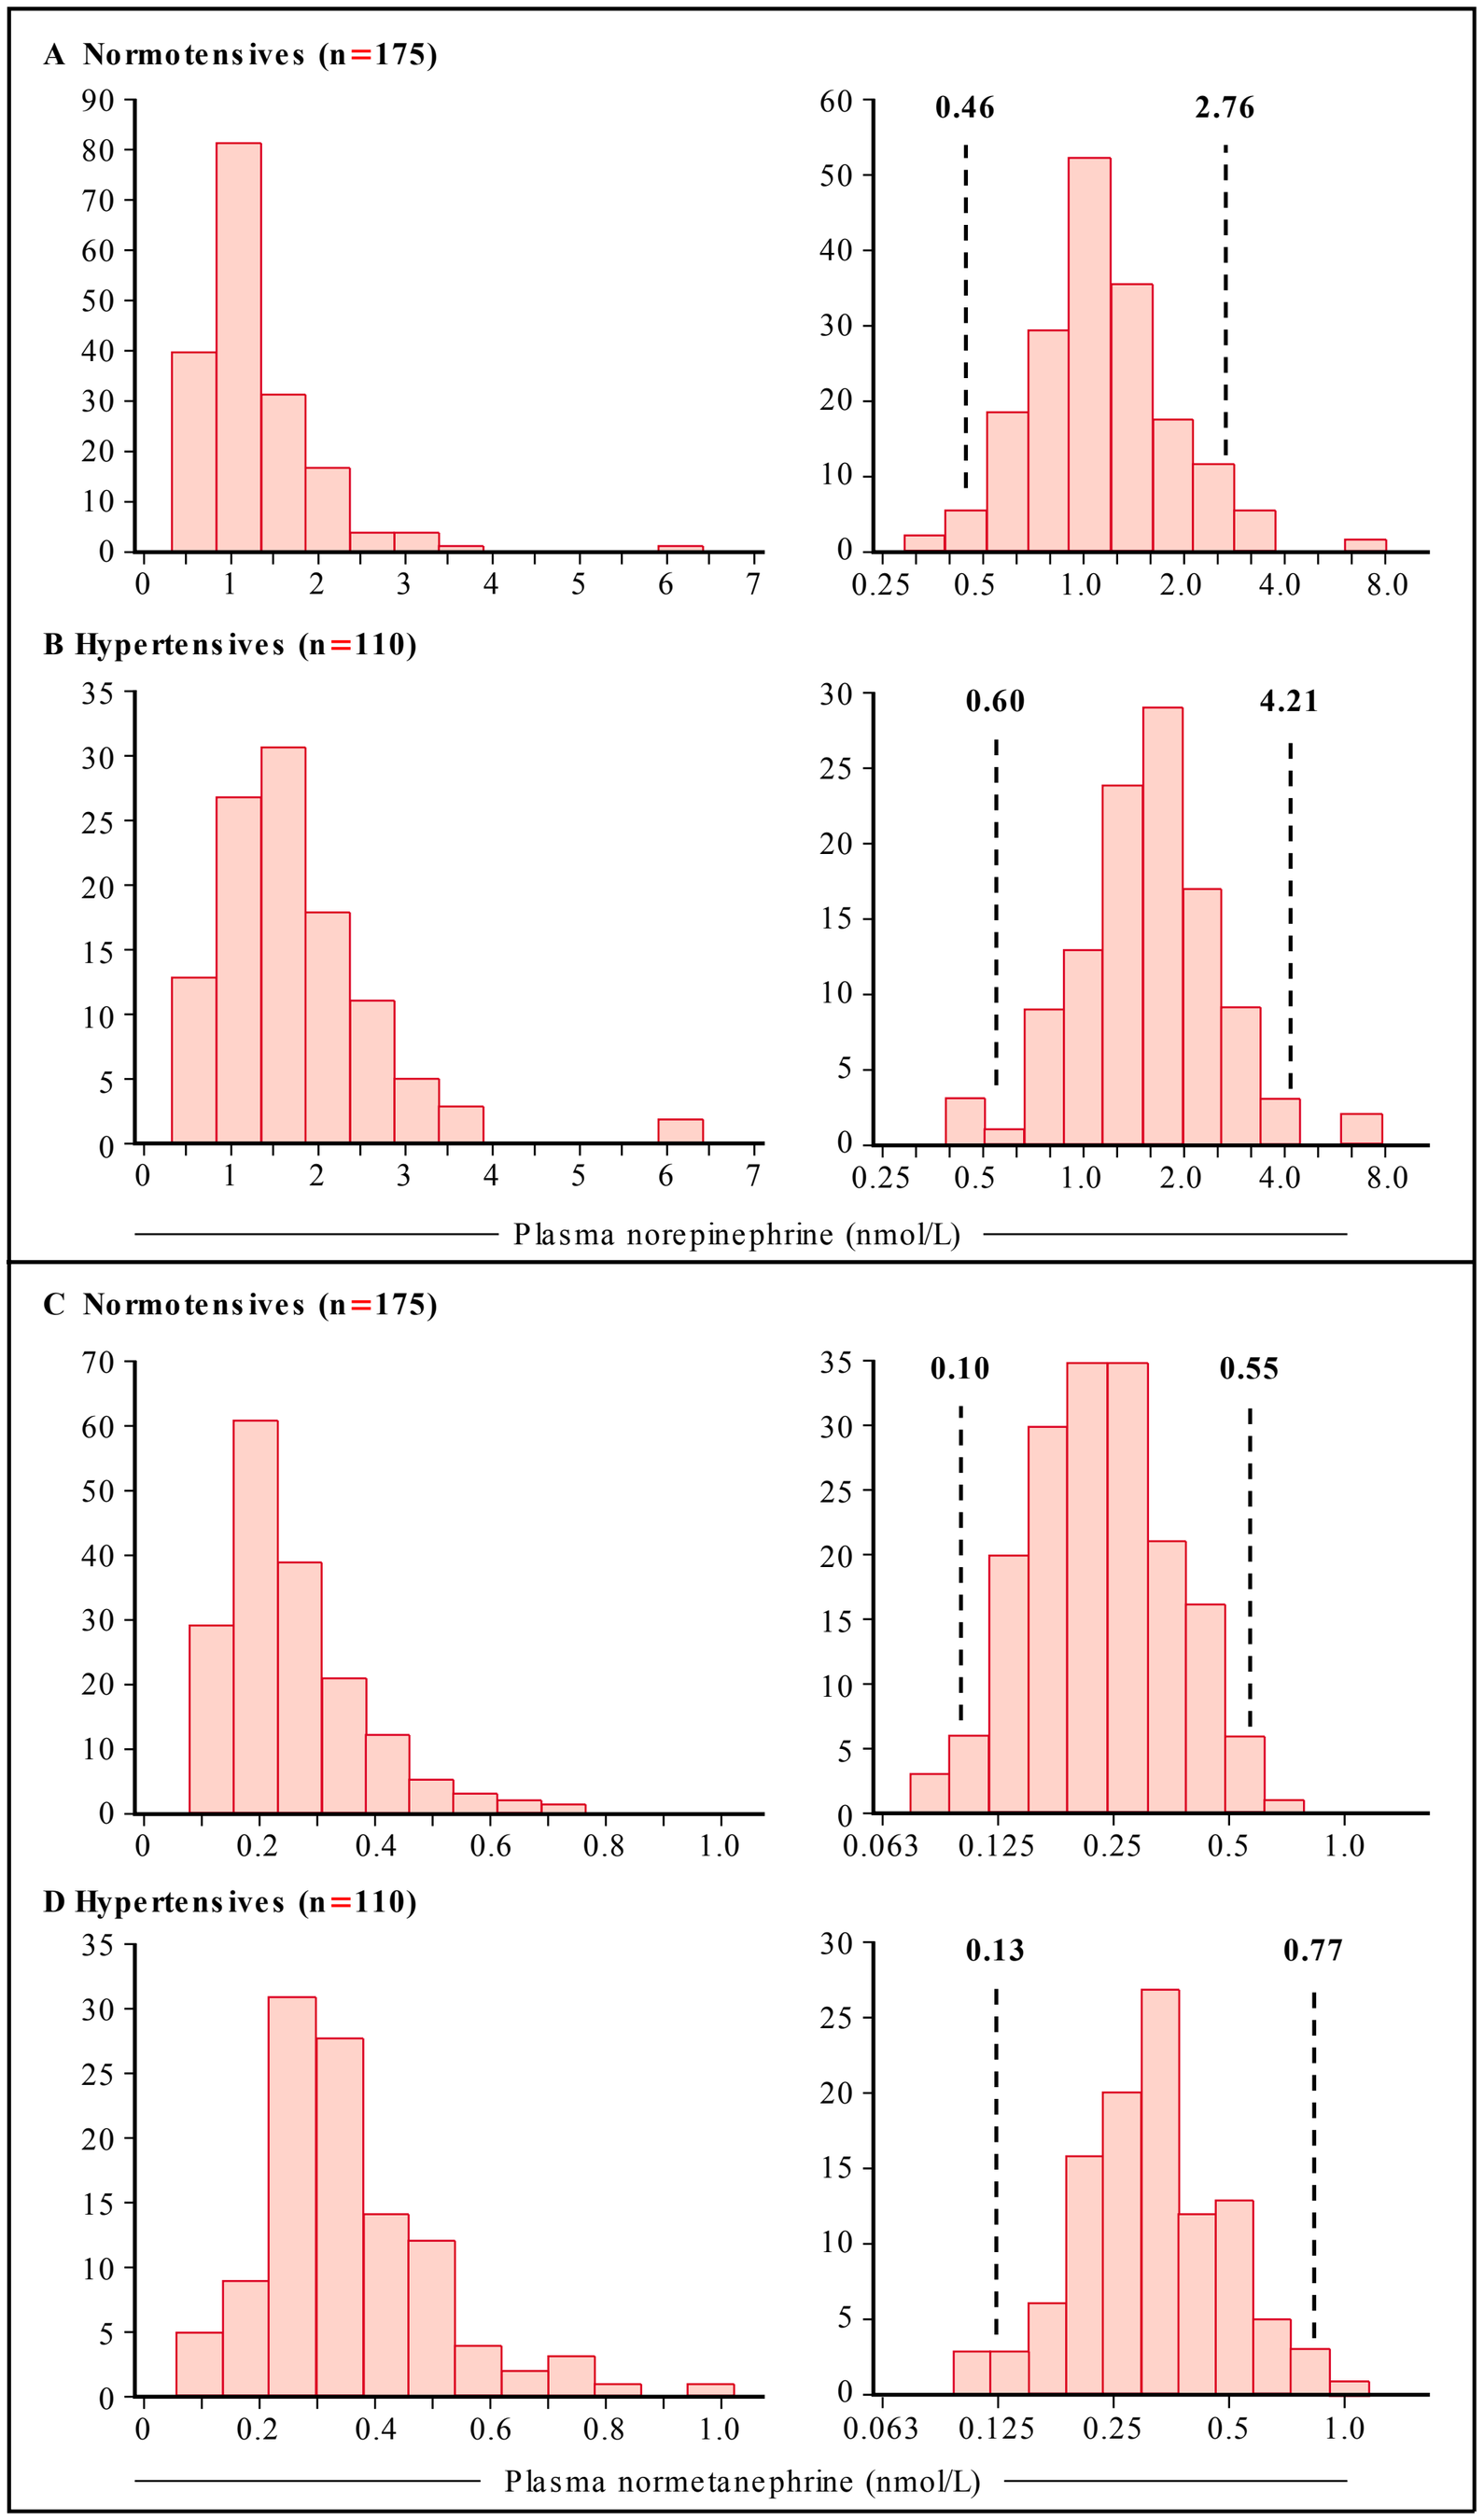

Figure 26-8 Frequency distributions for plasma norepinephrine (A and B) and plasma-free normetanephrine (C and D) in healthy normotensive volunteers (A and C) compared with patients with essential hypertension (B and D). Distributions shown in the panels on the right have been normalized by logarithmic transformation. The 95% confdence intervals (indicated by vertical dashed lines) were estimated using normalized distributions. Note that distributions in hypertensive individuals show a shift to higher plasma concentrations compared with distributions in normotensive individuals, with correspondingly higher lower and upper reference limits.

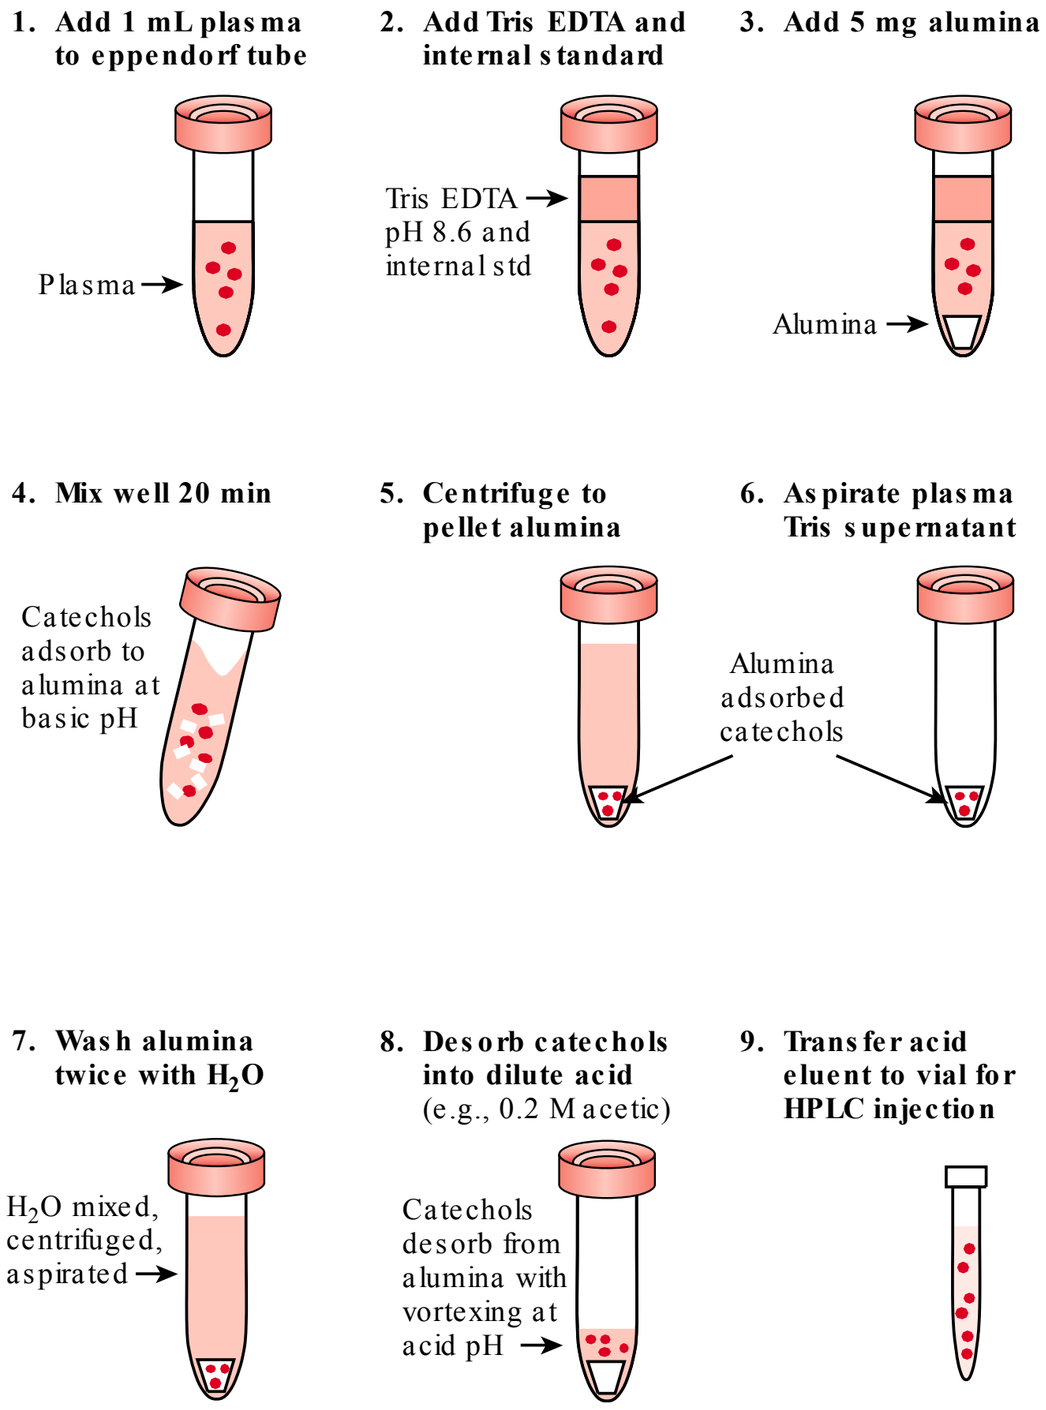

Figure 26-9 Procedure for alumina extraction of plasma catecholamines. In addition to extraction of the catecholamines (norepinephrine, epinephrine, and dopamine), this procedure allows extraction of other catechols, including 3,4-dihydroxyphenylglycol (the deaminated metabolite of norepinephrine and epinephrine), 3,4-dihydroxyphenylacetic acid (the deaminated metabolite of dopamine), and l-dopa, the precursor of dopamine.

Spectrophotometric methods for determination of VMA and HVA have been superseded by gas or liquid chromatography–based methods, employing today mainly mass spectrometric detection.[13,14] Mass spectrometric methods are highly specific and, along with combined measurements of VMA and HVA, allow with some methods additional measurement of 5-HIAA. Gas chromatography–based methods typically employ extraction of urinary analytes into an organic phase followed by derivatization of analytes in the dried down residue. Sample preparation is simpler still for LC-MS/MS methods, some of which involve only dilution of urine in a suitable injection vehicle.

Serotonin and 5-Hydroxyindoleacetic Acid

Analyses of serotonin, its deaminated acid metabolite, and 5-HIAA and its precusor, 5-hydroxytryptophan (5-HTP), provide important biomarkers for diagnosis of carcinoid tumor.[7] Typically, circulating serotonin is almost entirely confined to platelets, so that measurements are usually performed in (1) whole blood, (2) platelet-rich plasma, or (3) isolated platelet pellets. With sensitive analytical instruments, measurements are possible in platelet-free plasma, which has been proposed as an alternative matrix, useful for detection of serotonin-producing neoplasms at locations where venous outflow does not empty into the portal circulation.

Measurements of urinary serotonin are of less importance because the serotonin in this matrix reflects primarily clearance of plasma-free serotonin and renal decarboxylation of circulating 5-HTP. Nevertheless, urinary measurement is helpful in identifying tumors deficient in aromatic amino acid decarboxylase that produce substantial amounts of 5-HTP, which consequently shows up in urine as serotonin. Such tumors may be more directly detected by measurement of circulating 5-HTP.

Measurements of 5-HIAA are most commonly carried out in urine. As an end-product of serotonin production, 5-HIAA better reflects tumor burden than serotonin. Measurements in plasma after an overnight fast have been advocated as more reliable because they avoid the confounding influence of dietary serotonin.

Liquid chromatography with fluorometric or electrochemical detection remains the most frequently used method for measurements of the concentrations of serotonin and 5-HIAA. Usually these techniques have been developed for measuring serotonin and 5-HIAA separately, but some methods allow for simultaneous measurement of catecholamine and indoleamine acid metabolites (i.e., 5-HIAA, VMA, and HVA). This is usually dependent on differences in analyte chemistry (e.g., amine vs. carboxylic acid), which define the required sample purification procedure and the purified analyte that is detected. For detection of high concentrations of serotonin, as in platelet-rich plasma, simple methods of deproteinization of samples with perchloric acid or trichloroacetic acid before direct injection onto the high-performance liquid chromatography (HPLC) column are used.

Most HPLC assays for serotonin and 5-HIAA employ octadecylsilyl (C18) reversed-phase columns, although strong cation exchange columns have been used for serotonin. The chromatography is usually performed with an isocratic mobile phase at an acid pH that contains an organic modifier and perhaps an ion-pair reagent for serotonin measurements. As with catecholamines, serotonin is protonated in the pH range of 3 to 6, and addition of an anionic ion-pair reagent creates an uncharged conjugate, which enhances the affinity of serotonin for the hydrophobic stationary phase.

For measurement of very small amounts of serotonin or for specialized projects, HPLC with amperometric or coulometric detection is often favored over fluorometric detection. To increase their lower limit of detection, some HPLC procedures incorporate precolumn derivatization with fluorescent and chemiluminescent reagents, thereby achieving detection limits in the femtomole range. Electrochemical detection using amperometric or coulometric measurement is preferred for specific measurement of small quantities of 5-HIAA. Some HPLC systems use fluorometric detection, with or without derivatization, for a less demanding measurement of 5-HIAA.

As with measurements of metanephrines and catecholamines, use of mass spectrometric–based methods of quantification of serotonin and 5-HIAA is increasing. With these methods, sample clean-up procedures are simpler, enabling online sample purification.

Review Questions

1. The urinary metabolite measured as an indicator of norepinephrine synthesis is:
   a. dopamine.
   b. homovanillic acid (HVA).
   c. serotonin.
   d. vanillylmandelic acid (VMA).
2. False-positive elevations of 5-hydroxyindoleacetic acid (5-HIAA) in urine can occur if:
   a. an individual is a chronic alcoholic.
   b. a patient is receiving aspirin therapy.
   c. an individual has recently eaten fruit, such as bananas, kiwis, and plums.
   d. a patient is currently using tricyclic antidepressants.
3. The two urine metabolites that are most widely used for diagnosis of neuroblastoma are:
   a. HVA and VMA.
   b. VMA and 5-HIAA.
   c. HVA and 5-HIAA.
   d. dopamine and epinephrine.
4. Midgut neuroendocrine tumors release which of the following substances in large quantity when compared with tumors derived from other developmental gut components?
   a. 5-Hydroxytryptophan
   b. Serotonin
   c. Epinephrine
   d. Dopamine
5. The method most frequently used for measuring 5-HIAA in urine to detect serotonin production is:
   a. nephelometry.
   b. mass spectrometry.
   c. liquid chromatography.
   d. ion exchange chromatography.
6. Although a 24-hour urine collection is often considered a better specimen for catecholamine analysis, blood samples can be used. Specimen requirements include:
   a. collection in no anticoagulant and immediate freezing of the specimen at −80 °C.
   b. collection in potassium EDTA with preparation of a platelet-rich plasma sample.
   c. collection in sodium oxalate from a fasting upright individual.
   d. collection in heparin or EDTA anticoagulant from a fasting supine individual.
7. A catecholamine-producing tumor derived from the chromaffin cells of the adrenal medulla is referred to as a:
   a. neuroblastoma.
   b. pheochromocytoma.
   c. paraganglioma.
   d. gastroenteropancreatic neuroendocrine tumor.
8. True or false: More than 95% of the serotonin in the body is produced within the gastrointestinal tract.
   a. True
   b. False
9. Chromaffin cells are located in the___ and are responsible for synthesis of ___.
   a. kidney; renin
   b. brain; dopamine
   c. adrenal gland; epinephrine
   d. gut; serotonin
10. Epinephrine is also called:
    a. noradrenaline.
    b. adrenaline.
    c. metanephrine.
    d. serotonin.

Vitamins, Trace Elements, and Nutritional Assessment*

CHAPTER 27

Alan Shenkin, Ph.D., F.R.C.P., F.R.C.Path., and
Norman B. Roberts, M.Sc., Ph.D., C.Chem.

Objectives

1. Define the following:

Beriberi	Scurvy
Chemical speciation	Speciation methods
Hypervitaminosis	Trace element
Hypovitaminosis	Ultratrace element
Pellagra	Vitamer
Pernicious anemia	Vitamin

2. Classify the vitamins discussed in this chapter according to their water or fat solubility; discuss what these terms mean in relation to vitamin physiology.
3. State the chemical names of each vitamin discussed in this chapter.
4. Summarize the physiological roles of each vitamin discussed in this chapter.
5. Describe the symptoms of toxicity and deficiency, if any, for each vitamin discussed in this chapter; state the names of the specific disorders related to deficiency of vitamin B_{12}, C, niacin, and thiamine.
6. List the most common method of laboratory analysis for each vitamin discussed in this chapter.
7. Analyze and solve case study problems related to vitamin deficiency or toxicity.
8. State what is meant when an element is considered "essential."
9. Correlate the importance of trace elements passing from a charged ionized form to the uncharged form with the role that each element exerts in its respective metalloprotein.
10. List eight essential trace elements and summarize the physiological functions and clinical significance of each listed element.
11. Describe instrumental methods used in the analysis of trace elements; list two of these methods and their principles.
12. Outline appropriate specimen collection procedures and possible preanalytical variables associated with to trace element analysis.
13. List and describe two deficiency disorders of the following trace elements: chromium, copper, manganese, selenium, and zinc; list and describe at least one genetic disorder that affects each of the following: copper, zinc, and iron.
14. Appraise the possible roles of the following elements in human physiology, including function and clinical significance: boron, silicon, vanadium.
15. Analyze and solve case study problems related to trace element deficiency.

Key Words and Definitions

Acrodermatitis enteropathica A hereditary disorder due to defective zinc uptake.

Acute phase reaction (APR) A response of the body to inflammation that results in an increase or decrease in the plasma concentrations of a class of proteins known as acute phase reactants.

Apoenzyme A protein moiety of an enzyme that requires a coenzyme.

Avitaminosis A disease condition, described as a deficiency syndrome, that results from lack of a vitamin.

Beriberi A disease caused by a deficiency of thiamine (vitamin B_1) and characterized by polyneuritis, cardiac pathology, and edema.

*The authors gratefully acknowledge the original contributions of Donald B. McCormick, Harry L. Green, George G. Klee, David B. Milne, Gordon S. Fell, David Lyons, and Malcolm Baines, on which portions of this chapter are based. The authors are also grateful for the assistance of Juha and Leila Risteli in revising the "Vitamin C" section.

Key Words and Definitions—cont'd

Chemical speciation Refers to the molecular form of atoms of an element or a cluster of atoms of different elements in a given matrix.

Coenzyme A diffusible, heat-stable substance or organic molecule (sometimes derived from a vitamin) of low molecular weight that, when combined with an inactive protein called an apoenzyme, forms an active compound or a complete enzyme called a holoenzyme, which functions catalytically in an enzyme system.

Cofactor A natural reactant, usually a metal ion or a coenzyme, that is required in an enzyme-catalyzed reaction.

Essential nutrients Nutrients (proteins, minerals, carbohydrates, lipids, vitamins) necessary for growth, normal functioning, and maintenance of life; they must be supplied by food because they cannot be synthesized by the body.

Estimated average requirement (EAR) The daily intake of a specific nutrient estimated to meet the requirement in 50% of healthy people in an age- and gender-specific group. The EAR is used to calculate the recommended dietary allowance.

Glucose tolerance factor A biologically active complex of chromium and nicotinic acid that facilitates the reaction of insulin with receptor sites on tissues.

Hartnup disease An inborn error of metabolism characterized by a massive aminoaciduria involving a group of neutral monoaminomonocarboxylic amino acids sharing a common renal reabsorption mechanism.

Hemorrhagic disease of newborn A self-limited hemorrhagic disorder of the first days of life, caused by a deficiency of the vitamin K–dependent blood coagulation factors II, VII, IX, and X

Holoenzyme The functional (i.e., catalytically active) compound formed by the combination of an apoenzyme with its appropriate coenzyme.

Hypervitaminosis An unhealthy condition resulting from excessive amounts of a vitamin.

Hypovitaminosis An unhealthy condition resulting from too little of a vitamin; interchangeable with avitaminosis.

Kashin–Beck disease (KBD) A chronic, endemic osteochondropathy (disease of the bone).

Keshan disease A fatal, congestive cardiomyopathy caused by deficiency of essential trace elements in the diet.

Megaloblastic anemia Any anemia characterized by megaloblasts in the bone marrow, such as pernicious anemia.

Menkes disease An X-linked recessive disorder of copper metabolism caused by mutations in the ATP7A gene (locus: Xq12-q13), which encodes a copper transporter.

Nutriture The status of the body in relation to nutrition, generally or with regard to a specific nutrient such as a trace element.

Pellagra A clinical deficiency syndrome due to deficiency of niacin (or failure to convert tryptophan to niacin) and characterized by dermatitis, inflammation of mucous membranes, diarrhea, and psychic disturbances.

Pernicious anemia A deficiency in the production of red blood cells through a lack of vitamin B_{12}.

Recommended dietary allowance (RDA) The amount of nutrient and calorie intake per day considered necessary for maintenance of good health, calculated for males and females of various ages and recommended by the Food and Nutrition Board of the U.S. National Research Council. Popularly called recommended daily allowance.

Scurvy A condition due to deficiency of ascorbic acid (vitamin C) in the diet.

Systemic inflammatory response syndrome (SIRS) The systemic inflammatory response to a wide variety of severe clinical insults.

Speciation methods Techniques used to separate the chemical complexes of individual elements present in any particular medium.

Superoxide dismutase An enzyme of the oxidoreductase class that catalyzes the reduction of superoxide anions to hydrogen peroxide, protecting cells against dangerous levels of superoxide (oxygen).

Total parenteral nutrition (TPN) The practice of feeding a person intravenously, circumventing the gut.

Trace elements Inorganic molecules found in human and animal tissues in milligram per kilogram amounts or less.

Ultratrace elements Inorganic molecules found in human and animal tissues in microgram per kilogram amounts or less.

Vitamer Term used to describe any of a number of compounds that possess a given vitamin activity.

Vitamin An essential organic micronutrient that must be supplied exogenously and in many cases is the precursor to a metabolically derived coenzyme.

Wilson disease A rare, progressive, autosomal recessive disease due to a defect in metabolism of copper.

Zinc finger A finger-shaped fold in a protein that is created by the binding of specific amino acids in the protein to a zinc atom. Zinc-finger proteins regulate the expression of genes as well as nucleic acid recognition, reverse transcription, and virus assembly.

Adequate supplies of **vitamins** and **trace elements** are **essential nutrients** and critical for maintaining the health and development of humans (http://www.iom.edu/; accessed October 2, 2013).[1, 2-8,12] Table 27-1 summarizes the **recommended dietary allowance (RDA)** in the United States and population reference intakes from the European community for vitamins and trace elements. The consequences of an inadequate intake of trace elements are shown in Figure 27-1.

Vitamins

Historically, vitamin groups bear an Arabic subscript number following the letter either to designate structural and functional similarity (e.g., A_1 [retinol] and A_2 [3-dehydroretinol]) or to indicate the approximate order in which they are identified as members of the so-called B-complex (e.g., B_1 [thiamine] and B_2 [riboflavin]). Common chemical names are also used. These often reflect the presence of (1) some specific atom (thiamine), (2) a prime functional group (pyridoxamine), or (3) even a larger portion of the molecular structure (phylloquinone). Parts of some names reflect functional properties (cholecalciferol).

Another classification pertains to the relative solubility of vitamins. Those of the fat-soluble group (A, D, E, and K) are more soluble in organic solvents, whereas B-complex group vitamins and vitamin C are water soluble. This general separation based on solubility is useful not just for purposes of noting gross physical properties but also as a reminder that fat-soluble vitamins are (1) absorbed, (2) transported, and (3) stored for longer periods of time. Most water-soluble vitamins are retained less and excreted more in the urine. In general, water-soluble vitamins function as **coenzymes** for several important enzymatic reactions in both mammals and microorganisms. By contrast, fat-soluble vitamins generally do not function as coenzymes and are rarely used by microorganisms.

Thirteen known vitamins and vitameric groups essential to humans are individually discussed below and are listed in Table 27-2.

Vitamin A

Vitamin A serves many important functions in the body; its role in vision is of particular significance.

Chemistry

Vitamin A is the nutritional term for the group of compounds with a 20-carbon structure containing a methyl-substituted cyclohexenyl ring (β-ionone ring) and an isoprenoid sidechain (Figure 27-2), with (1) a hydroxyl group (retinol), (2) an aldehyde group (retinal), (3) a carboxylic acid group (retinoic acid), or (4) an ester group (retinyl ester) at the terminal C15. Retinol, the principal vitamin A **vitamer,** will oxidize reversibly to retinal—which shares all the biological activity of retinol—or will further oxidize to retinoic acid, which shows some of its biological activity. The principal storage forms of vitamin A are retinyl esters, particularly palmitate. Included in the vitamin A family are some dietary carotenoids (C40 polyisoprenoid compounds) that are classified as provitamin A because they

TABLE 27-1 Oral and Intravenous Micronutrient Intakes for Adults[15]

	RDA (USA)	PRI (Europe)	Amount in 2000 kcal Tube-Feed	IV Intake
Vitamins

*Adequate intake.
†Acceptable range.

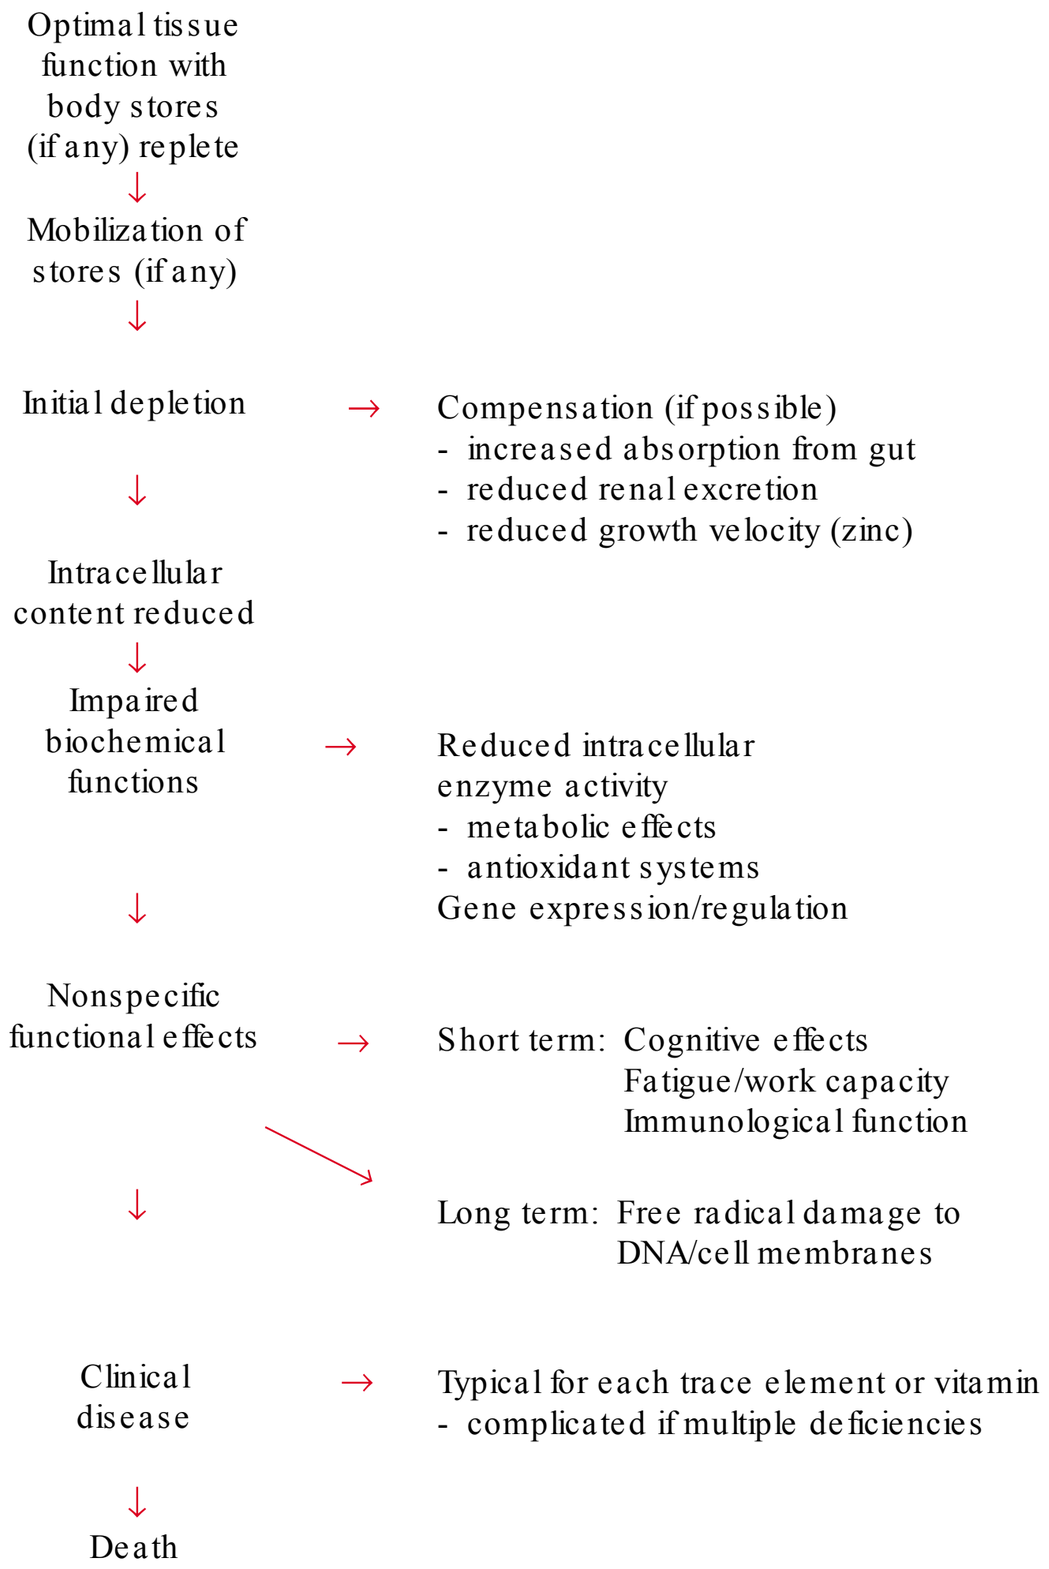

Figure 27-1 Consequences of inadequate mineral or trace element intake. (From Shenkin A, Allwood MC. Trace elements and vitamins in adult intravenous nutrition. In: Rombeau JL, Rolandelli RH, editors. Clinical nutrition: parenteral nutrition. Philadelphia: WB Saunders, 2001:60–79.)

are cleaved biologically to yield retinol. Examples include (1) α-carotene, (2) β-carotene, and (3) β-cryptoxanthin. Vitamin A compounds are yellowish oils or low-melting-point solids (depending on isomeric purity) that are practically insoluble in water but are soluble in organic solvents and mineral oil.

Dietary Sources

Preformed vitamin A is obtained from (1) liver, (2) other organ meats, (3) fish oils, (4) full cream milk, (5) butter, and (6) fortified margarines. The provitamin A carotenoids are obtained from yellow to orange pigment fruits and vegetables and from green leafy vegetables. The U.S. National Health and Nutrition Examination Survey (NHANES)-II indicated that approximately 25% of the vitamin A requirement was provided by carotenoids and about 75% by preformed retinol.

Absorption, Transport, Metabolism, and Excretion

Preformed vitamin A, most often in the form of retinyl ester, or carotenoids are subject to emulsification before being transported into the intestinal cell. There the retinyl esters are moved across the mucosal membrane and are hydrolyzed to retinol within the cell to be reesterified by cellular retinol-binding protein II and packaged into chylomicrons. These enter the mesenteric lymphatic system and pass into the systemic circulation.

Carotenoids, also in micellar form, are absorbed into the duodenal mucosal cells by passive diffusion. The efficiency of absorption of carotenoids is much less than for vitamin A. Once inside the mucosal cell, β-carotene is converted primarily to retinal by the enzyme β-carotene-15,15′-dioxygenase, and the retinal is converted by retinal reductase to retinol and is esterified. The newly synthesized retinyl esters then pass with chylomicrons via the lymphatic system to the liver, where uptake by parenchymal cells again involves hydrolysis. In the liver, retinol is bound with retinol-binding protein (RBP; MW ≈21,000 Da) and transthyretin (thyroxine-binding prealbumin) (MW ≈55,000 Da) in a 1:1:1 complex of sufficient size to prevent loss by glomerular filtration. Delivery of retinol to the tissue is controlled by the availability of the vitamin A protein complex in the circulation, although this control mechanism will be bypassed with large doses of retinol. Excretion of vitamin A occurs via the feces and urine, usually after conjugation or oxidation.

Functions

Vitamin A has a significant function in vision. All-trans-retinol is the predominant circulating form of vitamin A, and cells of the retina isomerize it to the 11-cis alcohol that is reversibly dehydrogenated to 11-cis retinal. This is sterically hindered geometrical isomer of the aldehyde combines as a lysyl-linked Schiff base with suitable proteins such as opsin to generate photosensitive pigments such as rhodopsin. Illumination of such pigments causes photoisomerization and release of all-trans-retinal and the protein—a process that couples the large conformational change to ion flux and optic nerve transmission. The all-trans-retinal is isomerized to the 11-cis isomer, which again combines with the liberated protein to reconstitute the photo pigment in a visual cycle, as shown in Figure 27-3.

Other functions of vitamin A include its role in (1) reproduction, (2) growth, (3) embryonic development, and (4) immune function. In normal growth and in maintenance of the integrity of epithelial cells, retinoic acid acts through the activation of retinoic acid receptors (RARs) and retinoid X receptors (RXRs) in the nucleus to regulate various genes that encode for (1) structural proteins, (2) enzymes, (3) extracellular matrix proteins, and (4) RBP and receptors. Retinol, its metabolites, and synthetic retinoids provide protective effects against the development of certain types of cancer by (1) blocking tumor promotion, (2) inhibiting proliferation, (3) inducing apoptosis, (4) inducing differentiation, or (5) combining these actions. Some caution is required, however, regarding the use of vitamin A or β-carotene supplements because they appear to be of no benefit in reducing the incidence of gastrointestinal cancer and indeed may increase the incidence of lung cancer and mortality in certain other cancers.

TABLE 27-2 Human Vitamin Requirements

Common Name	Trivial Chemical Name	General Roles	Symptoms of Deficiency or Disease	Direct and Indirect Assays
Fat Soluble				
Vitamin A	Retinol, retinal, retinoic acid	Vision, growth, reproduction	Nyctalopia, xerophthalmia, keratomalacia	Photometric, HPLC, fluorometric, RIA
Vitamins D_2, D_3	Ergocalciferol, cholecalciferol	Modulation of Ca^{2+} metabolism, calcification of bone and teeth	Rickets (young), osteomalacia (adult)	CPB, HPLC, RIA
Vitamin E	Tocopherols, tocotrienols	Antioxidant for unsaturated lipids, neurological and reproductive functions	Lipid peroxidation, including red blood cell fragility, hemolytic anemia (premature, newborn)	Photometric, HPLC, erythrocyte hemolysis
Vitamins K_1, K_2	Phylloquinones, menaquinones	Blood clotting, osteocalcins	Increased clotting time, RIA time, hemorrhagic disease (infant)	HPLC, prothrombin (abnormal prothrombin, PIVKA test)
Water Soluble				
Vitamin B_1	Thiamine	Carbohydrate metabolism, nervous function	Beriberi, Wernicke-Korsakoff syndrome	Fluorometric, transketolase, HPLC
Vitamin B_2	Riboflavin	Oxidation reduction reactions	Angular stomatitis, dermatitis, photophobia	Fluorometric, HPLC, glutathione reductase
Vitamin B_6	Pyridoxine, pyridoxal, pyridoxamine	Amino acid, phospholipid, and glycogen metabolism	Epileptiform convulsions, dermatitis, hypochromic anemia	HPLC, aspartate transaminase, urine pyridoxic acid
Niacin	Nicotinic acid, nicotinamide	Oxidation reduction reactions	Pellagra	Fluorometric, HPLC, niacinamide nicotinamide coenzymes
Folic acid	Pteroylglutamic acid	Nucleic acid and amino acid biosynthesis	Megaloblastic anemia, neural tube defects	CPB, microbiological, homocysteine
Vitamin B_{12}	Cyanocobalamin	Amino acid and branched chain keto acid metabolism	Pernicious and megaloblastic anemia, neuropathy	CPB, microbiological, RIA, methylmalonate
Biotin	—	Carboxylation reactions	Dermatitis	Microbiological, CPB, carboxylases, avidin binding
Pantothenic acid	—	General metabolism, acetyl and acyl transfer	Burning feet syndrome	Microbiological, RIA, CPB/HPLC
Vitamin C	Ascorbic acid	Connective tissue formation, antioxidant	Scurvy	Photometric, HPLC, enzymatic

CPB, Competitive protein binding; HPLC, high-performance liquid chromatography; PIVKA test, proteins induced by or involved in vitamin K antagonism or absence; RIA, radioimmunoassay.

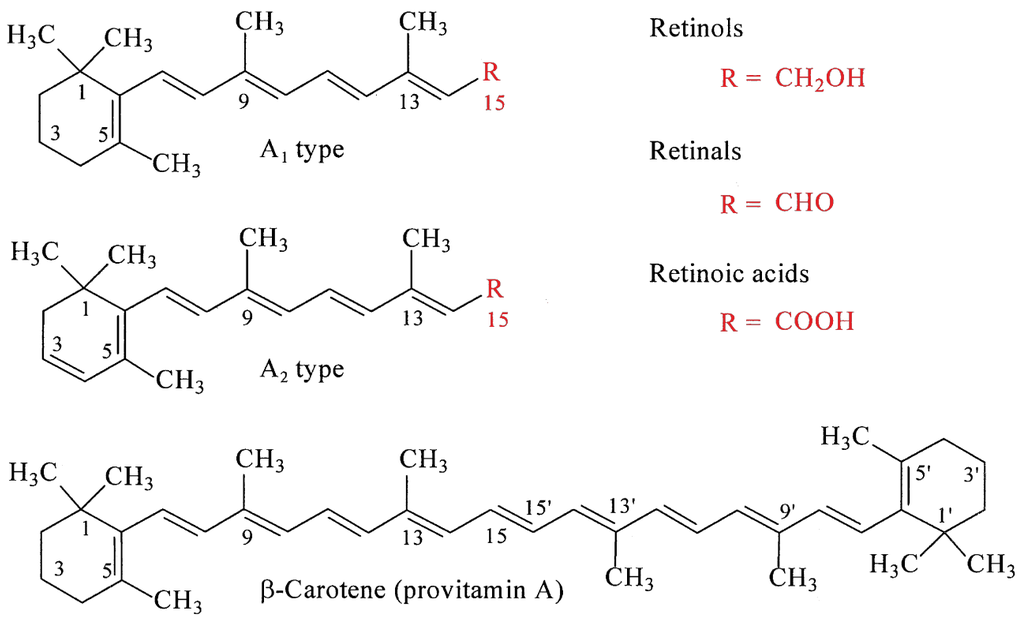

Figure 27-2 Vitaminic forms of A_1, A_2, and β-carotene.

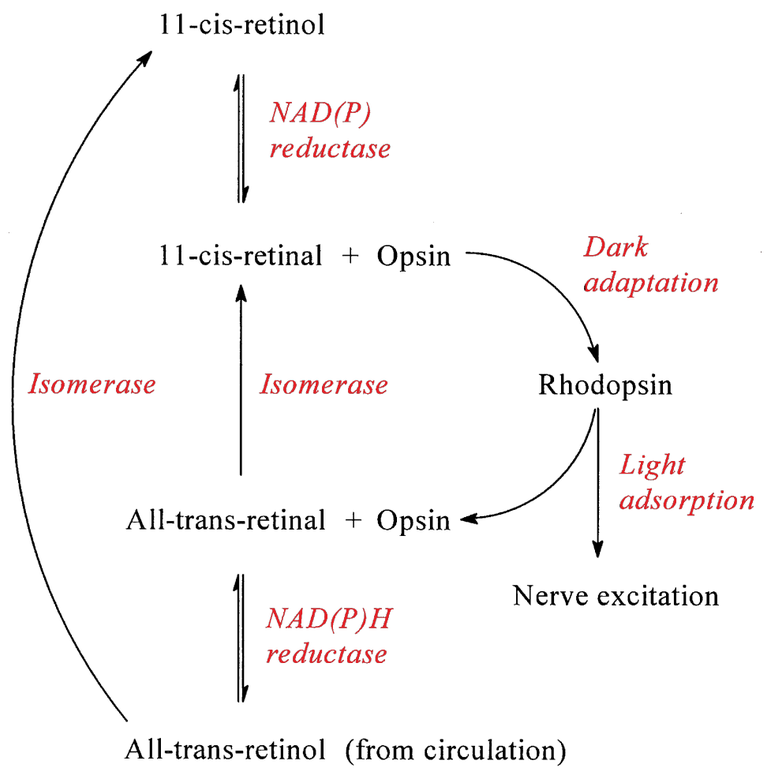

Figure 27-3 Participation of A vitamers in the visual cycle.

Requirements and Reference Nutrient Intakes[6,11]

Past studies suggest that intakes of retinol of 500 to 600 μg/d are required. For example, the Food and Nutrition Board of the U.S. Institute of Medicine recommends the retinol activity equivalent (RAE) as the basis of calculation of retinol intake. With this system, a ratio equivalence of 1:12:24 is recommended (12 μg β-carotene or 24 μg mixed carotenoids has the same biological activity as 1 μg retinol). With this system, current RDAs for vitamin A are 900 μg RAE for men 19 years and older and 700 μg RAE for women, with increased allowances for pregnancy and lactation.

Deficiency

Vitamin A deficiency primarily affects infants and children, and its prevalence is subject to World Health Organization (WHO) surveillance. Risk factors include (1) poverty, (2) low birth weight, (3) poor sanitation, (4) malnutrition, (5) infection, and (6) parasitism. Because hepatic accumulation of vitamin A occurs during the last trimester of pregnancy, preterm infants are relatively vitamin A deficient at birth. Providing a daily oral intake of vitamin A that meets the RDA of 400 μg RAE is therefore important. Infants with birth weights less than 1500 g (those under 30 weeks' gestation) have virtually no hepatic vitamin A stores and are at risk of vitamin A deficiency. Fat malabsorption, particularly caused by celiac disease or chronic pancreatitis, and protein-energy malnutrition predispose to vitamin A deficiency. Liver disease diminishes RBP synthesis, and ethanol abuse leads both to hepatic injury and to competition with retinol for alcohol dehydrogenase, which is necessary for the oxidation of retinol to retinal and retinoic acid. Vitamin A deficiency may lead to anemia, although the exact mechanism is not known.

The clinical features of vitamin A deficiency include degenerative changes in eyes and skin and poor dark adaptation (night blindness [nyctalopia]). More serious effects of deficiency are xerophthalmia, in which the conjunctiva becomes dry with small gray plaques with foamy surfaces (Bitot spots), and keratomalacia, which causes ulceration and necrosis of the cornea. Usually, associated skin changes include (1) dryness, (2) roughness, (3) papular eruptions, and (4) follicular hyperkeratosis.

Toxicity

Although vitamin A metabolism is tightly regulated, toxic effects of **hypervitaminosis** A have occurred as a result of ingestion of excess vitamin or as a side effect of inappropriate therapy. Hypervitaminosis A occurs (1) after liver storage of retinol and its esters exceeds 3000 μg/g tissue, (2) after more than 30,000 μg/d is ingested for months or years, or (3) when plasma vitamin A concentrations exceed 140 μg/dL (4.9 μmol/L). Acute toxicity from a single massive dose is rare. Chronic toxicity from moderately high doses taken for protracted periods is characterized by (1) bone and joint pain, (2) hair loss, (3) dryness and fissures of the lips, (4) anorexia, (5) benign intracranial hypertension, (6) weight loss, and (7) hepatomegaly.

Epidemiological and experimental evidence indicates that high vitamin A intake in humans, acting via 13-cis-retinoic acid, is teratogenic. The Food and Nutrition Board of the U.S. Institute of Medicine has recommended a tolerable upper intake concentration of 3000 μg/d of preformed vitamin A for men and lower concentrations for (1) women of child-bearing age, (2) infants, (3) children, and (4) adolescents. Carotenemia results from chronic excessive intake of carotene-rich foods, principally carrots. This condition, in which yellowing of the skin is observed, is benign because the excess carotene is deposited rather than converted to vitamin A.

Laboratory Assessment of Status

Measurement of the plasma concentration of vitamin A is widely used to assess vitamin A status. However, it is not an ideal indicator because vitamin A does not decline until liver stores become critically depleted. This is thought to occur at a concentration of approximately 20 μg/g of liver tissue. Early chemical methods, such as the Carr-Price and Neeld-Pearson methods, have largely been replaced by high-performance liquid chromatography (HPLC) methods. Both normal-phase and reverse-phase techniques have been used with (1) photometric, (2) electrochemical, or (3) mass spectrometric detectors.

As retinol circulates in plasma as a 1:1:1 complex with RBP and transthyretin, both of these hepatically produced proteins have been measured as an indicator of vitamin A status. RBP may be measured by nephelometry, but its circulating concentration may be affected by inadequate dietary (1) protein, (2) energy, or (3) zinc, all of which are necessary for RBP synthesis. Another confounding factor in the assessment of vitamin A status is the effect of the acute-phase response. Both RBP and transthyretin are negative acute-phase proteins, thus inflammatory changes will result in a transient fall in proteins and in plasma retinol. To distinguish inflammatory from nutritional causes of reduced plasma retinol concentrations, it is necessary to measure an acute-phase protein, such as C-reactive protein (CRP).

Reference Intervals

Guidance reference intervals for plasma vitamin A include the following: (1) 20 to 40 μg/dL (0.70 to 1.40 μmol/L) for 1- to 6-year-old children; (2) 26 to 49 μg/dL (0.91 to 1.71 μmol/L) for 7- to 12-year-old children; (3) 26 to 72 μg/dL (0.91 to 2.51 μmol/L) for 13- to 19-year-old adolescents; and (4) 30 to 80 μg/dL (1.05 to 2.80 μmol/L) for adults. Values above 30 μg/dL (1.05 μmol/L) are associated with appreciable reserves in the liver and correlate well with vitamin A intake. Within the reference interval, values for men are generally about 20% higher than those for women. The reference interval for plasma β-carotene is 10 to 85 μg/dL (0.19 to 1.58 μmol/L). Elevated concentrations are found in hypothyroid patients, in whom conversion to vitamin A is decreased, and in patients with hyperlipidemia associated with diabetes mellitus. The reference interval for plasma RBP is 3 to 6 mg/dL.

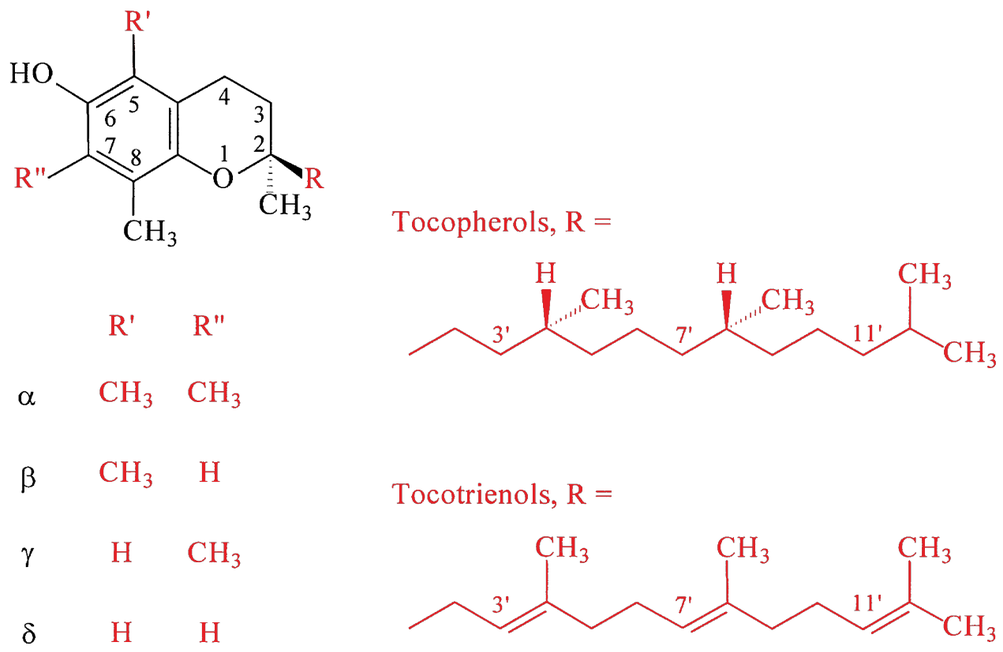
Vitamin D

Vitamin D plays an essential role as a hormone in the control of calcium and phosphorus metabolism (see Chapter 39).

Vitamin E

Vitamin E is an antioxidant that acts as a scavenger for molecular oxygen and free radicals and has a role in cellular respiration.

Chemistry



Vitamin E is the nutritional term for the group of naturally occurring tocopherols and tocotrienols that have biological activity similar to RRR-α-tocopherol (formerly d-α-tocopherol). Also note that RRR refers to its three stereo centers located at the 2, 4, and 8 positions of the tocopherol chain. The Greek letter prefixes α, β, γ, and δ indicate the presence or absence of methyl groups at positions 5 and 7 (Figure 27-4). Tocopherols and tocotrienols are (1) viscous oils at room temperature, (2) soluble in fat solvents, and (3) insoluble in aqueous solutions. Also, tocopherol and tocotrienols are stable to acid and heat in the absence of oxygen but labile to oxygen in alkaline solutions and to ultraviolet light.

Dietary Sources

The principal sources of dietary vitamin E are (1) oils and fats, particularly wheat germ oil and sunflower oil, (2) grains, and (3) nuts. Meats, fruits, and vegetables contribute little vitamin E. γ-Tocopherol is the major form of vitamin E in many plant seeds in the U.S. diet, but it is present at only one-quarter to one-tenth the concentration of α-tocopherol in human plasma.

Absorption, Transport, Metabolism, and Excretion

In the presence of bile, vitamin E is absorbed from the small intestine. Most forms of vitamin E are absorbed nonselectively and are secreted in chylomicron particles, which are then transported to the peripheral tissue (mainly adipose tissue) with the aid of lipoprotein lipase. The liver takes up the chylomicron remnants where the α-tocopherol is incorporated into very low-density lipoprotein (VLDL). Vitamin E is excreted via the bile and in the urine as tocopheronic acid and its β-glucuronide conjugate.

	R'	R"
α	CH_3	CH_3
β	CH_3	H
γ	H	CH_3
δ	H	H

Figure 27-4 Vitaminic forms of vitamin E.

Functions

Vitamin E is considered necessary for (1) neurological and reproductive functions, (2) protection of the red cell from hemolysis, (3) prevention of retinopathy in premature infants, and (4) inhibition of free-radical chain reactions of lipid peroxidation. The latter occurs mainly within the polyunsaturated fatty acids of membrane phospholipids. Tocopherols and tocotrienols inhibit lipid peroxidation largely because they scavenge lipid peroxyl radicals faster than the radical reacts with adjacent fatty acid sidechains or membrane proteins. The resultant tocopheryl or tocotrienyl radicals then react with further peroxyl radicals to produce tocopherones (nonradicals), or are regenerated by transfer of an electron to ascorbate to form the ascorbyl radical. Thus, vitamins E and C act synergistically to reduce lipid peroxidation (Figure 27-5). Many epidemiological surveys have shown an association between reduced vitamin E intake (and other dietary factors) and an increase in the incidence of chronic disease, particularly cardiovascular disease and cancer. However, most studies on supplementation have failed to show any benefit.

Requirements and Reference Nutrient Intakes[6]

The daily requirement for vitamin E is related to the cellular polyunsaturated fatty acid content. The minimum adult requirement for vitamin E is thought to be approximately 3 to 4 mg/d for those who ingest a diet containing the minimum requirement of essential fatty acids. However, in the year 2000, the U.S. Food and Nutrition Board increased the RDA for vitamin E for adults from 10 to 15 mg/d. Most European reference intakes are related to polyunsaturated fatty acid intake. Another departure in the newer recommendations was that the daily requirement must be met by RRR-α-tocopherol alone, as the other forms of vitamin E are not converted to α-tocopherol and are poorly recognized by the α-tocopherol transfer protein in the liver.

Deficiency

Premature and low birth weight infants are particularly susceptible to development of vitamin E deficiency because placental transfer is poor and infants have limited adipose tissue. Signs of deficiency include (1) irritability, (2) edema, and (3) hemolytic anemia. In general, symptoms of vitamin E deficiency are rare in children and adults, although deficiency has occurred in some conditions. Fat malabsorption states, such as cystic fibrosis and chronic cholestasis in children, have been known to cause neuropathy and hemolytic anemia, as does the genetic disorder abetalipoproteinemia (within which vitamin E is transported).

Toxicity

Excess vitamin E intake is usually achieved only by dietary supplementation and may cause deficiency of fat-soluble vitamins D and K by competitive absorption. A comprehensive review of the tolerance and safety of vitamin E suggested that intakes up to 3000 mg/d were safe. Reversible side effects of (1) gastrointestinal symptoms, (2) increased creatinuria, and (3) impaired blood coagulation have been observed at intakes of 1000 to 3000 mg/d. The U.S. Food and Nutrition Board has

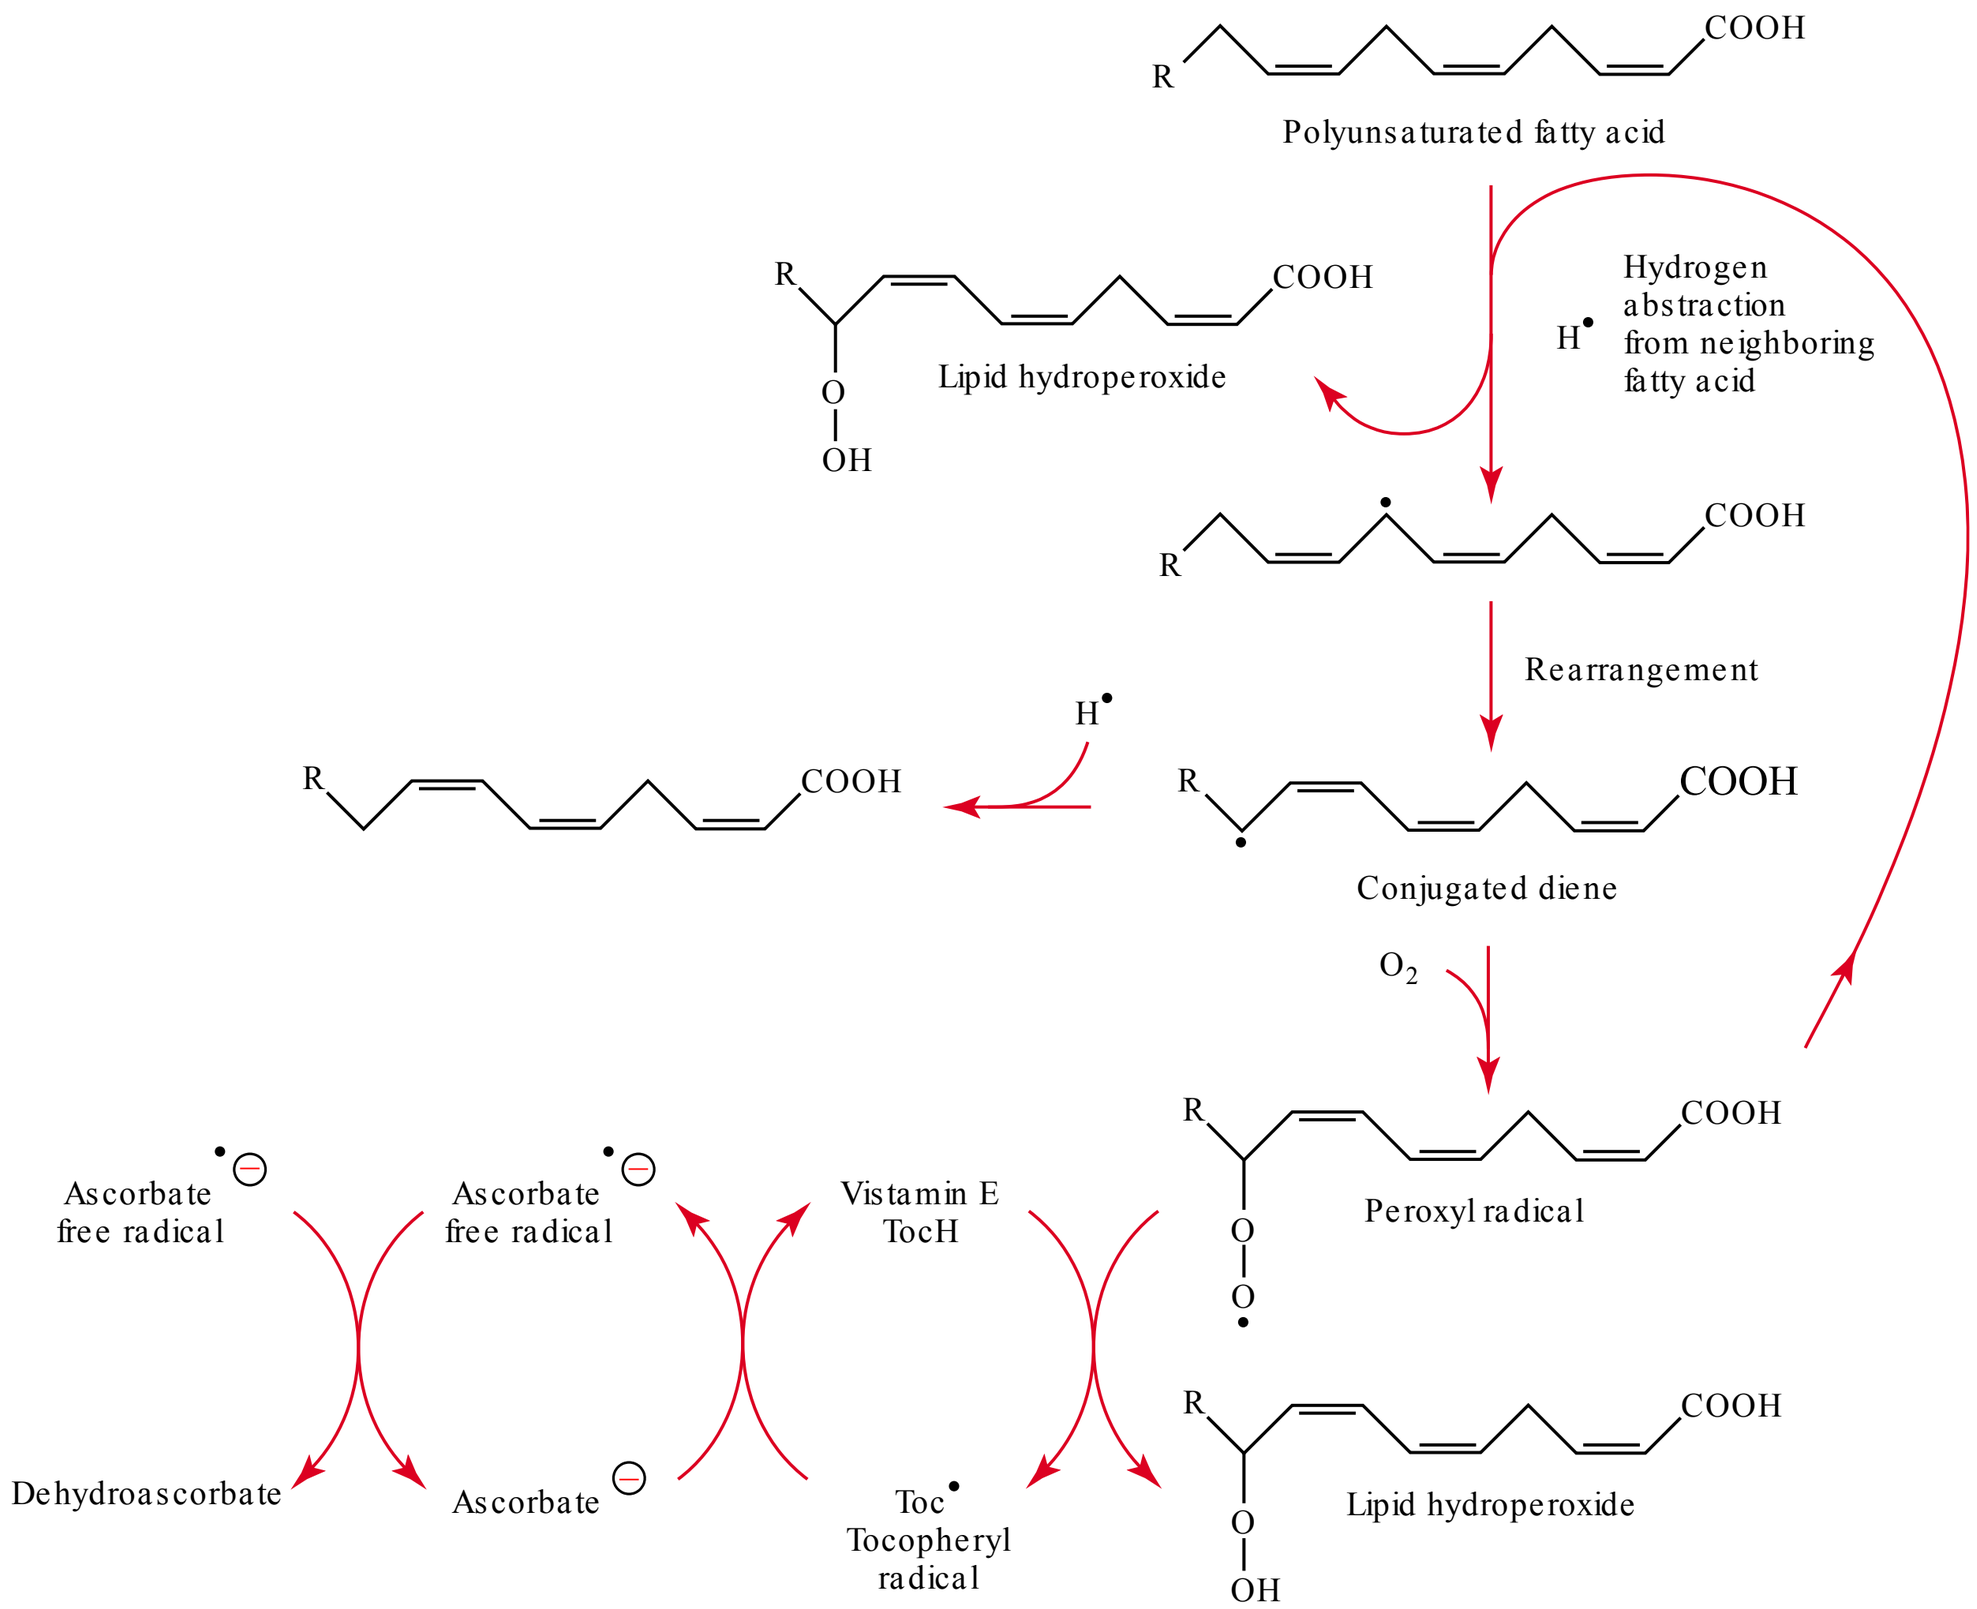


Figure 27-5 Synergistic action of vitamin E and ascorbate in radical chain breaking.

recommended a tolerable upper limit of 1000 mg/d of vitamin E for adults 19 years of age and older.

Laboratory Assessment of Status[11]

HPLC is presently the method of choice to quantify tocopherols in serum. α- and γ-Tocopherols are the principal vitamers seen, although others are detected with minor modifications to the analytical conditions. T in-layer and gas-liquid chromatography methods have been used to separate the tocopherols and the tocotrienols.

Reference Intervals

Guidance reference intervals for serum or plasma (heparin) vitamin E are (1) 0.1 to 0.5 mg/dL (2.3 to 11.6 μmol/L) for premature neonates; (2) 0.3 to 0.9 mg/dL (7 to 21 μmol/L) for children (1 to 12 years); (3) 0.6 to 1.0 mg/dL (14 to 23 μmol/L) for adolescents; and (4) 0.5 to 1.8 mg/dL (12 to 42 μmol/L) for adults.

Vitamin K

Vitamin K promotes clotting of the blood and is required for the conversion of several clotting factors and prothrombin; it is a topic of growing interest in bone metabolism.

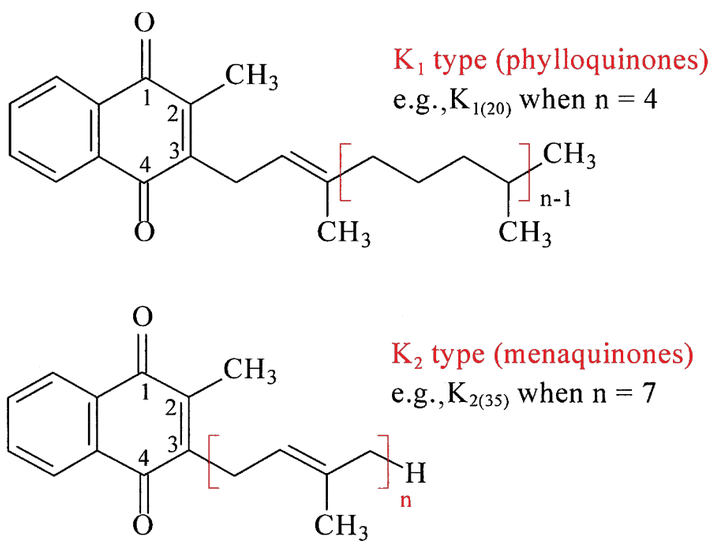

Figure 27-6 Vitaminic forms of vitamin K.

Chemistry

Compounds in the vitamin K series are 2-methyl-1,4-naphthoquinones, which are substituted with sidechains at carbon 3. T e two principal natural classes of vitamin K are the phylloquinones (K_1 type) synthesized in plants and the menaquinones (K_2 type) of bacterial origin (Figure 27-6). Several synthetic analogues and derivatives have been used in human nutrition. Most relate to or are derived from menadione (K_3), which lacks a sidechain substituent at position 3 but is converted to

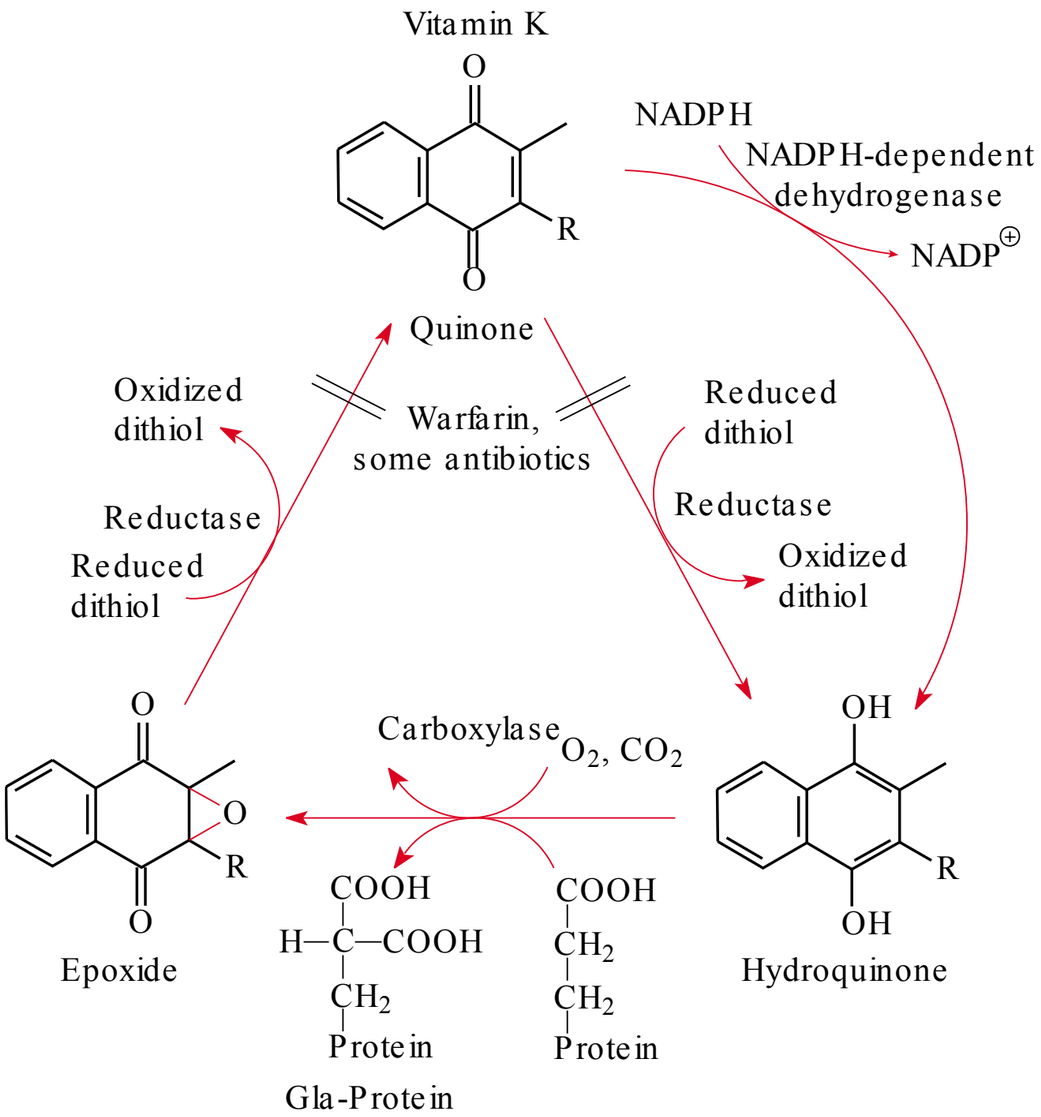

Figure 27-7 Metabolic cycling of vitamin K, the effect of warfarin, and the formation of Gla proteins.

menaquinone (MK). They are destroyed by alkaline solutions and reducing agents and are sensitive to ultraviolet light.

Dietary Sources

The main dietary sources of phylloquinones are (1) green vegetables, (2) margarines, and (3) plant oils. Menaquinones are obtained from (1) cheese, (2) other milk products, and (3) eggs.

Absorption, Transport, Metabolism, and Excretion

Absorption of natural vitamin K from the small intestine into the lymphatic system is facilitated by bile. Efficiency of absorption varies from 15% to 65%. Vitamins K_1 and K_2 are bound to chylomicrons for transport from mucosal cells to the liver. Menadione (K_3) is more rapidly and completely absorbed from the gut before it enters the portal blood. In the liver, intracellular distribution occurs mostly in the microsomal fraction. Release of vitamin K to the bloodstream allows association with circulating β-lipoproteins for transport to other tissue.

Within metabolically active and vitamin K–using tissue, especially liver, a microsomal vitamin K cycle exists (Figure 27-7). The vitamin (quinone) is normally reduced by a thiol-sensitive flavoprotein system to the hydroquinone, which then couples to oxygen and carbon dioxide to form the Gla protein (e.g., prothrombin). The 2,3-epoxide of vitamin K that is subsequently formed is reduced to the starting vitamin K quinones—a process that is antagonized by such vitamin K antagonists as warfarin. Only traces of urinary metabolites of vitamins K_1 and K_2 appear in urine. A considerable portion of vitamin K_3 is conjugated to form β-glucuronide and sulfate esters, which are excreted.

Functions

The essential and most thoroughly defined role of vitamin K is that of a dietary antihemorrhagic factor. Vitamin K–dependent carboxylase converts specific glutamyl residues in target proteins to γ-carboxyglutamyl (Gla) residues. This γ-carboxylation increases the affinity of these proteins for calcium. Vitamin K is also needed for formation of the Gla proteins (1) prothrombin (factor II), (2) proconvertin (factor VII), (3) plasma thromboplastin component (factor IX), and (4) Stuart factor (factor X). These, together with two other hemostatic vitamin K–dependent proteins, proteins C and S and Ca^{2+}, initiate a process to form thrombin, which then catalyzes the conversion of fibrinogen to a fibrin clot.

Proteins that contain γ-carboxyglutamyl are also abundant in bone tissue; osteocalcin accounts for up to 80% of the total γ-carboxyglutamyl content of mature bone. A further major Gla protein, matrix Gla protein (MGP)—which contain five residues of γ-carboxyglutamic acid—is found in (1) vascular smooth muscle, (2) bone, and many soft tissues such as (3) heart, (4) kidney, and (5) lungs. It is thought that MGP accumulates at sites of calcification, including calcified aortic valves and bone, and is a potent inhibitor of calcification.

Requirements and Reference Nutrient Intakes[6]

Although the human gut bacteria synthesize large quantities of menaquinones, absorption of these compounds has been difficult to demonstrate, however, dietary restriction of vitamin K does lead to evidence of inadequacy. Dietary reference intakes for vitamin K have recently been revised by the Food and Nutrition Board of the U.S. Institute of Medicine to 120 μg/d for men over 18 years of age and 90 μg/d for women, including those pregnant or lactating. Dietary intake of phylloquinone in North American and most European populations studied has been estimated at around 150 μg/d for those older than 55 years of age and around 80 μg/d for younger individuals.

Deficiency

Although vitamin K deficiency is uncommon in the adult, risk is increased in fat malabsorption states such as (1) bile duct obstruction, (2) cystic fibrosis, (3) chronic pancreatitis, and (4) liver disease. Risk is also increased by the use of drugs that interfere with vitamin K metabolism, such as the coumarin anticoagulants (e.g., warfarin) and some antibiotics (e.g., cephalosporin). Defective blood coagulation and demonstration of abnormal noncarboxylated prothrombin are at present the only well-established signs of vitamin K deficiency.

Hemorrhagic disease of the newborn results from (1) poor placental transfer of vitamin K, (2) hepatic immaturity leading to inadequate synthesis of coagulation proteins, and (3) low vitamin K content in early breast milk. Prothrombin concentrations in the newborn during this period are only about 25% of adult concentrations. Severe diarrhea and antibiotics used to suppress diarrhea exacerbate the situation, so that when prothrombin concentrations drop to below 5% of the adult concentration, bleeding has been seen to occur. This condition is prevented by prophylactic administration of 0.5

to 1.0 mg of phylloquinone intramuscularly, or 2.0 mg given orally, immediately after birth.

Toxicity

The use of high doses of naturally occurring vitamin K (K_1 and K_2) appears to have no harmful effect; however, menadione (K_3) treatment can lead to the formation of erythrocyte cytoplasmic inclusions, known as Heinz bodies, as well as hemolytic anemia.

Laboratory Assessment of Status[11]

Because of its relatively low plasma concentration (approximately 50 times lower than vitamin D and at least one thousand times lower than vitamins A or E), vitamin K has long presented an analytical challenge. Consequently, vitamin K status has traditionally been assessed by functional methods, primarily by noting its effect on clotting time. Prothrombin time (PT) is assessed by adding to recalcified plasma a portion of tissue thromboplastin and measuring clotting time against a normal control sample. In vitamin K deficiency, PT may rise to above 30 seconds (normal, 10 to 14 seconds). Attempts at cross-laboratory standardization have led to the introduction of the international normalized ratio (INR), whereby the PT is expressed as a fraction of the control time.

Assays based on reduced activity of vitamin K, such as immunoassay for undercarboxylated plasma prothrombin and osteocalcin, are more sensitive but are not widely used.

Direct measurement of plasma phylloquinone is probably the best indicator of vitamin K status and has been shown to correlate well with intake. HPLC methods typically require 0.5 to 2.0 mL of serum or plasma and involve (1) protein precipitation and lipid extraction (often into hexane), (2) solvent evaporation, (3) preparative LC (to isolate vitamin K from other lipids), (4) reevaporation of the vitamin K–rich fraction, (5) dilution in the mobile phase, and (6) HPLC with electrochemical or fluorometric detection, often after postcolumn reduction. Typical between-batch imprecision values are 11% to 18% (coefficient of variation [CV]), with limits of detection lower than 50 pmol/L.

Reference Interval

A guidance reference interval for plasma vitamin K is 0.13 to 1.19 ng/mL (0.29 to 2.64 nmol/L).

Vitamin B_1—Thiamine

Vitamin B_1—also known as thiamine—forms the coenzyme thiamine pyrophosphate (TPP). It is required for the essential decarboxylation reactions catalyzed by the pyruvate and 2-oxoglutarate complexes.

Chemistry

The structure of thiamine (3-[4-amino-2-methyl-pyrimidyl-5-methyl]-4-methyl-5-[β-hydroxyethyl]thiazole) is that of a pyrimidine ring, bearing an amino group and linked by a methylene bridge to a thiazole ring (Figure 27-8). Thiazole has a primary alcohol sidechain at C5, which is phosphorylated in vivo to produce thiamine phosphate esters,

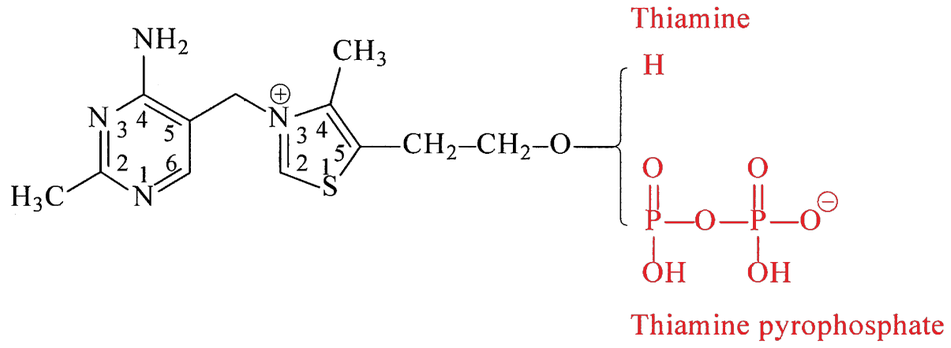

Figure 27-8 Thiamine and the pyrophosphate coenzyme.

the most common of which is TPP (also known as thiamine diphosphate, cocarboxylase). Monophosphate and triphosphate esters also occur.

Dietary Sources

Small quantities of thiamine and its phosphates are present in most plant and animal tissue, but the most abundant sources are unrefined cereal grains. Enrichment of flour and derived food products, particularly breakfast cereals, has considerably increased the availability of this vitamin.

Absorption, Transport, Metabolism, and Excretion

Thiamine absorption occurs primarily in the proximal small intestine. The absorbed thiamine undergoes intracellular phosphorylation, mainly to the pyrophosphate, but at the serosal membrane side 90% of the transferred thiamine is present in free form. Thiamine is carried by the portal blood to the liver. Free vitamin occurs in the plasma, but TPP is the primary cellular component. Approximately 30 mg is stored in the body: 80% as pyrophosphate, 10% as triphosphate, and the rest as thiamine and its monophosphate. The three tissue enzymes known to participate in the formation of phosphate esters are (1) thiaminokinase, (2) TPP-ATP phosphoryl-transferase (cytosolic 5′-adenylic kinase), and (3) thiamine triphosphatase.

About half of the body stores are found in (1) skeletal muscle, with much of the remainder in the (2) heart, (3) liver, (4) kidneys, and (5) nervous tissue (including the brain, which contains most of the triphosphate). The estimated half-life of thiamine is 9.5 to 18.5 days.

Functions

Thiamine is required by the body as the TPP in two general types of reaction: (1) oxidative decarboxylation of 2-oxo acids catalyzed by dehydrogenase complexes and (2) formation of 2-ketols (ketoses) as catalyzed by transketolase. TPP functions as the Mg^{2+}coordinated coenzyme for the so-called active aldehyde and transfers in multienzyme dehydrogenase complexes that affect decarboxylative conversion of 2-oxo acids to acyl-coenzyme A (acyl-CoA) derivatives, such as pyruvate dehydrogenase and 2-oxoglutarate dehydrogenase. These are often localized in the mitochondria, where efficient use in the Krebs tricarboxylic acid (citric acid) cycle follows.

Transketolase is a TPP-dependent enzyme found in the cytosol of many tissues, especially liver and blood cells, in which principal carbohydrate pathways exist. In the pentose phosphate pathway, which additionally supplies reduced NADPH necessary for biosynthetic reactions, this enzyme

catalyzes the reversible transfer of a glycoaldehyde moiety from the first two carbons of a donor ketose phosphate to the aldehyde carbon of an aldose phosphate.

Requirements and Reference Nutrient Intakes[2]

As thiamine is necessary for the metabolism of carbohydrates, fats, and alcohol, a direct correlation of need with the amount of metabolizable food intake is evident. The requirement is increased under situations in which metabolism is increased, such as in normal conditions of (1) increased muscular activity, (2) pregnancy, and (3) lactation, or in abnormal cases of (1) protracted fever, (2) post trauma, and (3) hyperthyroidism. Clinical signs of deficiency in adults are prevented by intakes of thiamine above 0.15 to 0.2 mg/1000 kcal, but 0.35 to 0.4 mg/1000 kcal may be closer to the amount necessary to maintain urinary excretion and TPP-dependent erythrocyte transketolase activity within reference intervals. The current RDA is 1.2 mg/d for adult males and 1.1 mg/d for adult females. Additional requirements are recommended for pregnancy and lactation.

Deficiency

Beriberi is a disease that results from thiamine deficiency. Clinical signs of thiamine deficiency primarily involve the nervous and cardiovascular systems. In the adult, symptoms most frequently observed are (1) mental confusion, (2) anorexia, (3) muscular weakness, (4) ataxia, (5) peripheral paralysis, (6) ophthalmoplegia, (7) edema (wet beriberi), (8) muscle wasting (dry beriberi), (9) tachycardia, and (10) an enlarged heart. In infants, symptoms appear suddenly and severely, often involving cardiac failure and cyanosis.

Thiamine deficiency occurs because of (1) inadequate intake caused by diets largely dependent on milled, nonenriched grains, such as rice and wheat, or (2) ingestion of raw fish containing microbial thiaminases. Chronic alcoholism often leads to thiamine deficiency caused by (1) reduced intake, (2) impaired absorption, and (3) reduced storage and may lead clinically to the Wernicke-Korsakoff syndrome. Other at-risk groups include (1) those receiving **total parenteral nutrition (TPN)** without adequate thiamine supplementation, (2) elderly patients taking diuretics, and (3) patients undergoing long-term renal dialysis.

Toxicity

No reports have described adverse effects resulting from consumption of excess thiamine from food and supplements (supplements of 50 mg/d are widely available without prescription).

Laboratory Assessment of Status[11]

Because the basic biological function of thiamine is to act as the pyrophosphate **cofactor** in a number of enzyme systems, two differing approaches to assessment of status are used. In one approach, the analyte, free or phosphorylated, is measured directly in a suitable body fluid or tissue. In the other approach, its properties as an enzymatic cofactor are exploited in a functional assay. Both approaches have associated advantages and disadvantages, each supplying some, but not all, of the information necessary for full assessment of thiamine adequacy. In clinical practice, direct measurement is now used more frequently.

The most commonly used enzyme for the functional assay is transketolase, and several methods are available for its measurement. With the Brin procedure, activities of holo forms and apo forms of transketolase in erythrocyte hemolysates are measured before and after the addition of TPP. The transketolase activation test consists of two tests: one a measurement of basal activity, and the other assesses the degree to which basal activity is increased by exogenous TTP; each may be influenced by different factors. Evidence suggests that chronic deficiency states of thiamine may decrease the synthesis of the **apoenzyme.** In comparison studies against erythrocyte TPP concentrations, better correlations were obtained with basal activity rather than with the activation coefficient.

Direct measurement of circulating thiamine concentrations may be made in (1) plasma, (2) erythrocytes, or (3) whole blood. The plasma (or serum) concentration is thought to reflect recent intake and involves mainly unphosphorylated thiamine at low concentrations (around 10 to 20 nmol/L). Because the erythrocyte contains approximately 80% of the total thiamine content of whole blood, mainly as the pyrophosphate, and erythrocyte thiamine stores deplete at a similar rate to other major organs, HPLC measurement of TPP in erythrocytes is a good indicator of body stores. Typical HPLC methods include (1) a protein precipitation step, (2) precolumn or postcolumn formation of the fluorophore thiochrome, usually with alkaline ferricyanide, (3) isocratic separation, and (4) fluorometric measurement. Whole blood samples may be analyzed in a manner similar to that used for washed erythrocytes.

Reference Intervals

Guidance reference intervals for erythrocyte transketolase activity include the following: 0.75 to 1.30 U/g Hb (48.4 to 83.9 kU/mol Hb) for percent TPP effect (activation), 0% to 15% normal, 16% to 25% marginally deficient, and >25% severely deficient with clinical signs. For direct TPP concentration measurements, typical intervals are 173 to 293 nmol/L erythrocytes and 90 to 140 nmol/L whole blood.

Vitamin B_2—Riboflavin

Vitamin B_2, also known as riboflavin, is an essential component of flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN)—coenzymes that are involved in many redox reactions.

Chemistry

Vitamin B_2 refers to riboflavin and its related metabolites, which act as cofactors to several reduction oxidation enzymes. The parent compound, riboflavin (7,8-dimethyl-10-[1′-d-ribityl]isoalloxazine), is a yellow fluorescent compound. Its major physiological role is to act as a precursor for FMN (riboflavin-5′-phosphate) and FAD. FMN is formed from riboflavin by flavokinase-catalyzed phosphorylation, and FAD

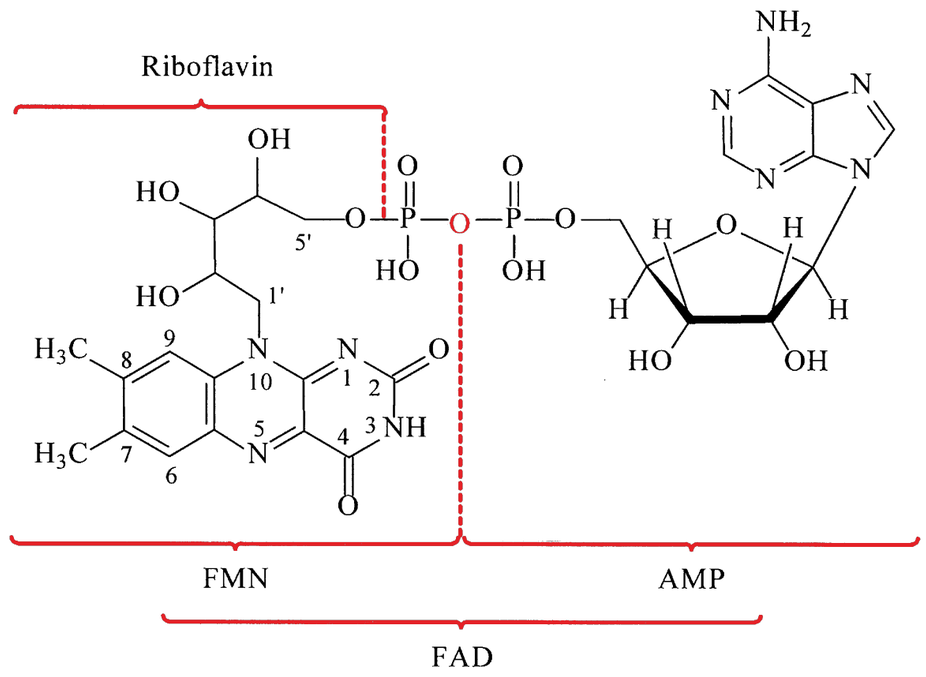

Figure 27-9 Ribofavin and FMN as components of FAD.

is formed from FMN and ATP by the action of FAD synthetase (Figure 27-9). Flavins are stable during exposure to heat but are decomposed by light.

Dietary Sources

Rich sources of coenzyme forms of the vitamin are (1) liver, (2) kidney, and (3) heart. Many (4) vegetables are also good sources, as is (5) milk, but cereals are rather low in flavin content. However, current practices of fortification and enrichment of cereal products have made them significant contributors to the daily requirement.

Absorption, Transport, Metabolism, and Excretion

Most dietary riboflavin is consumed as a complex of food protein with the coenzymes FMN and FAD. T ese coenzymes are released from noncovalent attachment to proteins by gastric acidification. T e vitamin is primarily absorbed in the proximal small intestine by a saturable transport system that is rapid and proportional to intake before reaching a plateau at doses near 27 mg riboflavin per day. Bile salts appear to facilitate the uptake. T e transport of flavins in human blood involves loose binding to albumin and tight binding to a number of globulins, particularly immunoglobulins. Uptake of riboflavin into the cells of organs is a process that requires a specific carrier at physiological concentrations. At higher concentrations, uptake occurs by passive diffusion.

Conversion of riboflavin to coenzymes occurs within the cellular cytoplasm of most tissue, but particularly in (1) small intestine, (2) liver, (3) heart, and (4) kidney. T e obligatory first step is ATP-dependent phosphorylation of the vitamin catalyzed by flavokinase. T e FMN product is complexed with specific apoenzymes to form several functional flavoproteins, but the larger quantity is further converted to FAD in a second ATP-dependent reaction catalyzed by FAD synthetase (pyrophosphorylase). Because little storage of riboflavin occurs, urinary excretion reflects dietary intake.

Functions

T e riboflavin coenzymes are capable of both one- and two-electron transfer processes and play a pivotal role in coupling two-electron oxidation of most organic substrates to the one-electron transfer of the respiratory chain. Additionally, flavoproteins catalyze (1) dehydrogenation reactions, (2) hydroxylations, (3) oxidative decarboxylations, (4) deoxygenations, and (5) reductions of oxygen to hydrogen peroxide. Other major functions of riboflavin include drug metabolism in conjunction with the cytochrome P_{450} enzymes and lipid metabolism.

Flavins also have pro-oxidative and antioxidative functions. T ey are thought to contribute to oxidative stress by producing superoxide and to catalyze the production of hydrogen peroxide. As an antioxidant, FAD is a coenzyme to glutathione reductase in the regeneration of reduced glutathione from oxidized glutathione, which is necessary for the removal of lipid peroxides. Riboflavin deficiency is associated with increased lipid peroxidation. Flavins also have homocysteine-lowering properties; FAD is a cofactor to methylenetetrahydrofolate reductase in the remethylation of homocysteine.

Requirements and Reference Nutrient Intakes[2]

Assessment of riboflavin requirements is based on the relationship of dietary intake to overt signs of (1) hyporiboflavinosis, (2) urinary excretion of the vitamin, (3) erythrocyte riboflavin content, and (4) erythrocyte glutathione reductase activity. Based on these considerations, the current RDA has been set at 1.3 mg/d for adult men and 1.1 mg/d for adult women . Additional requirements are suggested in pregnancy and lactation.

Defciency

Deficiency of riboflavin is characterized by (1) sore throat, (2) hyperemia, (3) edema of the pharyngeal and oral mucous membranes, (4) cheilosis, (5) angular stomatitis, (6) glossitis (magenta tongue), (7) seborrheic dermatitis, and (8) normochromic, normocytic anemia. However, some of these symptoms, such as glossitis and dermatitis, when encountered in the field, may have resulted from other complicating deficiencies.

Although riboflavin has a wide distribution in foodstuffs, many people live for long periods on low intakes; consequently, minor signs of deficiency are common in many parts of the world. In addition to poor intake, functional deficiency has been induced by diseases, such as hypothyroidism and adrenal insufficiency, which inhibit the conversion of riboflavin to its coenzyme derivatives. Because flavin coenzymes are widely distributed in intermediary metabolism and are involved in the metabolism of (1) folic acid, (2) pyridoxine, (3) vitamin K, and (4) niacin, deficiency will affect enzyme systems other than those requiring flavin coenzymes.

Toxicity

Probably as a result of its limited solubility and limited gastric absorption, no adverse effects have been associated with ingestion of riboflavin appreciably above RDA concentrations.

Laboratory Assessment of Status[11]

Riboflavin status is assessed by (1) determination of urine riboflavin excretion, (2) a functional assay using the activation coefficient of stimulation of the enzyme glutathione reductase by FAD, or (3) direct measurement of riboflavin or its metabolites in plasma or erythrocytes.

Urinary riboflavin is measured by fluorometric and microbiological procedures, but for specificity, HPLC combined with fluorometric detection is the method of choice. Under conditions of adequate intake, the amount excreted per day is more than 120 μg or 80 μg/g creatinine. Conditions that cause negative nitrogen balance and administration of antibiotics and certain psychotropic drugs (phenothiazine derivatives) increase urinary riboflavin as a consequence of tissue depletion and displacement.

A commonly used functional method for assessing riboflavin status consists of determining erythrocyte glutathione reductase activity and the increase in activity on incubation with exogenous FAD. Most methods measure the rate of change of absorbance at 340 nm caused by oxidation of NADPH and have been automated to produce rapid throughputs and CVs of less than 2% within run, although some have used fluorescence detection. In long-standing riboflavin deficiency, apoenzyme activity may be reduced, leading to a misleading activation coefficient calculation.

The most widely used methods in current clinical practice include direct measurements of riboflavin, FMN, and FAD in plasma or erythrocytes by (1) HPLC, usually with fluorescence detection after protein precipitation or by (2) capillary zone electrophoresis with laser-induced fluorescence detection.

Reference Intervals

The reference intervals when a fluorometric method is used for erythrocyte riboflavin are 10 to 50 μg/dL (266 to 1330 nmol/L), and for plasma concentrations of riboflavin, 4 to 24 μg/dL (106 to 638 nmol/L). Guidance reference intervals for the activation coefficient of erythrocyte glutathione reductase by FAD are 1.20 (adequacy), 1.21 to 1.40 (marginal deficiency), and 1.41 and above (deficiency).

Vitamin B_6—Pyridoxine, Pyridoxamine, and Pyridoxal

Pyridoxine (pyridoxol), pyridoxamine, and pyridoxal are the three natural forms of vitamin B_6. They are converted to pyridoxal phosphate, which is required for synthesis, catabolism, and interconversion of amino acids.

Chemistry

The three natural forms—(1) pyridoxine (pyridoxol) (PN), (2) pyridoxamine (PM), and (3) pyridoxal (PL)—are 4-substituted 2-methyl-3-hydroxyl-5-hydroxymethyl pyridines (Figure 27-10). During metabolic conversion, each vitamer becomes phosphorylated at the 5-hydroxymethyl position. Although both pyridoxamine-5′-phosphate (PMP) and pyridoxal-5′-phosphate (PLP, P-5′-P) interconvert as coenzyme forms during aminotransferase (transaminase)-catalyzed reactions, PLP is the coenzyme form that participates in the largest number of B_6-dependent enzyme reactions.

Dietary Sources

Vitamin B_6 is widely distributed in animal and plant tissue, where phosphorylated forms, particularly PLP, predominate. Meat, poultry, and fish are good sources, as are yeast, certain seeds, bran, and bananas. Fortified ready-to-eat cereals have become an important dietary source. The common commercial form of the vitamin is pyridoxine hydrochloride, which is a water-soluble, white, crystalline solid.

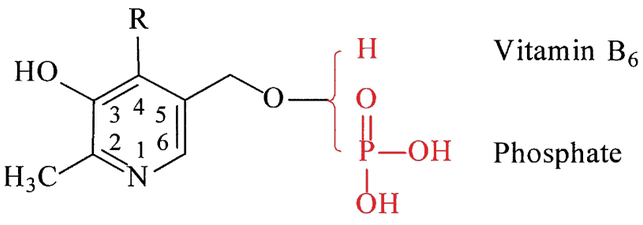

Figure 27-10 Free and phosphorylated forms of vitamin B_6. R = CH_2OH for pyridoxine, CH_2NH_2 for pyridoxamine, and CHO for pyridoxal.

Absorption, Transport, Metabolism, and Excretion

Food sources of animal origin contain mainly PLP with some PMP, whereas plant sources also contain pyridoxine-5′-glucoside, which is absorbed in a different manner. The phosphorylated sources are hydrolyzed by the intraluminal action of intestinal alkaline phosphatase, but pyridoxine-5′-glucoside is less effectively hydrolyzed by nonspecific glycosidase within cells. The nonphosphorylated vitamers are readily absorbed by the mucosal cells through a process of passive diffusion. Here, as in other cells requiring vitamin B_6, the unphosphorylated vitamers may be "metabolically trapped" as the phosphorylated forms by cytoplasmic pyridoxal kinase responsible for catalyzing the ATP-dependent phosphorylation of all three vitamin forms. The vitamers are unphosphorylated before transport to the liver via the portal vein.

Figure 27-11 shows the intracellular metabolism of vitamin B_6. Most cells contain a cytosolic FMN-dependent pyridoxine (pyridoxamine)-5′-phosphate oxidase responsible for catalyzing the oxygen-dependent conversion of pyridoxine phosphate and pyridoxamine phosphate to PLP (and hydrogen peroxide). PLP enters directly into subcellular organelles, such as hepatocyte mitochondria, and binds for catalytic function with numerous specific apoenzymes throughout the cell. The erythrocyte, in addition, traps PLP as a conjugate Schiff base with hemoglobin. Vitamin B_6 in muscle accounts for 80% of body stores, mostly as PLP bound to glycogen phosphorylase. Total body stores of vitamin B_6 are thought to be about 1 mmol.

Release of free vitamin, mainly pyridoxal, occurs when physiological, nonsaturating concentrations of vitamin are absorbed. The phosphates are then hydrolyzed by nonspecific alkaline phosphatase located on the plasma membrane of cells. Some PLP is released into the circulation by the liver. Although PLP is the principal tissue form of vitamin B_6 and pyridoxal constitutes much of the circulating vitamin, the main catabolite excreted in urine is 4-pyridoxic acid (4-PA).

Functions

As coenzyme PLP, vitamin B_6 functions in more than 100 reactions involved in the metabolism of macronutrients. Especially diverse are PLP-dependent enzymes that are involved in amino acid metabolism, which link amino acid metabolism with ketogenic and glucogenic reactions. Other examples of

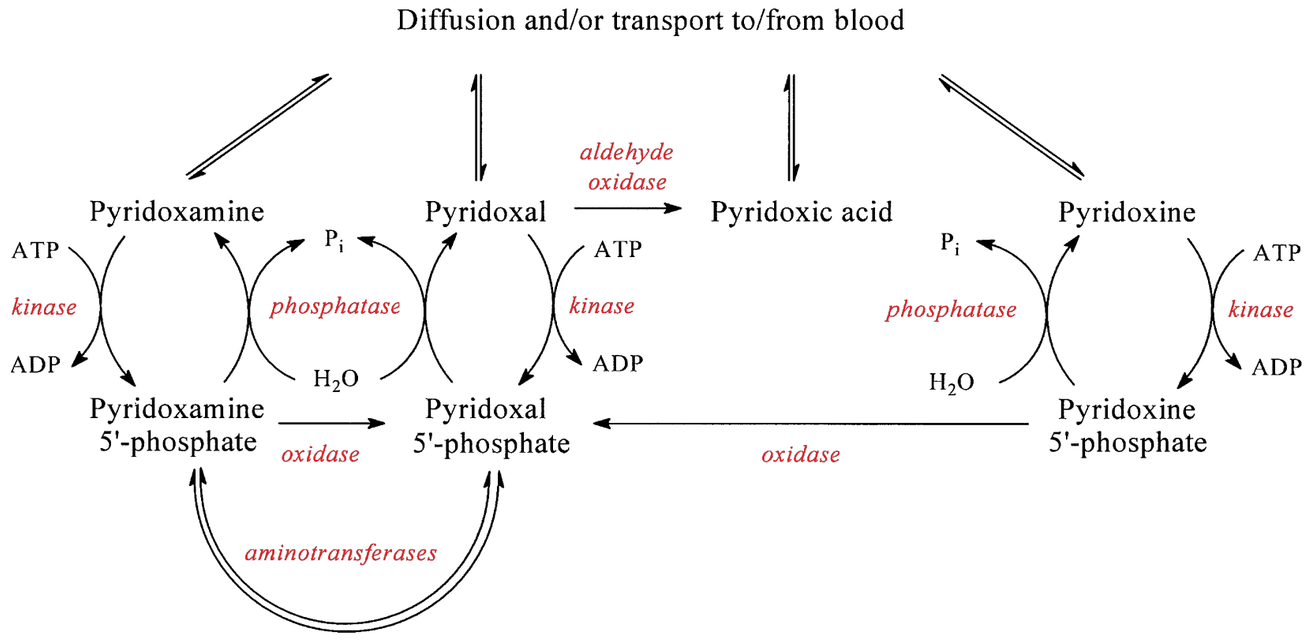

Figure 27-11 Metabolism of vitamin B_6.

PLP-requiring enzymes are (1) the amino acid decarboxylases that lead to formation of amines (e.g., epinephrine, norepinephrine, serotonin, γ-aminobutyrate); (2) cysteine desulfhydrase and serine hydroxymethyltransferase, which use PLP to effect the loss or transfer of amino acid sidechains; (3) phosphorylase, which catalyzes phosphorolysis of the α-1,4-linkages of glycogen; and (4) cystathionine beta-synthase, which is involved in the transsulfuration pathway of homocysteine. Additionally, the biosynthesis of heme depends on the early formation of 5-aminolevulinate from PLP-dependent condensation of glycine and succinyl-CoA, followed by decarboxylation, and an important role in lipid metabolism is the PLP-dependent condensation of l-serine with palmitoyl-CoA to form 3-dehydrosphinganine—a precursor of sphingomyelins.

Requirements and Reference Nutrient Intakes[2]

Requirements for vitamin B_6 are largely dependent upon protein intake. A ratio of 0.016 mg of vitamin B_6/g of protein intake has been suggested for normal adults and may be extrapolated to children and adolescents. Proposed RDAs are 1.3 mg/d for men to age 50 years and 1.7 mg/d for men over 50 years, 1.3 mg/d for women 19 to 50 years and 1.5 mg/d for women over 50 years. Additions of 0.6 and 0.5 mg B_6 per day are suggested in pregnancy and lactation, respectively.

Deficiency

Deficiency of vitamin B_6 alone is uncommon and is more usual in association with deficits in other vitamins of the B-complex. As with other water-soluble vitamins that function as coenzymes, progressive symptoms of deficiency of the vitamin are dependent upon the relative affinity of the coenzyme for a given apoenzyme and the extent to which the **holoenzyme**-catalyzed reaction is essential. Some drug interactions lead to **hypovitaminosis** (**avitaminosis**) of B_6. These involve the antituberculosis drug isoniazid (isonicotinic acid hydrazide), which forms hydrazones with pyridoxal and PLP; penicillamine; and the antiparkinsonian drugs benserazide, carbidopa, and theophylline.

Vitamin B_6–responsive inborn errors of metabolism include (1) infantile convulsions, in which the apoenzyme for glutamate decarboxylase has poor affinity for the coenzyme; (2) xanthurenic aciduria, in which affinity of the mutant kynureninase for PLP is decreased; and (3) homocystinuria, which is caused by a similarly defective cystathionine β-synthase . In these cases, increased amounts (200 to 1000 mg/d) of administered vitamin B_6 are required for life. Low vitamin B_6 status (together with low vitamin B_{12} and folate status) in humans has been linked to hyperhomocysteinemia, which is an independent risk factor for cardiovascular disease.

Clinically, electroencephalographic abnormalities appear within 3 weeks and epileptiform convulsions are a common finding in young vitamin B_6–deficient individuals. In addition, skin changes, including dermatitis with cheilosis and glossitis, may occur. Hematological manifestations include a decrease in the number of circulating lymphocytes and possibly a normocytic, microcytic, or sideroblastic anemia.

Toxicity

Although no adverse effects have been observed with high intake of vitamin B_6 from food sources, high oral supplemental doses have been observed to produce neurotoxic and photosensitive effects. Based on the end point of development of sensory neuropathy, current U.S. recommendations have set a tolerable upper intake concentration of 100 mg/d for adults.

Laboratory Assessment of Status[11]

As with other B vitamins that act as coenzymes, biochemical assessment of vitamin B_6 is accomplished by direct chemical analysis of the vitamer or its metabolites or by completion of functional tests. For example, analytical techniques are used to measure (1) PLP in plasma or red cells, (2) its metabolite 4-PA in urine or plasma, (3) the activity and activation coefficient of the red cell aminotransferases (aspartate and alanine), and (4) the tryptophan load metabolite excretion test. As no single analyte adequately reflects status, a combination of these markers is often used.

Plasma PLP and plasma or urine 4-PA are most commonly measured by HPLC. PLP is measured by HPLC with fluorescence detection following precolumn fluorophore formation as a semicarbazone or as a pyridoxic acid phosphate. The natural fluorescence of 4-PA is measured. A homogeneous, nonradioactive recombinant enzymatic method for PLP has been

described that uses 5 μL of plasma and has a lower limit of detection of 5 nmol/L.

Functional assessment of vitamin B_6 status is achieved by measuring the activity of red cell aspartate (or alanine) aminotransferase and its activation coefficient on incubation with PLP. T ese tests are less robust than those for vitamins B_1 and B_2 and are considered less useful. Measurement of urinary tryptophan metabolites, particularly xanthurenic acid, after an oral load (2 to 5 g) of l-tryptophan, is used in studies of vitamin B_6 **nutriture** because changes are recognized early and measurements are relatively easy to obtain.

Reference Intervals

A guidance reference interval for plasma PLP is 5 to 30 ng/mL (20 to 121 nmol/L). Plasma concentrations less than 5 ng/mL (20 nmol/L) are judged deficient. Activation coefficients less than about 1.5 for aspartate aminotransferase and 1.2 for alanine aminotransferase are considered normal but may depend somewhat on the assay method used.

Vitamin B_{12}—Cyanocobalamin

Vitamin B_{12} is also known as cyanocobalamin. It is a water-soluble hematopoietic vitamin that is required for the maturation of erythrocytes.

Chemistry

Vitamin B_{12} is a generic term that refers to a group of physiologically active substances chemically classified as cobalamins or corrinoids. T ey are composed of tetrapyrrole rings surrounding central cobalt atoms and nucleotide sidechains attached to the cobalt. T e cobalamin tetrapyrrole ring, exclusive of cobalt and other sidechains, is called a corrin. All compounds that contain this corrin nucleus are corrinoids. T e cobalt-corrin complex is termed cobamide (Figure 27-12).

Cobalamins differ in the nature of additional side groups bound to cobalt. Examples include (1) methyl (methylcobalamin), (2) 5′-deoxyadenosine ([deoxyadenosyl or adenosyl] cobalamin), (3) hydroxyl (hydroxocobalamin), (4) H_2O (aquocobalamin), and (4) cyanide (cyanocobalamin). Cyanocobalamin is a stable compound that forms dark red, needle-like crystals. It is the reference compound used to calibrate serum cobalamin methods. T e predominant physiological form of cobalamin in serum is methylcobalamin, whereas that in cytosols is adenosylcobalamin. Cyanocobalamin has a molecular weight of 1355 Da and is gradually destroyed on exposure to light.

Dietary Sources

All vitamin B_{12} is ultimately the product of microbial synthesis, and because plants do not use this vitamin, the main dietary sources are (1) meat and meat products, (2) dairy products, (3) fish and shellfish, and (4) fortified ready-to-eat cereals.

Absorption, Transport, Metabolism, and Excretion

Uptake of vitamin B_{12} from the intestine into the circulation is a complex mechanism, involving five separate vitamin B_{12}–binding molecules, receptors, and transporters. Vitamin B_{12} released from food in the stomach is bound to haptocorrin (R protein, a salivary protein) and travels with it into the intestine, where haptocorrin is digested by pancreatic enzymes. T e liberated vitamin B_{12} then binds to intrinsic factor (IF), a glycoprotein with a molecular weight of approximately 50 kDa, which is produced by the gastric mucosa. When the vitamin B_{12}/IF complex reaches the distal ileum, it is bound by receptors on the surface of mucosal epithelial cells and then enters the cells. Within the mucosal epithelial cells, the vitamin B_{12}/IF complex is dissociated, and the vitamin B_{12} then binds with transcobalamin II (TcII). T is complex is transported across the cell membrane bound to a TcII receptor and then is released into the plasma of the mucosal capillaries and subsequently into the blood in the portal vein. Almost all of the vitamin B_{12} is taken up by hepatocytes as the blood in the portal vein passes through the liver. It is stored in the liver and is released to plasma to meet physiological demands. If the quantity of vitamin B_{12} exceeds the capacity of hepatocyte receptors, most of the excess is excreted by the kidneys. Normally, approximately 1 mg of vitamin B_{12} is stored in the liver—a quantity equivalent to the daily metabolic requirement for 2000 days. T us, when the dietary supply of vitamin B_{12} is interrupted or mechanisms of absorption are impaired, vitamin B_{12} deficiency does not become evident for 5 years or longer.

Vitamin B_{12} is continually secreted in the bile, but most is reabsorbed and available for metabolic functions. If circulating vitamin B_{12} concentrations exceed the binding capacity of the blood, the excess will be excreted in the urine. In most circumstances, however, the greatest losses of vitamin B_{12} occur through the feces.

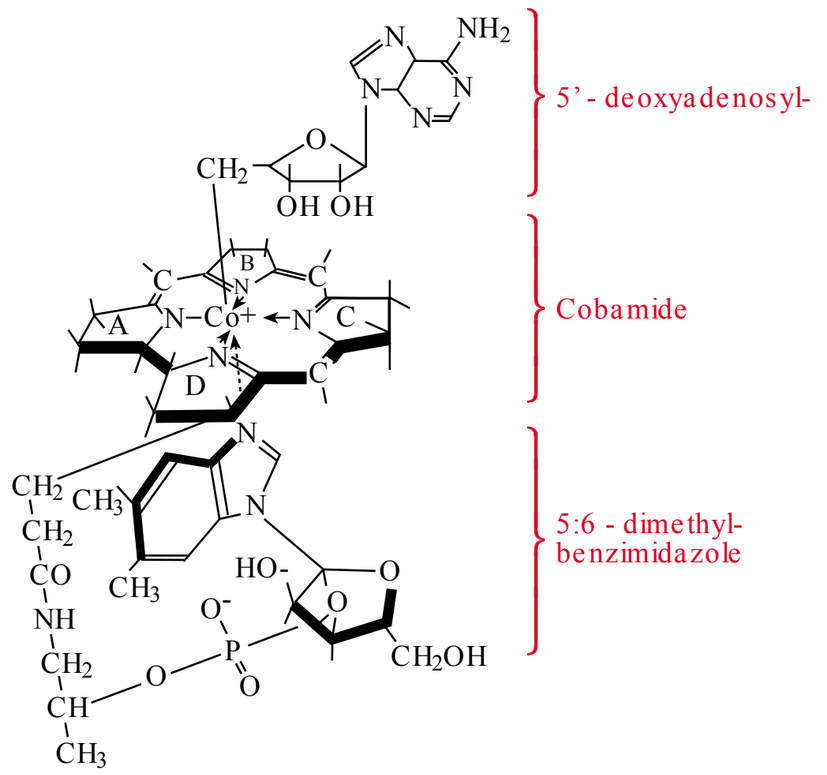

Figure 27-12 The structure of 5′-deoxyadenosyl cobalamin. (Modifed from Chanarin I: The megaloblastic anemias, 2nd edition. Oxford: Blackwell Scientifc, 1979.)

Functions

Vitamin B_{12} is required in coenzyme form for more than 12 different enzyme systems. In humans it is required for the conversion of (1) l-methylmalonyl CoA to succinyl-CoA and (2) homocysteine to methionine. Congenital defects of mutase

synthesis or inability to synthesize adenosyl-cobalamin (adenosyl-Cbl) results in life-threatening methylmalonic aciduria and metabolic ketoacidosis. Congenital defects in methionine synthase or the synthesis of methyl-Cbl results in severe hyperhomocysteinemia.

Requirements and Reference Nutrient Intakes[2]

Total body stores of vitamin B_{12} are estimated to be between 2 and 5 mg in the adult man, of which about 1 mg is found in the liver and a smaller amount in the kidney. A daily obligatory loss of vitamin B_{12} of about 0.1% of body pool, irrespective of size, has been observed,[12] suggesting that the daily requirement to maintain stores would vary from 2 to 5 μg. The daily diet of individuals in Western countries contains between 5 and 30 μg of vitamin B_{12}, with average ingestion of 7 to 8 μg/d by adult men and 4 to 5 μg/d by adult women. Additional small amounts may be available through synthesis of vitamin B_{12} by intestinal microorganisms. Of the amount ingested, between 1 and 5 μg is absorbed.

The RDA for vitamin B_{12} is based on the amount necessary for maintenance of hematological status and normal serum vitamin B_{12} concentrations, and assumes 50% absorbance of ingested vitamin B_{12}. The RDA for adults (19 to 50 years) has been set at 2.4 μg/d, with an increase to 2.6 μg/d during pregnancy and to 2.8 μg/d in lactation.

Deficiency

Deficiency of vitamin B_{12} in humans is associated with megaloblastic anemia and neuropathy. The most common cause of vitamin B_{12} deficiency is **pernicious anemia**, an autoimmune disease in which chronic atrophic gastritis results from antibodies to gastric parietal cells and IF, directed against gastric parietal cell H^+/K^+-ATPase. Pernicious anemia may also occur in children as the result of failure of IF secretion or secretion of biologically inactive IF. Other groups at risk of vitamin B_{12} deficiency include those (1) older than 65 years of age; (2) with malabsorption; (3) who are vegetarians; (4) with autoimmune disorders; or (5) taking prescribed medication known to interfere with vitamin absorption or metabolism, including (1) nitrous oxide, (2) phenytoin, (3) dihydrofolate reductase inhibitors, (4) metformin, (5) proton pump inhibitors, and (6) infants with suspected metabolic disorders.

Intestinal malabsorption of vitamin B_{12} may be caused by gastrectomy or ileal resection, with an inverse relationship between the length of ileum resected and the absorption of vitamin B_{12}. Other causes of malabsorption are (1) tropical sprue, (2) inflammatory disease of the small intestine, (3) intestinal stasis with overgrowth of colonic bacteria, which consume the vitamin B_{12} ingested by the host, and (4) human immunodeficiency virus (HIV) infection. Vegetarians have a lower intake of vitamin B_{12} than omnivores, and although clinical signs of deficiency are uncommon, biochemical markers of status may indicate functional vitamin B_{12} deficiency. A large number of disorders are associated with cobalamin deficiency in infancy or childhood. Of these, the most commonly encountered is the Imerslund-Gräsbeck syndrome, a condition characterized by inability to absorb vitamin B_{12}, with or without IF, and proteinuria. It appears to be due to an inability of intestinal mucosa to absorb the vitamin B_{12}/IF complex. The second most common of these is congenital deficiency of gastric secretion of IF.

The hematological effects of vitamin B_{12} deficiency are indistinguishable from those of folate deficiency. The classic morphological changes in the blood, in approximate order of appearance, are (1) hypersegmentation of neutrophils, (2) macrocytosis, (3) anemia, (4) leukopenia, and (5) thrombocytopenia, with megaloblastic changes in bone marrow accompanying peripheral blood changes. All bone marrow lesions are reversed with vitamin B_{12} therapy.

In addition to hematological changes, vitamin B_{12} deficiency has been known to result in a demyelinating disorder of the central nervous system. This disorder has been known to lead to other serious and often irreversible neurological conditions, such as (1) burning pain or loss of sensation in the extremities, (2) weakness, (3) spasticity and paralysis, (4) confusion, (5) disorientation, and (6) dementia. This disorder has been given the name subacute combined degeneration of the spinal cord.

Toxicity

No adverse effects have been associated with excess vitamin B_{12} intake from food or supplements in healthy people.

Laboratory Assessment of Status[11]

Both direct and indirect functional tests are available for assessing vitamin B_{12} status. Indirect tests include (1) assays for urinary and serum concentrations of methylmalonic acid (2) assays for plasma homocysteine, (3) the deoxyuridine suppression test, and (4) the vitamin B_{12} absorption test.

Microbiological competitive protein binding (CPB) and immunoassays have been used for direct quantification of serum vitamin B_{12}. The microbiological assays have been largely replaced by other, more convenient and accurate methods, although they remain reference methods for determination of biologically active vitamin B_{12}. Commercial kits are available for the CPB assays of vitamin B_{12}. In a widely used CPB assay, vitamin B_{12} (cobalamin) competes with ^{57}Co-labeled cobalamin for a limited number of binding sites on IF.

Most immunoassay methods use solid-phase separation by immobilizing the IF binder on beads or magnetic particles. The free vitamin B_{12} then remains in the supernatant, and the bound analytes become part of the solid-phase suspension. For simultaneous folate/vitamin B_{12} measurement, a gamma-scintillation counter that discriminates between the energy concentrations of ^{57}Co (for vitamin B_{12}) and those of ^{125}I (for folate) is required. In addition, multiple automated and semi-automated systems are available for measuring vitamin B_{12} and folate by using, for example, chemiluminescence as a signal.

Indirect tests assess the functional adequacy of vitamin B_{12}. Serum methylmalonic acid concentration is increased when lack of adenyl-Cbl causes a block in the conversion of methylmalonyl-CoA to succinyl-CoA. Plasma total homocysteine concentration is a sensitive indicator of vitamin B_{12} status because methyl-Cbl is required for the remethylation

of homocysteine to methionine, but it is not specific because of elevations in deficiency of folate and vitamins B_6 and B_{12}. Measurement of holotranscobalamin II is potentially useful as a specific marker of biologically available vitamin B_{12} because only cobalamin bound to TcII is specifically available for uptake by all cells. Methods have been described for the measurement of holotranscobalamin in serum; one uses an immobilized monoclonal antibody to human transcobalamin, followed by measurement of released cobalamin by CPB. The method is available as a commercial kit.

The Schilling test is primarily a test of vitamin B_{12} absorption, not of status, but it permits differentiation of causes of vitamin B_{12} deficiency (e.g., pernicious anemia, intestinal malabsorption). The usual procedure is to measure radioactivity in a 24-hour urine sample, which is collected after oral administration of 0.5 μg of radioactive Co-labeled vitamin B_{12} after an overnight fast. In healthy individuals, 8% or more of the dose administered is excreted in the urine, whereas in people with pernicious anemia, less than 7% (often 0% to 3%) is excreted. A confirmatory test for lack of IF requires ingestion of vitamin B_{12} and IF.

Reference Intervals

The WHO defined a serum vitamin B_{12} concentration of less than 150 ng/L (110 pmol/L) as deficient, and one of 201 ng/L (147 pmol/L) or higher as acceptable.

Serum methylmalonic acid concentrations less than 376 nmol/L have been considered acceptable in an elderly U.S. population, as have concentrations less than 320 nmol/L in a group of older Dutch subjects.

Vitamin C—Ascorbic Acid

Vitamin C (l-ascorbic acid) serves as a reducing agent in several important hydroxylation reactions in the body.

Chemistry

The term vitamin C refers to all molecules that exhibit antiscorbutic properties in humans and includes both ascorbic acid and its oxidized form, dehydroascorbic acid (DHA) (Figure 27-13). Plants and most animals possess the ability to synthesize the vitamin from d-glucose via the lactones of d-glucuronic and l-gulonic acids. Humans and some mammals, however, lack l-gulonolactone oxidase, the enzyme that catalyzes the formation of 2-oxo-l-gulonolactone, which spontaneously tautomerizes to l-ascorbic acid. Hence daily intake for humans and some mammals is essential.

L-Ascorbic acid Dehydroascorbic acid

Figure 27-13 l-Ascorbic and dehydroascorbic acids.

Dietary Sources

Excellent sources of the vitamin are (1) citrus fruits, (2) berries, (3) melons, (4) tomatoes, (5) green peppers, (6) broccoli, (7) Brussels sprouts, and (8) leafy green vegetables.

Absorption, Transport, Metabolism, and Excretion

Gastrointestinal absorption of ascorbic acid occurs through a combination of sodium-dependent active transport at low concentrations and simple diffusion at high concentrations. The absorbed ascorbic acid moves rapidly from the intestinal cell into the blood by a process of facilitated diffusion. Ascorbate uptake by cells is mediated by sodium-dependent transporters and DHA via facilitated-diffusion glucose transporters. Vitamin C is found in most tissue, but glandular tissue, such as the (1) pituitary, (2) adrenal cortex, (3) corpus luteum, and (4) thymus, has the highest amounts. The retina has 20 to 30 times the plasma concentration. The body pool of vitamin C is approximately 2 g and the biological half-life about 16 days. Excretion of unchanged ascorbate occurs increasingly with increased dosage, with almost all of an ingested dose greater than 500 mg excreted over 24 hours. DHA that is not recycled may be irreversibly delactonized to 2,3-diketogulonic acid and further degraded to oxalic acid for urine excretion.

Functions

Ascorbic acid acts as a cofactor for a number of mixed function oxidases in processes in which it promotes enzyme activity by maintaining metal ions in their reduced form (particularly iron and copper). These include three different hydroxylating enzymes that take part in the intracellular biosynthesis steps of collagenous proteins. Each has different substrate specificities and two or more isoenzymes (e.g., prolyl 4-hydroxylase [EC 1.14.11.2], has at least 2 isoenzymes; prolyl 3-hydroxylase [EC 1.14.11.7], has at least 2 isoenzymes; and lysyl hydroxylase [EC 1.14.11.4], has at least 3 isoenzymes).[10] Functionally, prolyl 4-hydroxylase is regarded as the most important, as it produces 4-hydroxyproline, the content of which must be above a certain threshold value if the collagen is to be kept in its triple-helical conformation at body temperature. Other processes in which ascorbic acid is involved include (1) carnitine biosynthesis, where it serves as a cofactor to 6-N-trimethyl-lysine hydroxylase and butyrobetaine hydroxylase; (2) degradation of tyrosine via 4-OH phenylpyruvate dioxygenase; (3) synthesis of adrenal hormones via dopamine β-hydroxylase; (4) biosynthesis of corticosteroids and aldosterone; (5) hydroxylation of cholesterol in the formation of bile acids; (6) and folate metabolism and leukocyte functions.

Ascorbic acid, one of the most effective water-soluble antioxidants in biological fluids, scavenges physiologically important reactive oxygen species and reactive nitrogen species. The ascorbyl radical is relatively stable because of resonance stabilization of the unpaired electron. Ascorbate will regenerate other small molecule antioxidants, including (1) α-tocopherol, (2) reduced glutathione, (3) urate, and (4) β-carotene, from their respective radical species, and thus may prevent oxidative damage to biological macromolecules, including DNA, lipids, and proteins.

Requirements and Reference Nutrient Intakes[4]

The amount of vitamin C sufficient to alleviate and cure the clinical signs of **scurvy** is only 10 mg/d, which is probably near the minimum requirement in humans. This amount, however, is not adequate to maintain near saturation of tissue in the adult human male or to maintain an optimal nutritional state. Current recommendations of the U.S. Institute of Medicine include an RDA for adult males of 90 mg/d and 75 mg/d for females, with increases for pregnancy and lactation. Some special groups, such as smokers, should take an additional 35 mg/d.

Deficiency

Protracted deficiency of vitamin C leads to the classic disease of scurvy, which still occurs in many countries. Those most at risk of the disease include (1) elderly men, particularly those who live alone, (2) those with alcohol dependence, (3) smokers, (4) those who have unbalanced diets, (5) some mentally ill patients, (6) renal failure patients undergoing peritoneal dialysis or hemodialysis, and (7) some patients with cancer. Lack of vitamin C leads to an inability to form adequate intercellular substance in connective tissue and is reflected in swollen, tender, often bleeding or bruised loci at joints and in other areas where structurally weakened tissue does not withstand stress. Some scorbutic patients may (1) develop anemia, (2) display radiological changes characteristic of osteoporosis, or (3) die suddenly from heart failure. Conditions of vitamin C deficiency that might reflect its role as an antioxidant include (1) increased risk of coronary heart disease, as demonstrated in a cohort of Finnish men, and (2) increased risk of death by stroke in a cohort of elderly British people.

Toxicity

Vitamin C is generally well tolerated by healthy subjects, and ingestion of supplements of 2 to 4 g/d—as taken by some for prevention or amelioration of the common cold—is usually without hazard, although gastrointestinal irritation has been experienced. Other potential but rare adverse effects include (1) increased oxalate excretion and kidney stone formation, (2) increased uric acid excretion, (3) excess iron absorption, (4) lowered vitamin B_{12} concentrations, (5) systemic conditioning, and (6) "rebound" scurvy. Ingestion of amounts of vitamin C greater than 200 mg/d shows little increase in plasma steady-state concentrations, which suggests that overload of vitamin C is unlikely. The tolerable upper limit for vitamin C in adults has been set at 2 g/d.

Laboratory Assessment of Status[11]

At present no useful functional tests of vitamin C adequacy are available, thus laboratory assessment of status is made by direct measurement of (1) plasma, (2) urine, or (3) tissue concentrations of ascorbic acid, total vitamin C, or (rarely) metabolite. Plasma ascorbate concentration is considered to be a reliable indicator of ascorbate intake and has been measured photometrically by oxidation with 2,4-dinitrophenylhydrazine to form the red bis-hydrazone, or with 2,4-dichlorophenol-indophenol, which is reduced to a colorless form. A more specific approach is to use the enzyme ascorbate oxidase to convert ascorbate to dehydroascorbate, which is then coupled with o-phenylene diamine to form a product that is measured by fluorimetry or by photometry. HPLC methods are more specific but more time-consuming. Detection may occur by precolumn derivatization to the fluorescent quinoxaline, or by electrochemical or coulometric means. Leukocyte ascorbic acid is considered to be a better indicator of body stores than plasma ascorbate, but it has not been widely adopted because of technical problems. Urinary excretion and red blood cell (RBC) concentrations have not been found to be specific and useful indices of vitamin C status although measurement of urinary concentrations of ascorbic acid, especially after a load test, has been found helpful in the clinical diagnosis of scurvy.

Reference Intervals

With adequate intake of vitamin C, plasma concentrations of total vitamin (ascorbic acid plus dehydroascorbic acid) are between 0.4 and 1.5 mg/dL (23 and 85 μmol/L). A value lower than 0.2 mg/dL (11 μmol/L) is considered deficient. The guidance reference interval for vitamin C concentrations in leukocytes is 20 to 53 μg/10^8 leukocytes (1.14 to 3.01 fmol/leukocyte), with concentrations less than 10 μg/10^8 leukocytes (0.57 fmol/leukocyte) considered deficient.

Biotin

Biotin is also known as vitamin H. It is the prosthetic group for a number of carboxylation reactions.

Chemistry

Biotin is cis-tetrahydro-2-oxothieno[3,4-d]-imidazoline-4-valeric acid (Figure 27-14). The vitamin in most organisms is found mainly bound to protein. In addition, some biotin is linked noncovalently as a complex with avidin, a protein in egg white.

Dietary Sources

Good sources of biotin include (1) liver, (2) kidney, (3) pancreas, (4) eggs, (5) yeast, and (6) milk. Poor sources of the vitamin include (1) cereal grains, (2) fruits, (3) most vegetables, and (4) meat.

Absorption, Transport, Metabolism, and Excretion

Biotin in the diet is largely protein bound, and digestion by gastrointestinal enzymes produces biotinyl peptides, which may be further hydrolyzed by intestinal biotinidase to release biotin. Avidin, a protein found in raw egg whites, binds biotin tightly and prevents its absorption. The peptide biocytin

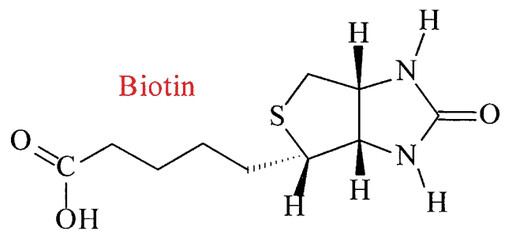

Figure 27-14 Biotin.

(ε-N-biotinyl lysine) is resistant to hydrolysis by proteolytic enzymes in the intestinal tract but together with biotin is readily absorbed. Sodium-dependent multivitamin transporter (SMVT) is a carrier for biotin for which pantothenic acid and lipoate compete. It is located in the intestinal brush border membrane and transports biotin against a sodium ion concentration gradient. The enzyme biocytinase in plasma and erythrocytes catalyzes the hydrolysis of biocytin to yield free biotin. Biotin is cleared from the circulating blood more rapidly in deficient than in normal mammals. It is taken up by such tissues as (1) liver, (2) muscle, and (3) kidney, and (4) is localized in cytosolic and mitochondrial carboxylases.

About half of absorbed biotin is excreted as the metabolites bisnorbiotin and biotin sulfoxide.

Functions

The principal biochemical function of biotin in man is to serve as a cofactor for carboxylation reactions. Five carboxylases are found in human tissue. One of these, an acetyl-CoA carboxylase, is inactive and may act as a storage vehicle for biotin. The others are carboxylases for (1) acetyl-CoA, (2) propionyl-CoA, (3) β-methylcrotonyl-CoA, and (4) pyruvate. These enzymes operate via a common mechanism, which involves phosphorylation of bicarbonate by ATP to form carbonyl phosphate. This is followed by transfer of the carboxyl group to the sterically less hindered nitrogen of the biotin moiety. The resulting N(1)-carboxybiotinyl enzyme then exchanges the carboxylate function with a reactive center in a substrate. With cytosolic acetyl-CoA carboxylase, the product is malonyl-CoA, which is used for fatty acid biosynthesis. In mitochondria, pyruvate carboxylase catalyzes the formation of oxaloacetate, which, together with acetyl-CoA, forms citrate. The other carboxylases are involved in the metabolism of odd-numbered fatty acids and branched chain fatty acids.

Requirements and Reference Nutrient Intakes[2]

Biotin does not have a current RDA. Intestinal microflora makes a significant contribution to the body pool of available biotin, making determination of the dietary requirement difficult. As a consequence, an adequate intake (AI) recommendation for adults 19 years and older is 30 μg/d. An additional 5 μg/d is recommended for the lactating mother.

Deficiency

Biotin deficiency is uncommon but may be seen (1) with prolonged consumption of raw egg whites, (2) in TPN without biotin supplementation, and (3) in patients with a genetic deficiency of biotinidase. Deficiencies 1 and 2 may be complicated by effects on gut flora that produce biotin. Symptoms include (1) anorexia, (2) nausea, (3) vomiting, (4) glossitis, (5) pallor, (6) depression, and (7) a dry scaly dermatitis.

Toxicity

No adverse effects of biotin in doses up to 300 times normal dietary intake have been reported among patients with biotinidase deficiency.

Laboratory Assessment of Status[11]

Traditionally, biotin has been measured in biological samples by microbiological assay, where whole blood is first digested with papain or acid hydrolysis to release free biotin, samples of which are then added to a biotin-deficient medium inoculated with a test organism, such as Lactobacillus plantarum. Other methods for unbound biotin include avidin-binding assays, for which a competitive protein-binding radioisotope assay is set up with ^{3}H-labeled biotin or a nonradioactive enzyme-linked sorbent assay using streptavidin as the binding agent. Urinary excretion of biotin and 3-hydroxyisovaleric acid appears to be a better indicator of biotin status than blood concentrations.

Reference Intervals

Typical reference interval values for whole blood biotin by a microbiological method are 0.5 to 2.20 nmol/L.

Folic Acid

Folic acid serves as a carrier of one-carbon groups in many metabolic reactions.

Chemistry

Folate and folic acid are generic terms for a family of compounds that function as coenzymes in the processing of one-carbon units. They are derived from pteroic acid (Pte), to which one or more molecules of glutamic acid are attached. Pteroic acid is composed of a pteridine ring joined to a p-aminobenzoic acid residue (Figure 27-15). When pteroic acid is conjugated with one molecule of l-glutamic acid, pteroylglutamic acid (PteGlu) is formed; this is then reduced to dihydrofolic acid (H_2PteGlu or DHF/FH_2) or to tetrahydrofolate (H_4PteGlu or THF/FH_4). Only the reduced forms are biologically active. Other folate derivatives have multiple glutamic acid residues ($H_4PteGlu_n$). Multiple forms of folic acid occur with substitutions of functional groups, such as (1) methyl, (2) formyl, (3) methylene, (4) hydroxymethyl, and (5) others at nitrogen atoms in the pteroic acid residue, usually N^5 or bridging N^5 and N. The principal form is 5-methyltetrahydrofolate.

Dietary Sources

Principal food sources of folate are (1) liver, (2) spinach, (3) other dark green leafy vegetables, (4) legumes, such as kidney and lima beans, and (5) orange juice. In countries where cereal fortification with folate is established, this is often the major source of dietary folate. Since the U.S. Food and Drug Administration (FDA) program of fortification of all enriched grain products with folic acid (140 μg per 100 g) began in 1998, study populations have shown doubling of mean plasma folate concentrations.

Absorption, Transport, Metabolism, and Excretion

Folate is absorbed from dietary sources as reduced methyl- and formyl-tetrahydropteroylpolyglutamates. The bioavailability of folate from food sources, however, is variable. The bioavailability of supplemental folic acid may be as high as 100% for supplements taken on an empty stomach compared with about 50% for food folates. Polyglutamate forms

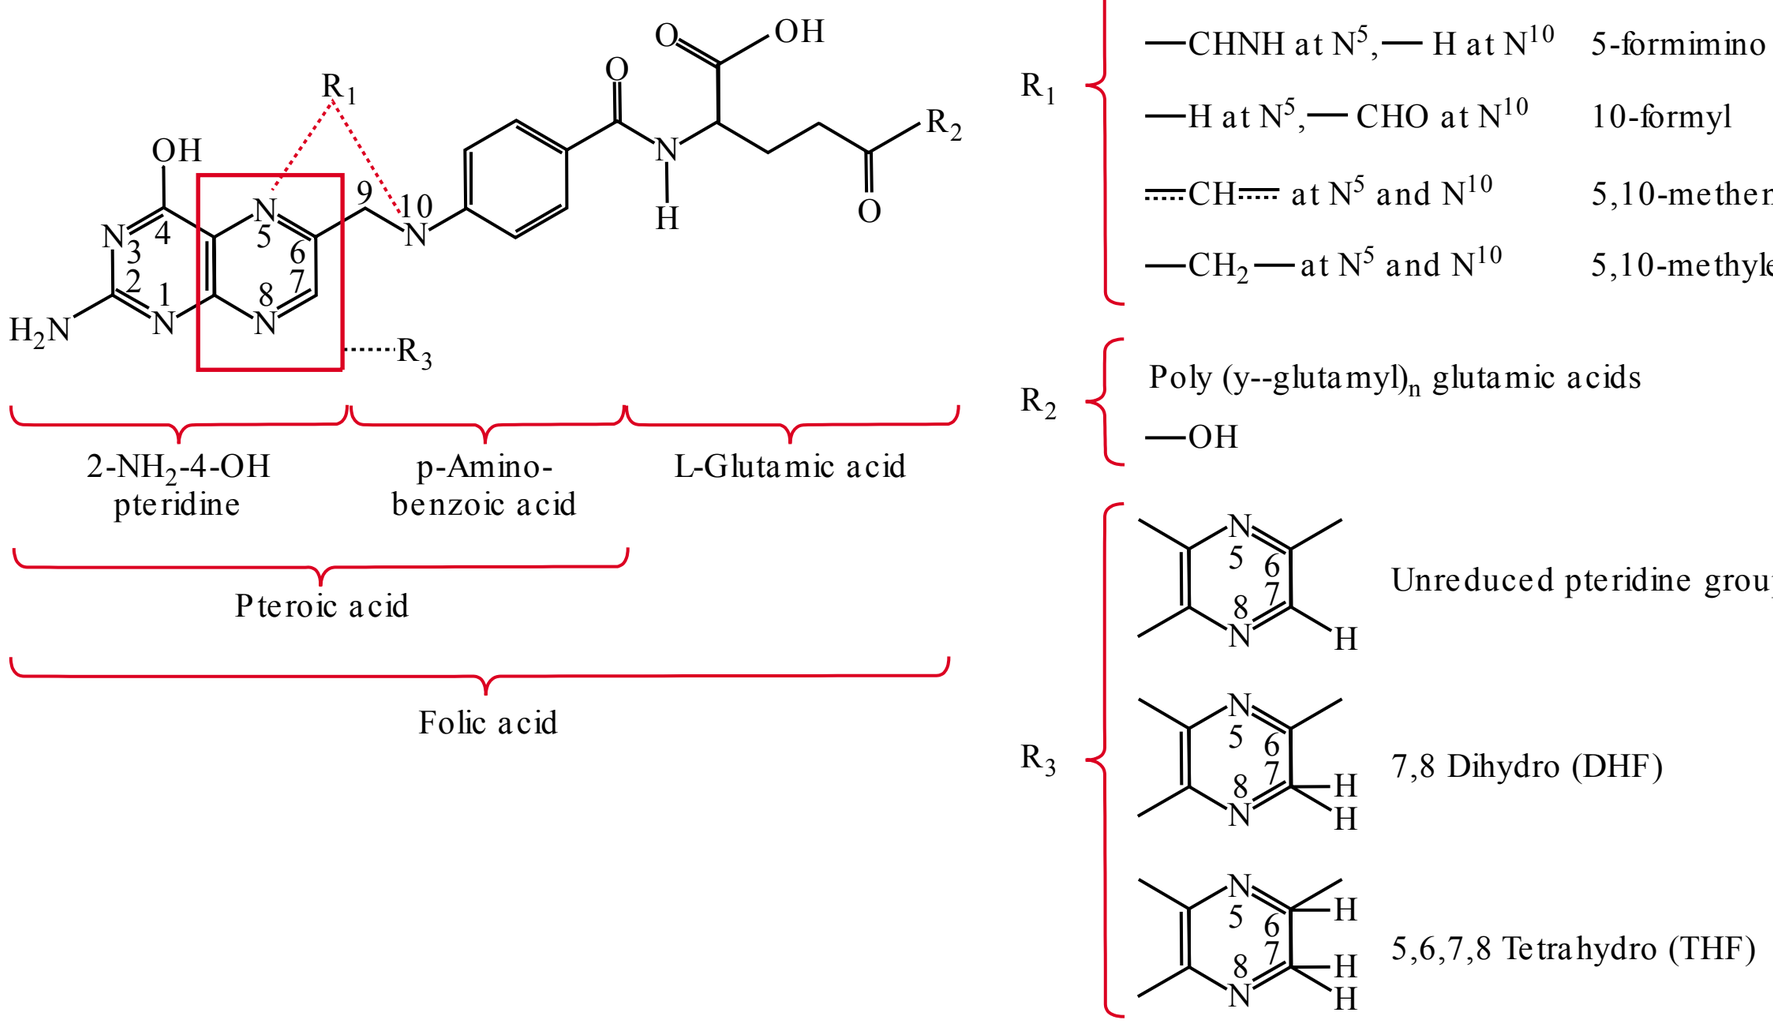

Figure 27-15 Structure of folic acid.

of folate present in food are first converted to monoglutamates by pteroylpolyglutamate hydrolase in the intestinal mucosa. Absorption of monoglutamyl folates at low concentration occurs by a saturable transport process with an additional apparently nonsaturable absorption mechanism when intestinal folate concentrations exceed 5 to 10 μmol/L. After cellular uptake, most of the folate is reduced and methylated and enters the circulation as 5-methyltetrahydrofolate (5-MTHF), circulating loosely bound to albumin or to a lesser degree to a high-affinity folate-binding protein. Uptake by (1) kidney, (2) placenta, and (3) choroid plexus cells occurs with membrane-associated folate-binding proteins that act as folate receptors. Once within the cell, 5-MTHF is demethylated and is converted to the polyglutamyl form by folylpolyglutamate synthase, which helps to retain folate within the cell. For release into the circulation, the polyglutamates are reconverted to monoglutamates by polyglutamate hydrolase.

Folic acid and vitamin B_{12} metabolism are linked by the reaction that transfers a methyl group from 5-MTHF to cobalamin. In cases of cobalamin deficiency, folate is "trapped" as 5-MTHF, is "metabolically dead," and is not recycled as tetrahydrofolate (THF).

Protein-free plasma folate is filtered at the glomerulus, and most is reabsorbed by the proximal renal tubules. Folate is predominantly excreted by catabolism after cleavage of the C9-N10 bond to produce p-aminobenzoylpolyglutamates, which then are hydrolyzed to monoglutamates and are N-acetylated before excretion. Biliary excretion of folate has been estimated at about 100 μg/d, but much of this is reabsorbed in an enterohepatic circulation.

Functions

Folate coenzymes, together with coenzymes derived from vitamins B_{12}, B_6, and B_2, are essential for one-carbon metabolism. Biochemically, a carbon unit from serine or glycine is transferred to THF to form methylene-THF, which is then (1) used in the synthesis of thymidine (and incorporation into DNA), (2) oxidized to formyl-THF for use in the synthesis of purines (precursors of RNA and DNA), or (3) reduced to methyl-THF, which is necessary for the methylation of homocysteine to methionine. Much of this methionine is converted to S-adenosylmethionine, a universal donor of methyl groups to (1) DNA, (2) RNA, (3) hormones, (4) neurotransmitters, (5) membrane lipids, and (6) proteins. Different folates are involved in these reactions, depending on the chemical state of the single-carbon fragments transferred.

Folic acid also is involved in the metabolism of homocysteine. Elevations in plasma homocysteine concentrations have been shown to be independent risk factors for coronary artery disease and probably cerebrovascular disease. T e involvement of folate in its coenzyme forms with homocysteine and methionine metabolism is summarized in Figure 27-16. Folate is the principal micronutrient determinant of homocysteine status, and supplementation with folate has been used as a treatment modality to reduce circulating homocysteine concentrations. T e extent to which this is associated with clinical benefit remains unclear.

Requirements and Reference Nutrient Intakes[2]

Total body stores of folate are estimated to be between 12 and 28 mg. Studies suggest a minimum daily requirement of between 60 and 280 μg to replace losses. In calculating

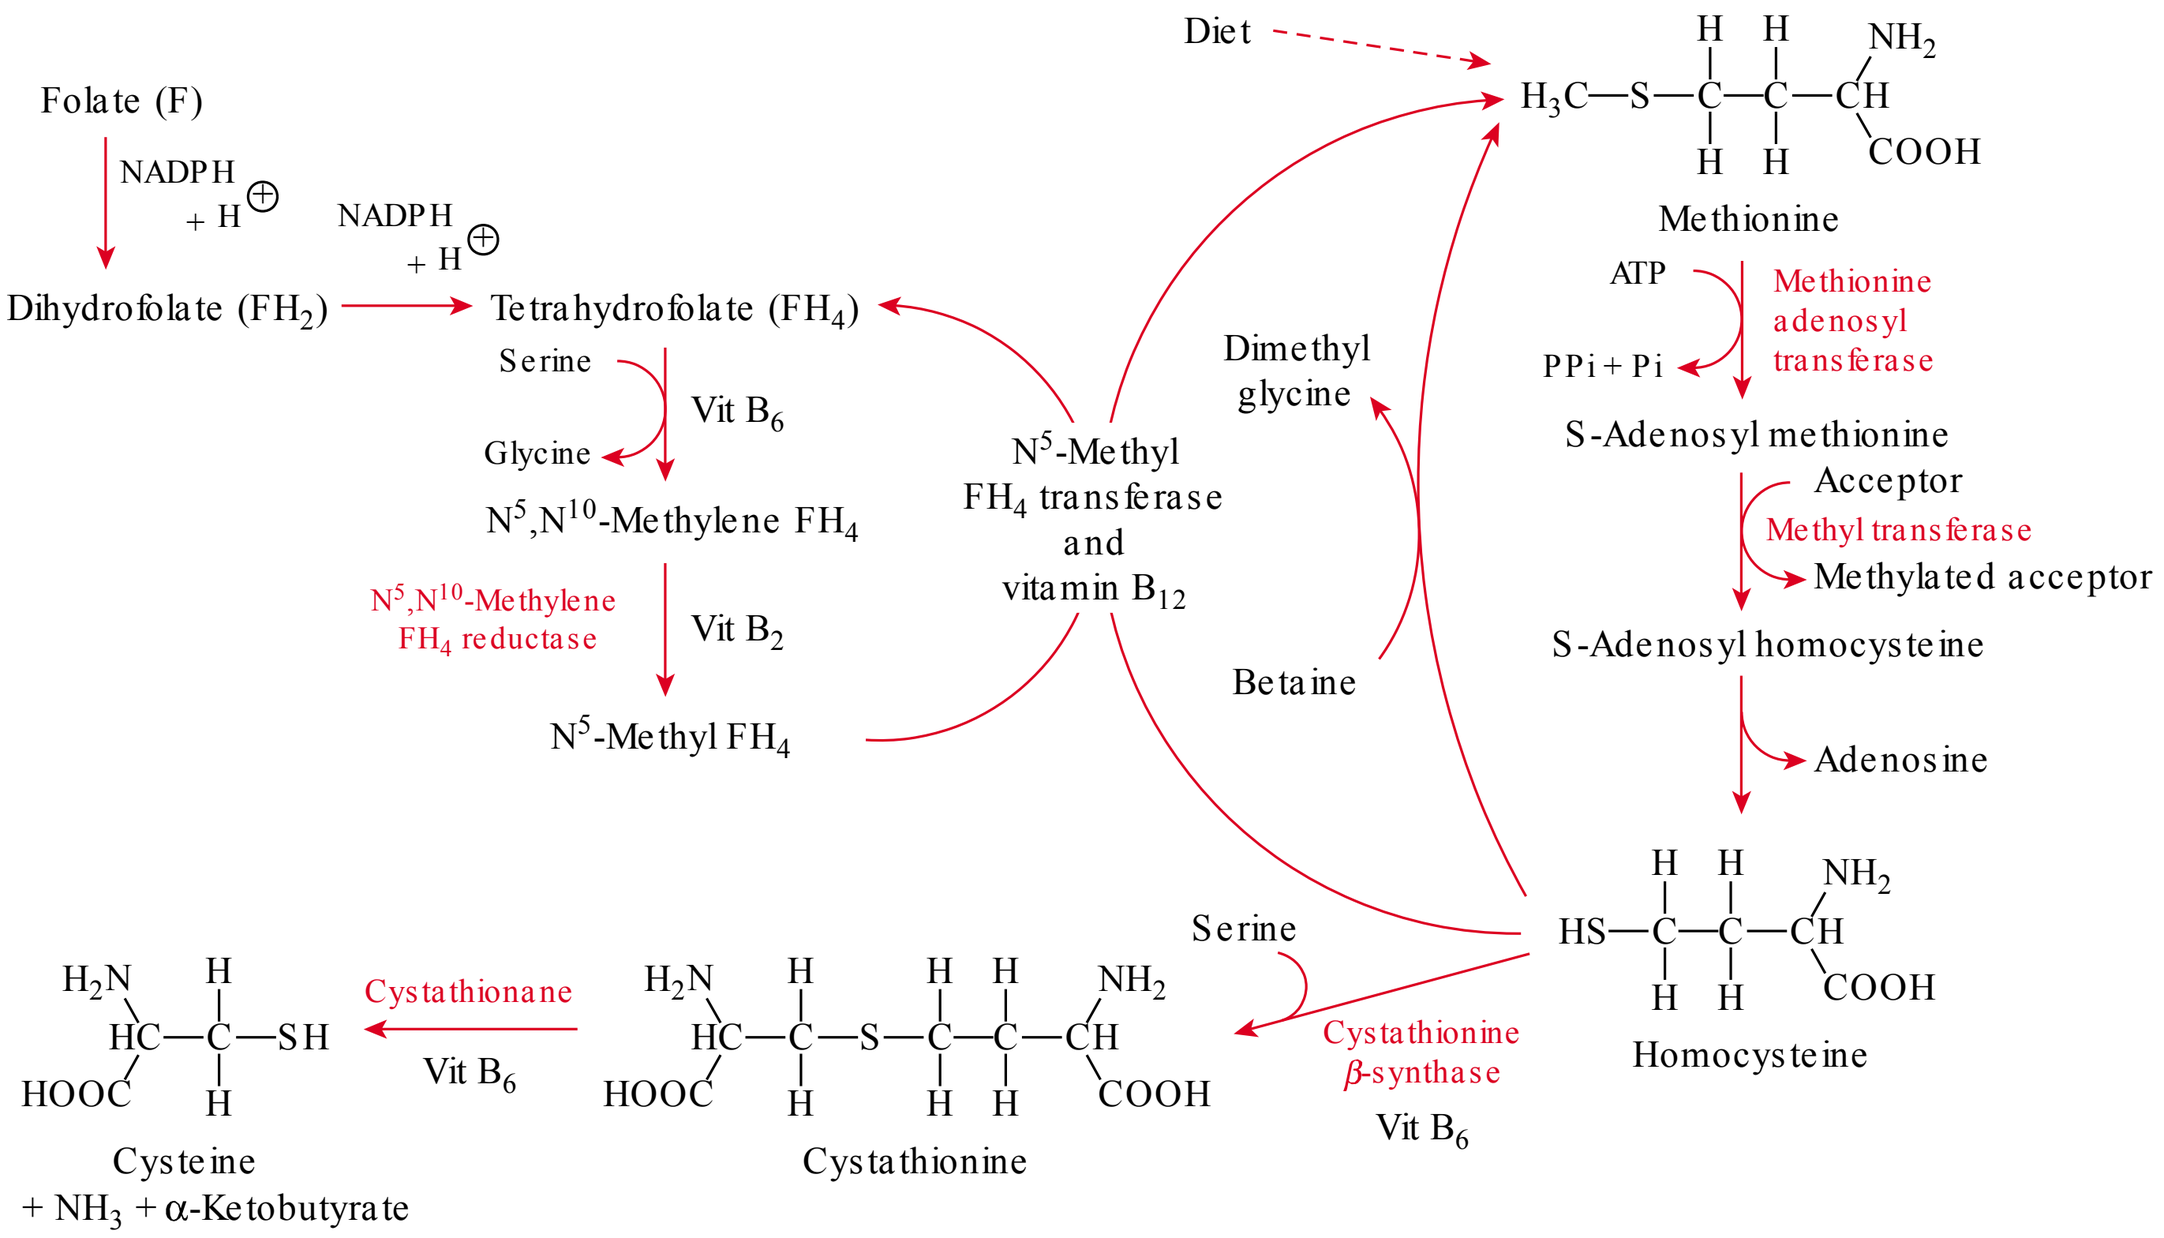

Figure 27-16 Metabolism of homocysteine and methionine.

nutritional requirements, the concept of the dietary folate equivalent (DFE) has been used to adjust for the nearly 50% lower bioavailability of food folate compared with supplemental folic acid. Current RDAs of the U.S. Institute of Medicine are 400 μg/d DFE for adults 19 years and older, 600 μg/d DFE in pregnancy, and 500 μg/d DFE for lactating women.

Deficiency

Deficiency of folate may result from (1) the absence of intestinal microorganisms (gut sterilization), (2) poor intestinal absorption (e.g., after surgical resection, in celiac disease or sprue), (3) insufficient dietary intake (including chronic alcoholism), (4) excessive demands as in pregnancy, liver disease, and malignancies, (5) administration of antifolate drugs (e.g., methotrexate), and (6) anticonvulsant therapy (leading to increased folate requirements, especially during pregnancy). **Megaloblastic anemia** (characterized by large, abnormally nucleated erythrocytes in the bone marrow) is the major clinical manifestation of folate deficiency, although sensory loss and neuropsychiatric changes may also occur.

Pregnancy brings increased demand upon folate stores caused by increased DNA synthesis and one-carbon transfer reactions, and low serum folate concentrations in pregnancy are associated with adverse outcomes. Additionally, many observational studies have confirmed a reduction in risk of neural tube defects (NTDs) with periconceptional folic acid supplementation.

Several enzyme polymorphisms affect folate metabolism. The most extensively studied of these is 5,10-methylenetetrahydrofolate reductase (MTHFR), the enzyme responsible for the irreversible reduction of 5,10-MTHF to 5-methyltetrahydrofolate (5-MTHF), the methyl donor of homocysteine to methionine. The homozygous TT variant has an incidence of around 12% in Asian and Caucasian populations and loss of enzyme activity of about 50%, whereas the heterozygous CT variant has an incidence of up to 50% in some populations. Another enzyme involved in folate metabolism, methionine synthase, has been shown to have at least two relatively prevalent polymorphisms, although these are thought to be benign. Absorption of folate from polyglutamyl folate food sources is thought to be reduced by a variant of glutamate carboxypeptidase II.

Toxicity

No adverse effects have been reported to result from the consumption of folate-fortified foods, thus any signs of toxicity are associated with supplemental folate. Most of the limited evidence suggests that excessive folate supplementation, typically in doses up to 10 mg/d, will precipitate or exacerbate neuropathy in vitamin B_{12}–deficient individuals, and it is this end point that has been used to set a tolerable upper intake concentration of 1 mg/d from fortified food or supplements for adults. One recognized complication of folate supplementation is that it "masks" vitamin B_{12} deficiency because the associated anemia responds to folate alone. This may delay treatment of the deficiency, allowing neurological abnormalities to progress.

Laboratory Assessment of Status[11]

Folate status may be reliably assessed by direct measurement of (1) serum, (2) erythrocyte, or (3) whole blood concentrations,

and its metabolic function as coenzyme may be assessed by direct measurement of metabolite concentrations, such as plasma homocysteine. Serum folate concentrations are considered indicative of recent intake, not of tissue stores, but serial measurements have been used to confirm adequate intake. Whole blood or erythrocyte folate concentrations are more indicative of tissue stores and have been shown to have a moderate correlation with liver folate concentrations.

CPB assays have largely replaced microbiological procedures for the measurement of serum, whole blood, or erythrocyte folate.

Reference Intervals

Data collected from the NHANES of 1988 to 1994 in the United States produced reference intervals of 2.6 to 12.2 μg/L (6.0 to 28.0 nmol/L) for serum folate and 103 to 411 μg/L (237 to 945 nmol/L) for erythrocyte folate; however, these data were collected before mandatory flour fortification. Biochemical deficiency has been defined as a concentration <1.4 μg/L (<3.2 nmol/L) for serum folate and <110 μg/L (<253 nmol/L) for erythrocyte folate.

Niacin and Niacinamide

Niacin and niacinamide (nicotinamide and nicotinic acid amide) are converted to the ubiquitous redox coenzymes nicotinamide-adenine dinucleotide $(NAD)^+$ and nicotinamide-adenine dinucleotide phosphate $(NADP)^+$.

Chemistry

The term niacin refers to (1) nicotinic acid (pyridine-3-carboxylic acid), (2) its amide niacinamide (nicotinamide), and (3) derivatives that show the same biological activity as nicotinamide. A distinction between the two primary vitamin forms has to be considered, however, when some aspects of their metabolism are considered, especially their different pharmacological actions at high doses. The structures of both vitamers and of the two coenzyme forms are shown in Figure 27-17.

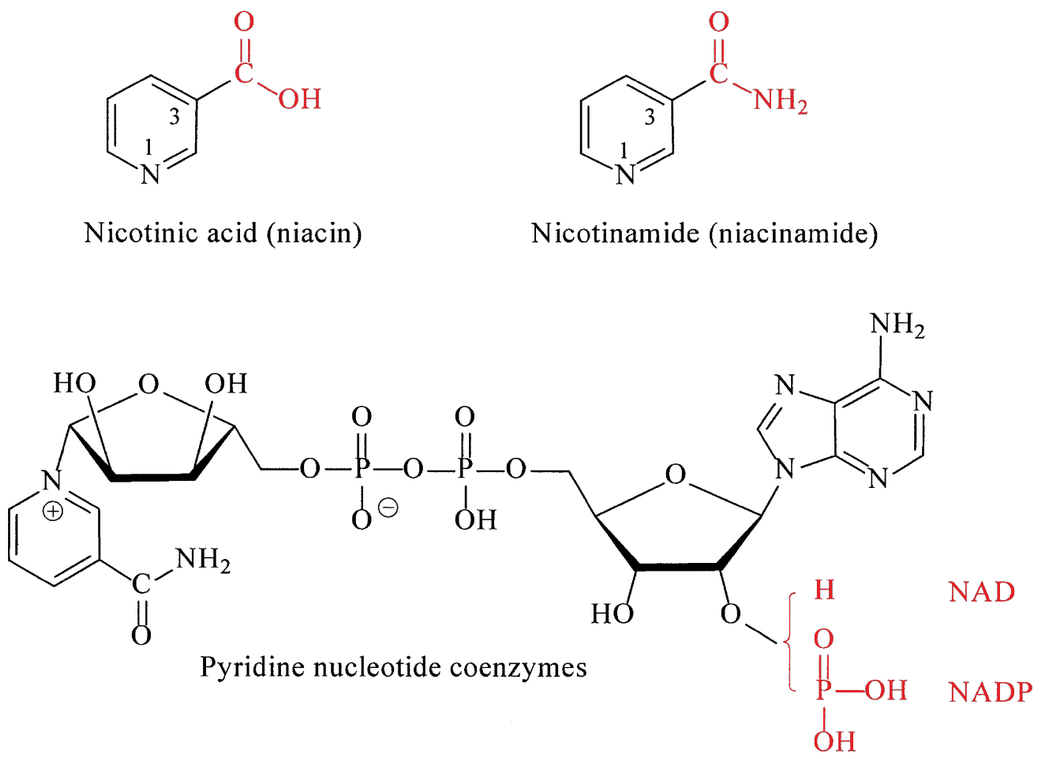

Figure 27-17 Niacin, niacinamide, and coenzyme.

Dietary Sources

Sources of niacin include (1) yeast, (2) lean meats, (3) liver, (4) poultry, (5) milk, (6) canned salmon, and (7) several leafy green vegetables. Additionally, some plant foodstuffs, especially cereals such as corn and wheat, contain niacin bound to various peptides and sugars in forms nutritionally not readily available (niacinogens or niacytin). Because tryptophan is a precursor of niacin, protein provides a considerable portion of niacin equivalent (as much as two-thirds of the niacin requirement). In countries where fortification of processed cereals is practiced, this may provide up to 20% of niacin intake.

Absorption, Transport, Metabolism, and Excretion

Dietary NAD^+ and $NADP^+$ are hydrolyzed by enzymes in the intestinal mucosa to release nicotinamide, which, together with any nicotinic acid, is rapidly absorbed in both the stomach and the intestine by Na^+-dependent facilitated diffusion at low concentrations and passive diffusion at higher concentrations. Nicotinamide is the main circulating form in the plasma after absorption or release from hydrolyzed liver NAD; it then diffuses into most tissues requiring NAD. Once inside the cells, both nicotinic acid and nicotinamide are converted to coenzyme forms. In the tissue, most of the vitamin is present as nicotinamide in NAD and NADP, although the liver may contain a significant fraction of the free vitamin. Little storage of niacin as such has been noted.

Excess niacin is excreted mainly as N-methylnicotinamide (NMN) after methylation in the liver.

Functions

Niacin is essential for the coenzymes NAD and NADP, in which nicotinamide acts as an electron acceptor or a hydrogen donor in a large number of redox reactions. Many of the enzymes function as dehydrogenases and catalyze such diverse reactions as the conversion of (1) alcohols to aldehydes or ketones, (2) hemiacetals to lactones, (3) aldehydes to acids, and (4) certain amino acids to keto acids.

Most dehydrogenases using NAD or NADP function reversibly. Glutamate dehydrogenase, for example, favors the oxidative direction, whereas others, such as glutathione reductase, preferentially catalyze reduction. Nicotinic acid, when used as a pharmaceutical agent, has important antiatherogenic properties. It effectively (1) lowers triglycerides, (2) raises HDL cholesterol, and (3) shifts LDL particles to a less atherogenic phenotype.

Requirements and Reference Nutrient Intakes[2]

Requirements for niacin are expressed as niacin equivalents (NEs), which account for the contribution of tryptophan derived from protein. The median intake of preformed niacin from food in the United States is 28 mg for men and 18 mg for women, and a study of two Canadian populations showed corresponding values of 41 mg and 28 mg/d. Additionally, the average U.S. diet supplies between 0.7 and 1.1 g of tryptophan per day. Based on niacin metabolite excretion data, current RDAs are 16 mg/d of NE for men and 14 mg/d for women. An increase of 4 NE per day during pregnancy

is recommended, and an increase of 3 NE is recommended daily for lactation.

Deficiency

Pellagra is the classic deficiency disease of the human that has been found most often among those who subsist chiefly on corn (maize), which is low in both niacin and tryptophan. Although its pathogenesis has been attributed to a deficiency of these two factors, other associated complicating factors include lack of (1) PLP, (2) FAD, and (3) iron, which are functional in the conversion of tryptophan to niacin. Pellagra is an occasional secondary manifestation of carcinoid syndrome, in which up to 60% of tryptophan is catabolized to 5-OH tryptophan and serotonin; **Hartnup disease**, an autosomal recessive disorder in which several amino acids, including tryptophan, are poorly absorbed; and treatment with the antituberculous drug isoniazid, which competes with PLP. The typical presentation of pellagra is that of a chronic wasting disease associated with (1) dermatitis, (2) dementia, and (3) diarrhea.

Toxicity

Although no toxic effects have been associated with niacin intake from naturally occurring food, the use of supplements and pharmacological doses of niacin has produced adverse effects in some individuals. In disorders of reduced tryptophan availability, such as Hartnup disease and carcinoid syndrome, daily niacin doses of 40 to 200 mg may be required, and in the treatment of dyslipidemias, up to 6 g daily may be used. Such doses are commonly associated with vascular dilation or "flushing"—a burning, tingling sensation of the face (that may be reddened), arms, and chest—and are thought to be mediated by prostaglandins. Other side effects of high-dose niacin treatment are (1) pruritus, (2) nausea, (3) vomiting, and (4) diarrhea, although these symptoms often abate with continued therapy. Symptoms of flushing have been taken as an end point sign in the formulation of a tolerable upper intake concentration for niacin, which has been set at 35 mg/d for adults.

Laboratory Assessment of Status[11]

At present, no blood markers are commonly used as indicators of niacin status. Most assessments of niacin nutriture have been based on the urinary measurement of N′-methylnicotinamide and N′-methyl-2-pyridone-5-carboxamide. Normally, adults excrete 20% to 30% of niacin in the form of methylnicotinamide and 40% to 60% as the pyridone. An excretion ratio of pyridone to methylnicotinamide of 1.3 to 4.0 is thus normal, but latent niacin deficiency is indicated by a value below 1.0. HPLC methods are currently the methods of choice, although some capillary electrophoresis methods have been developed.

Reference Intervals

A guidance reference interval for the excretion rate of N′-methylnicotinamide is 2.4 to 6.4 mg/d (17.5 to 46.7 μmol/d) or 1.6 to 4.3 mg/g creatinine (11.7 to 31.4 μmol/g creatinine).

Pantothenic Acid

Pantothenic acid is a component of coenzyme A that is required for the metabolism of fat, protein, and carbohydrate via the citric acid cycle.

Chemistry

Pantothenic acid is of ubiquitous occurrence in nature, where it is synthesized by most microorganisms and plants from pantoic acid (d-2,4-dihydroxy-3,3-dimethylbutyric acid) and β-alanine. Addition of both cysteamine at the C-terminal end and phosphorylation forms 4′-phosphopantetheine, which serves as a covalently attached prosthetic group of acyl carrier proteins and as part of CoA (Figure 27-18). The most common commercial synthetic form is the calcium salt.

Dietary Sources

Pantothenic acid is widely distributed in foods, mostly within CoA-containing compounds, and is particularly abundant in (1) animal sources, (2) legumes, (3) whole grain cereals, (4) egg yolk, (5) kidney, (6) liver, and (7) yeast.

Absorption, Transport, Metabolism, and Excretion

Pantothenic acid is taken in as dietary CoA compounds and 4′-phosphopantetheine and is hydrolyzed by pyrophosphatase and phosphatase in the intestinal lumen to (1) dephospho-CoA, (2) phosphopantetheine, and (3) pantetheine, which are further hydrolyzed to pantothenic acid. The vitamin is primarily absorbed as pantothenic acid through a saturable process at low concentrations and by simple diffusion at higher ones. The saturable process is facilitated by a sodium-dependent multivitamin transporter. After absorption, pantothenic acid enters the circulation and is taken up by cells in a manner similar to its intestinal adsorption. The synthesis of CoA from pantothenate is regulated by pantothenate kinase. Pantothenic acid is excreted in the urine after hydrolysis of CoA compounds by enzymes that cleave phosphate and the cysteamine moieties.

Functions

Pantothenic acid has two major metabolic roles (1) as part of CoA and (2) as the prosthetic group of the acyl-carrier protein (ACP). In the former role, CoA is involved primarily in acetyl

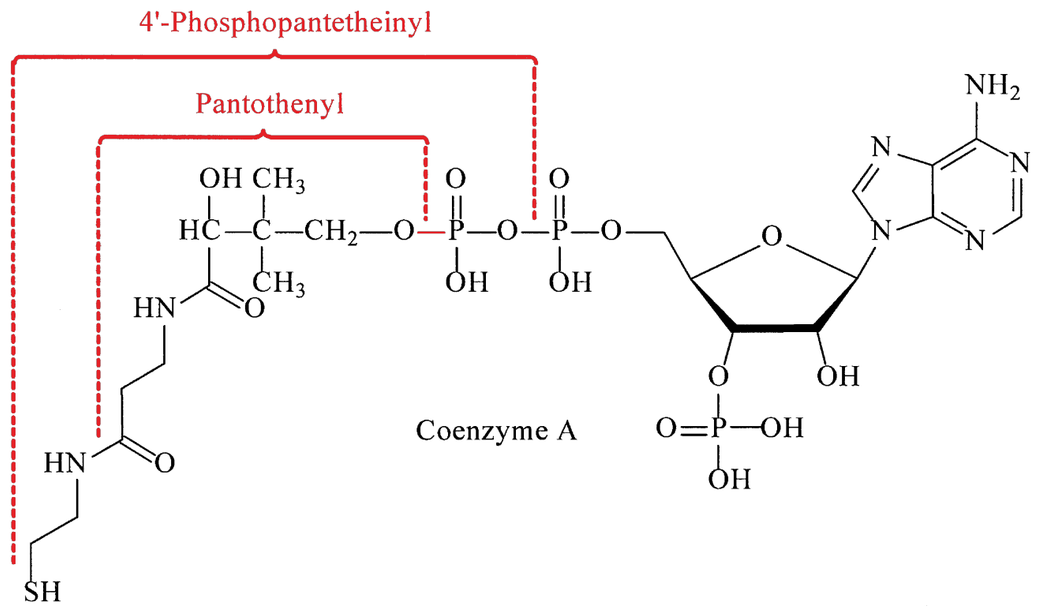

Figure 27-18 Pantothenate and 4′-phosphopantetheine as components of CoA.

and acyl transfer reactions in catabolic processes of carbohydrate, lipid, and protein chemistry. As the 4′-phosphopantetheine moiety of ACP, the phosphodiester-linked prosthetic group uses the sulfhydryl terminus to exchange with malonyl-CoA to form an ACP-S malonyl thioester, which chain-elongates during fatty acid biosynthesis .

Requirements and Reference Nutrient Intakes[2]

The daily intake of pantothenic acid has been set at 5 mg/d for those over 13 years of age. An additional 1 mg/d is suggested in pregnancy, and an additional 2 mg/d is suggested for lactating mothers.

Deficiency

The widespread availability of pantothenic acid in food is commensurate with its many roles and makes an uncomplicated dietary deficiency of pantothenate unlikely in humans. Symptoms produced in volunteers fed pantothenate-antagonist or semisynthetic diets virtually free of pantothenate included (1) irascibility, (2) postural hypotension and rapid heart rate on exertion, (3) epigastric distress with anorexia and constipation, (4) numbness and tingling of the hands and feet, (5) hyperactive deep tendon reflexes, and (6) weakness of finger extensor muscles. Historically, pantothenic acid deficiency has been associated with the syndrome of "burning feet" experienced by prisoners in the Second World War in Asia, which was relieved only by pantothenic acid supplementation, not by other B-group vitamins.

Toxicity

No adverse effects have been reported, with the exception of occasional mild diarrhea, with oral pantothenic acid at doses as high as 20 g/d.

Laboratory Assessment of Status[11]

No convenient or reliable functional tests of pantothenic acid status are available, thus assessment is made by direct measurement of whole blood or urine pantothenic acid concentrations. Urine measurements are perhaps the easiest to conduct and interpret, and concentrations are closely related to dietary intake. Whole blood measurements are preferred to measurements of plasma, which contains only free pantothenic acid and is insensitive to changes in pantothenic acid intake. Concentrations of pantothenic acid in all of the above fluids have been measured by microbiological assay, most commonly with the use of Lactobacillus plantarum. Other techniques that have been used include (1) radioimmunoassay, (2) gas chromatography, (3) gas chromatography–mass spectrometry, and (4) a stable isotope dilution assay. CoA and ACP have been measured by enzymatic methods.

Reference Intervals

Urinary excretion of pantothenic acid of less than 1 mg/d is considered abnormally low. Suspicion of inadequate intake is further supported when whole blood concentrations are less than 100 µg/L. A guidance reference interval for pantothenic acid in whole blood or serum is 344 to 583 µg/L (1.57 to 2.66 µmol/L), and for urinary excretion is 1 to 15 mg/d (5 to 68 µmol/d).

Trace Elements[15]

The term trace element was originally used to describe the residual amount of inorganic analyte quantitatively determined in a sample. Sensitive analytical methods now provide accurate determination of most inorganic micronutrients present at very low concentrations in body fluids and tissue.[13,14] Those present in body fluids (µg/dL) and in tissue (mg/kg) are still widely referred to as "trace elements" and those found at ng/dL or µg/kg as "**ultratrace elements**." The corresponding dietary requirements are quoted in mg/d or µg/d, respectively. An element is considered essential when the signs and symptoms induced by a deficient diet are uniquely reversed by an adequate supply of the particular trace element (Figure 27-19).

Overview of Chemistry

Important factors that need to be considered for the understanding of trace elements and how they function, include (1) ionic forms, (2) relative solubilities, (3) possible organo complex formation, and (4) **chemical speciation**. This approach will serve as a proper basis for understanding physiological function, as well as relevant approaches to measurement.

Analytical Considerations

Analytical factors that have to be considered in the measurement of trace elements include (1) specimen requirements, (2) preanalytical factors, (3) collection equipment, (4) methodology, and (5) quality assurance.

Specimen Requirements

Specimens commonly submitted for direct trace element analysis include (1) whole blood, (2) blood plasma, and (3) serum. Direct determination of trace elements, however, is performed on any body fluid or tissue. For example, tissue samples for analysis may be obtained by needle biopsy (liver or bone) or after autopsy. Hair and nail samples are obtained noninvasively and are used to assess toxic metal exposure, but problems of

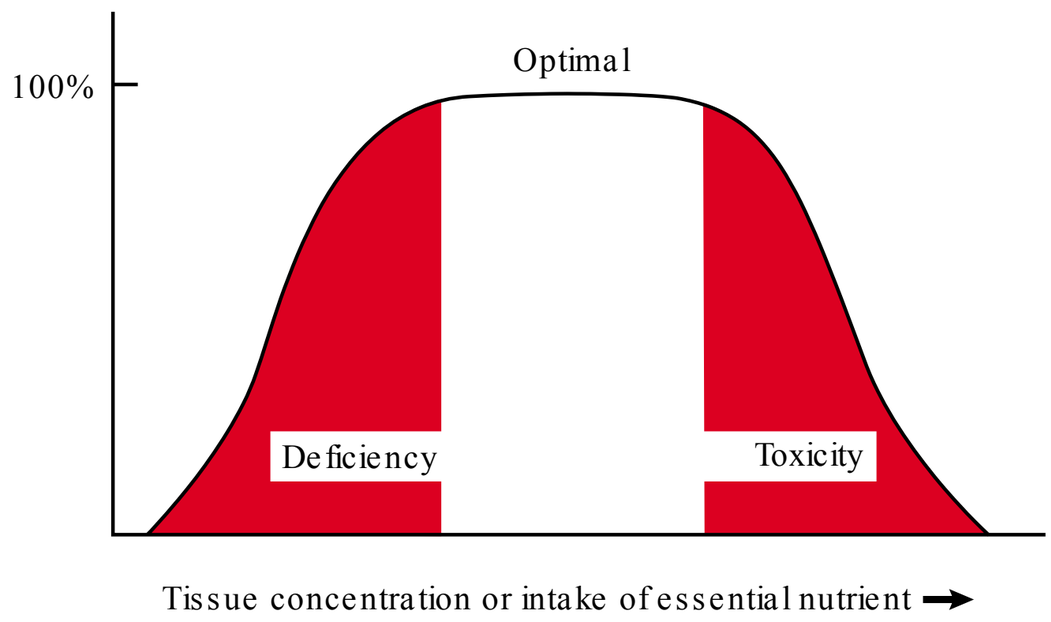

Figure 27-19 Model of the relationship between tissue concentration and intake of an essential nutrient and dependent biological function.

external contamination from (1) environmental pollution, (2) cosmetics, or (3) shampoos, are difficult to control.

The concentration of essential trace elements in nucleated cells has been determined in various types of leukocytes and in platelets. However, separation of white cells and platelets in whole blood before trace element analysis is subject to serious problems of contamination.

Preanalytical Factors

Numerous variables affect trace element determinations before analysis of the sample is undertaken, and these require careful control. For example, (1) age, (2) sex, (3) ethnic origin, (4) time of sampling in relation to food intake, (5) time of day, (6) history of medication, and (7) tobacco usage should be recorded when reference intervals from healthy control populations are established. For interpretation of results, knowledge of the extent of any **acute-phase reaction (APR)** is required.

Note that the APR is a response of the body to inflammation that results in a number of biochemical and physiological changes, including an increase or decrease in the plasma concentrations of a class of proteins known as acute phase reactants. Of particular relevance to this chapter, most trace element and vitamin concentrations in plasma are also markedly affected. In 1992, the Consensus Conference Committee of the American College of Chest Physicians/Society of Critical Care Medicine discussed the topic of sepsis and decided that APR was a part of the more general condition they termed the **systemic inflammatory response syndrome (SIRS)**.[2] As appropriate, SIRS is used instead of APR in the discussions that follow.

Collection Equipment

The choice of container for sample collection is important because contamination from (1) rubber, (2) cork, and (3) colored plastics has been a problem. For blood plasma, plastic tubes with lithium heparin as an anticoagulant are suitable for most analyses. For blood serum, plain glass containers have been used. For the ultratrace metals (Mn, Cr), special arrangements have to be made to collect blood via plastic cannulae or siliconized steel needles, and then the sample is placed into acid-washed containers. Trace metal Vacutainers are available commercially. It is good practice to run dilute acid blanks through all containers and collection systems to ensure that all batches remain as free from contamination as possible.

For 24-hour urine collection, it is important that urine is not collected into disposable fiber or stainless steel containers, and polyethylene bottles with glacial acetic acid should be used as the preservative, although bottles rinsed well with ultrapure deionized water are also appropriate.

Methodology

The detection limits of analytical methods used for determination of trace and ultratrace elements in biological specimens are important because concentrations of trace and ultratrace elements are in the nanogram per gram to microgram per gram range. In practice, the concentration of a trace or ultratrace element should be at least 10 times the detection limit of the method, thus ensuring sufficient accuracy and precision.

The most commonly used analytical methods are summarized in the following sections.

Spectrophotometry

When applied to the analysis of trace elements, spectrophotometric methods are based on the use of a color-forming reagent; however, they lack specificity. Interferences occur in (1) hemolyzed, (2) lipemic, and (3) icteric samples. In practice, this technique is sensitive only for the more abundant trace elements, such as (1) iron, (2) zinc, and (3) copper.

Atomic Absorption Spectrophotometry (AAS)

AAS is widely used for determination of Zn and Cu in serum (see Chapter 9). This technique cannot be used to measure Cu in urine, for which the more sensitive but technically more demanding electrothermal atomization-atomic absorption spectrometry (ETA-AAS) is required. With this technique, sample volumes as small as 10 µL are sequentially volatilized and atomized in a graphite tube. This technique is useful in situations in which the sample volume is limiting, or for which elements with low limits of detection are required, such as selenium or manganese. Optical background correction systems using a deuterium lamp or employing the Zeeman effect are now standard components of ETA-AAS instrumentation (see Chapter 9). Flame and electrothermal types of AAS are single element techniques, and the methods used for different elements have to be run sequentially; this is wasteful in terms of time and sample.

Inductively Coupled Plasma–Optical Emission Spectrometry (ICP-OES)

ICP-OES is replacing AAS, and its use has led to lower limits of detection. It offers a wide dynamic range (e.g., three orders of magnitude for most elements) that allows performance of simultaneous analyses on a single diluted aliquot of sample. The high temperature of the plasma (7500 °C) renders the technique largely free of chemical interferences, but (1) matrix effects, (2) background, and (3) spectral interferences are greater than those in AAS.

Inductively Coupled Plasma–Mass Spectrometry (ICP-MS)

This technique is more sensitive than ETA-AAS or ICP-OES and is now the method of choice for ultratrace elements. Polyatomic interferences are more likely at masses less than 80. ICP-MS has been used to measure stable isotopes and to conduct stable isotope tracer experiments and isotope dilution analysis. The principles of mass spectrometry are discussed in Chapter 13 .

Accelerator Mass Spectrometry

Accelerator mass spectrometry (AMS) differs from other forms of mass spectrometry in that it accelerates ions to extraordinarily high kinetic energies before mass analysis. This makes possible the detection of naturally occurring, long-lived radioisotopes, such as ^{10}Be, ^{36}Cl, ^{26}Al, and ^{14}C. The special property of AMS compared with other mass spectrometric methods is its power to separate a rare isotope from an

abundant neighboring mass (e.g., ^{14}C from ^{12}C). For this reason, the technique is particularly useful in drug kinetic studies, where only very small amounts of actual labeled drug are required (i.e., at low µg concentration).

Other Techniques

Other techniques have been applied to elemental analysis, including X-ray–based techniques that have lower limits of detection at the µg/g concentration achievable for most sample materials. For thin sections of tissue, femto gram concentrations have been detected and reported for µ-synchrotron radiation X-ray fluorescence analysis (µ-SRXRF) stations installed at second-generation synchrotrons; with this technique, it is possible to map the three-dimensional (3D) orientation of metal in tissue (e.g., bone).

Speciation Methods of Assessment

Speciation methods involve techniques to separate the chemical complexes of individual elements present in any particular medium; these are now regarded as crucial for an understanding of the (1) absorption, (2) utilization, (3) function of elements and (4) problems of excess and potential toxicity. Recent developments have coupled separative with analytical procedures, in particular with ICP-OES or ICP-MS. T is application has enabled analysis of several elements and study of their distribution in plasma in various abnormal clinical states (e.g., uremia). T e low limit of detection of ICP-MS has enabled the low sample requirement of capillary electrophoresis to be coupled in this way.

Coupling of analytical procedures such as ICP-MS with ion exchange chromatography specifically configured to measure the elements attached to small molecules (e.g., organic acids) allows chemical speciation not only of the organo complexes but also of chemically ionized states of the elements in solution. It is possible to model such speciation in physiological fluids using established affinity constants and commercial computer programs. Such a model predicts that the major small species of elements will be complexed with citric acid (e.g., iron); obviously this will affect cellular uptake of the elements.

T e European Virtual Institute for Speciation Analysis (EVISA) is a service provider in the field of speciation analysis. T e EVISA Web portal (www.speciation.net/; accessed October 7, 2013) is a primary source for all those seeking information about chemical species with respect to (1) analysis, (2) biological activity (toxicity, nutritional value, metabolism), (3) legislation (laws, rules, standards), and (4) research in related fields.

Quality Assurance Considerations

An effective quality assurance scheme for trace or ultratrace element analyses requires incorporation of the following into each batch of analyses: (1) reagent blanks, (2) replicate analyses to assess precision, (3) calibrators of trace elements of interest in the expected concentration range of specimens analyzed, and (4) a control or reference solution with known or certified concentrations of trace elements to be determined to assess accuracy and batch-to-batch precision. T e reference material should be of the same matrix type and should contain approximately the same quantities of analytes as the specimens. It is essential that trace element laboratories participate in external quality assessment programs.

Individual Trace Elements

Trace elements that are discussed below include (1) chromium, (2) cobalt, (3) copper, (4) fluoride, (5) manganese, (6) molybdenum, (7) selenium, and (8) zinc.

Chromium

Chromium occurs naturally in various crystal materials. It is a transitional element with many industrial uses and is discharged into the environment as industrial waste.

Chemistry

Chromium (atomic number 24, relative atomic mass 51.99) is a transition metal that occurs in biology with valence 3^+ or 6^+, each with markedly different properties. Trivalent Cr^{3+} is considered an essential trace element that enhances the action of insulin. Hexavalent Cr^{6+} is a strong oxidant that causes tissue damage, although it is normally rapidly reduced to Cr^{3+} during contact with foodstuffs and gastric contents.

A biologically active form of Cr^{3+} is known as **glucose tolerance factor** (GTF) and is found in brewer's yeast, but its function remains uncertain. Its structure is thought to be an octahedral chromium complex, with two molecules of nicotinic acid having and four coordination sites linked to glutamic acid, glycine, and cysteine.[13]

Dietary Sources

Estimates of the amount of chromium in foodstuffs vary because of analytical difficulties and contamination associated with contact with stainless steel during food processing, storage, and cooking. Good sources of chromium include (1) processed meats, (2) whole grain products, (3) green beans, (4) broccoli, and (5) some spices. T e estimated dietary intake for adults in the United States ranges from 20 to 30 µg/d. Supplements that contain chromium are taken by about 8% of adults in the United States.

Absorption, Transport, Metabolism, and Excretion

Intestinal absorption of Cr^{3+} ranges from 0.4% to 2.5% of the quantity ingested with fecal output being mainly unabsorbed dietary chromium. After absorption, chromium binds to plasma transferrin with an affinity similar to that of iron. It then concentrates in human (1) liver, (2) spleen, (3) other soft tissue, and (4) bone. Urine chromium output is around 0.2 to 0.3 µg/d; the amount excreted is dependent upon intake.

Functions

A low-molecular-weight intracellular octapeptide (LMWCr), also known as chromodulin, is thought to bind Cr^{3+} and enhance the response of insulin receptors. Its proposed mode of action includes the following: (1) Inactive insulin receptors on cell membranes are converted to an active form by binding circulating insulin; (2) this binding stimulates movement into

cells of chromium bound to plasma transferrin; (3) chromium then binds to apoLMWCr, converting it to an active form that binds to the insulin receptors and potentiates kinase activity; and (4) as plasma glucose and insulin fall to normoglycemic concentrations, the LMWCr factor is released from the cell to terminate its effects.

Requirements and Reference Nutrient Intakes[6]

Because evidence has been insufficient to set an **estimated average requirement (EAR)**, an average intake based on estimated intakes has been set at 35 μg Cr per day for men and 25 μg Cr per day for women. No tolerable upper limit has been set for dietary Cr^{3+} intake.

Deficiency

Clinical signs of human chromium deficiency were first clearly described in patients receiving parenteral nutrition for a prolonged period. All published case histories have had similar presentations, with previously stable patients developing (1) insulin-resistant glucose intolerance, (2) weight loss, and, in some cases, (3) neurological deficits. Addition of substantial amounts of Cr^{3+} to the intravenous regimen (150 to 200 μg/d) reversed glucose intolerance and reduced insulin requirements with eventual improvement in neurological disorders.

Clinical Significance

Chromium is thought to play a role in (1) impaired glucose tolerance, (2) diabetes, and (3) cardiovascular disease.

Impaired Glucose Tolerance and Diabetes. Poor chromium nutritional status may be a factor in impaired glucose tolerance in some patients. However, the variability of dietary chromium intake and the lack of an easily usable laboratory or clinical marker to identify those patients with poor chromium status have created difficulties. A meta-analysis investigating 15 randomized controlled trials on the effects of chromium on (1) glucose, (2) insulin, and (3) glycated hemoglobin (HbA_{1c})[11] concluded that no effect was caused by chromium on glucose or insulin in nondiabetic participants, and that the data for persons with diabetes were inconclusive.

It has been suggested that a short-term dosage of less than 1000 μg Cr per day may be a useful additional treatment for type 2 diabetes. Monitoring of kidney function and clinical assessment of dermatological changes are required. The dosages used suggest a pharmacological role for chromium, and potential toxicity has to be considered. Chromium therapy in the control and prevention of diabetes is therefore of considerable interest and is the subject of much controversy.

Cardiovascular Disease. Chromium depletion has long been thought to be associated with increased cardiovascular risk. Reports of favorable lipid responses to chromium supplementation have been published.

Toxicity

Hexavalent chromium is a recognized carcinogen, and industrial exposure to fumes and dusts containing this metal is associated with increased incidence of (1) lung cancer, (2) dermatitis, and (3) skin ulcers (see Chapter 32).

Cr^{3+} species are relatively nontoxic, in part because of their poor intestinal absorption and rapid excretion in urine. However, chromium picolinate is a widely used dietary supplement, and this compound has been reported to cause renal and hepatic damage when used at high doses.

In addition, markedly increased concentrations (up to 1000-fold) have been observed in both plasma (12 μg/L [620 nmol/L]) and urine (50 μg/L [2600 nmol/L]) in patients with problem hip prostheses. These may be raised in any patient receiving chrome-cobalt prostheses. No harmful effects of these high concentrations have been observed.

Laboratory Assessment of Status[11]

A beneficial response of glucose-intolerant patients to chromium supplementation is presently the only means of confirming chromium deficiency. No practicable method of assessing intracellular chromium depletion is yet available. Furthermore, it has been known since early animal experiments were conducted that circulating chromium is not in equilibrium with physiologically important reserves.

Direct determination of chromium in blood plasma or serum is possible only if great care is taken to prevent contamination before and during analysis. Sample collection procedures have to avoid any contact with stainless steel, so all-plastic phlebotomy systems or siliconized steel needles should be used, and samples should be stored in acid-washed containers.

Detection of increased amounts of chromium in urine confirms recent occupational or environmental exposure to excess chromium.

Reference Values

Very low values are now considered as normal for serum (0.1 to 0.2 μg/L [2 to 3 nmol/L]) and for urine (<0.2 μg Cr per L (<3 nmol/L).

Cobalt

Cobalt is essential for humans as an integral part of vitamin B_{12} (cobalamin). No other function for cobalt in the human body is known. Details of vitamin B_{12} biochemistry and function were discussed previously. The microflora of the human intestine is not able to use cobalt to synthesize physiologically active cobalamin. The human vitamin B_{12} requirement must be supplied by the diet. Free (nonvitamin B_{12}) cobalt does not interact with the body vitamin B_{12} pool. However, exposure to the kidney of increasing concentrations of cobalt ions may cause release of the hypoxia-inducible factor (HIF), leading to release of erythropoietin and an increase in erythropoiesis.

Reference values in plasma are less than 1 μg/L and in urine are usually less than 2 μg/g creatinine. Increased exposure through industrial uses, particularly with hard metal saw blades, leads to high mean urinary Co concentrations. Increases are also associated with hip prostheses for which concentrations can be markedly raised with no evidence of overt toxicity.

Copper

Copper is an important trace element that is associated with various metalloproteins.

Chemistry

Copper (atomic number 29, relative atomic mass 63.54) has Cu^{1+} and Cu^{2+} oxidation states in biological systems. The simple exchange between these ions gives the element important redox properties. Because of their high electron affinities, these ions are the most strongly bound to organic molecules of all essential trace metals. For example, copper in biological material is complexed with (1) proteins, (2) peptides, and (3) other organic ligands. An elaborate series of binding and transport proteins inside cells protects the genome from copper-generated free-radical attack. This keeps the concentration of free copper in the cytoplasm very low (around 10^{-15} mol/L). The copper metalloenzyme superoxide dismutase (SOD) protects against random free-radical damage both in the cytoplasm and in blood plasma.

Dietary Sources

The copper content of food is variable and is affected by applications to crops of copper-containing fertilizers and fungicidal sprays and the use of copper-containing cooking vessels. The metal is most plentiful in (1) organ meats, such as liver and kidney, with relatively large amounts also found in (2) shellfish, (3) nuts, (4) whole grain cereals, and (5) cocoa-containing products. The median intake of copper in the United States is around 1.0 to 1.6 mg/d.

Absorption, Transport, Metabolism, and Excretion

The extent of small intestinal copper absorption varies with dietary copper content and is around 50% at low copper intakes (less than 1 mg Cu per day) but only 20% at higher intakes (>5 mg Cu per day). Absorption is reduced by other dietary components, such as zinc (via metallothionein), molybdate, and iron, and is increased by amino acids.

Absorbed copper is transported to the liver bound to albumin in portal blood, where it is incorporated by hepatocytes into cuproenzymes and other proteins and then is exported in peripheral blood mainly as ceruloplasmin to tissue and organs. Although two-thirds of the 80 to 100 mg total body copper content is located in skeleton and muscle, the liver is the key organ in copper homeostasis. Ceruloplasmin is a positive acute-phase reactant that is increased during infection and after tissue injury. A smaller amount of copper in plasma (<10%) is bound to albumin. An overview of copper metabolism is illustrated in Figure 27-20.

Between 0.5 and 2.0 mg of copper per day is excreted via bile into feces. Patients with cholestatic jaundice or other forms of liver dysfunction are therefore at risk of copper accumulation caused by failure of excretion. Urine copper output is normally less than 60 μg/d.

Functions

Copper is a catalytic component of numerous enzymes and is a structural component of other important proteins in humans, animals, plants, and microorganisms.

Energy Production. Cytochrome c oxidase is a multisubunit complex that contains copper and iron. Located on the external face of mitochondrial membranes, the enzyme catalyzes a four-electron reduction of molecular oxygen, which is necessary for ATP production.

Connective Tissue Formation. Protein-lysine 6-oxidase (lysyl oxidase) is a cuproenzyme that is essential for stabilization of extracellular matrixes, specifically the enzymatic cross-linking of collagen and elastin. The enzyme is highly associated with connective tissue and is located in (1) aorta, (2) dermal connective tissue, (3) fibroblasts, and (4) cytoskeleton of many other cells.

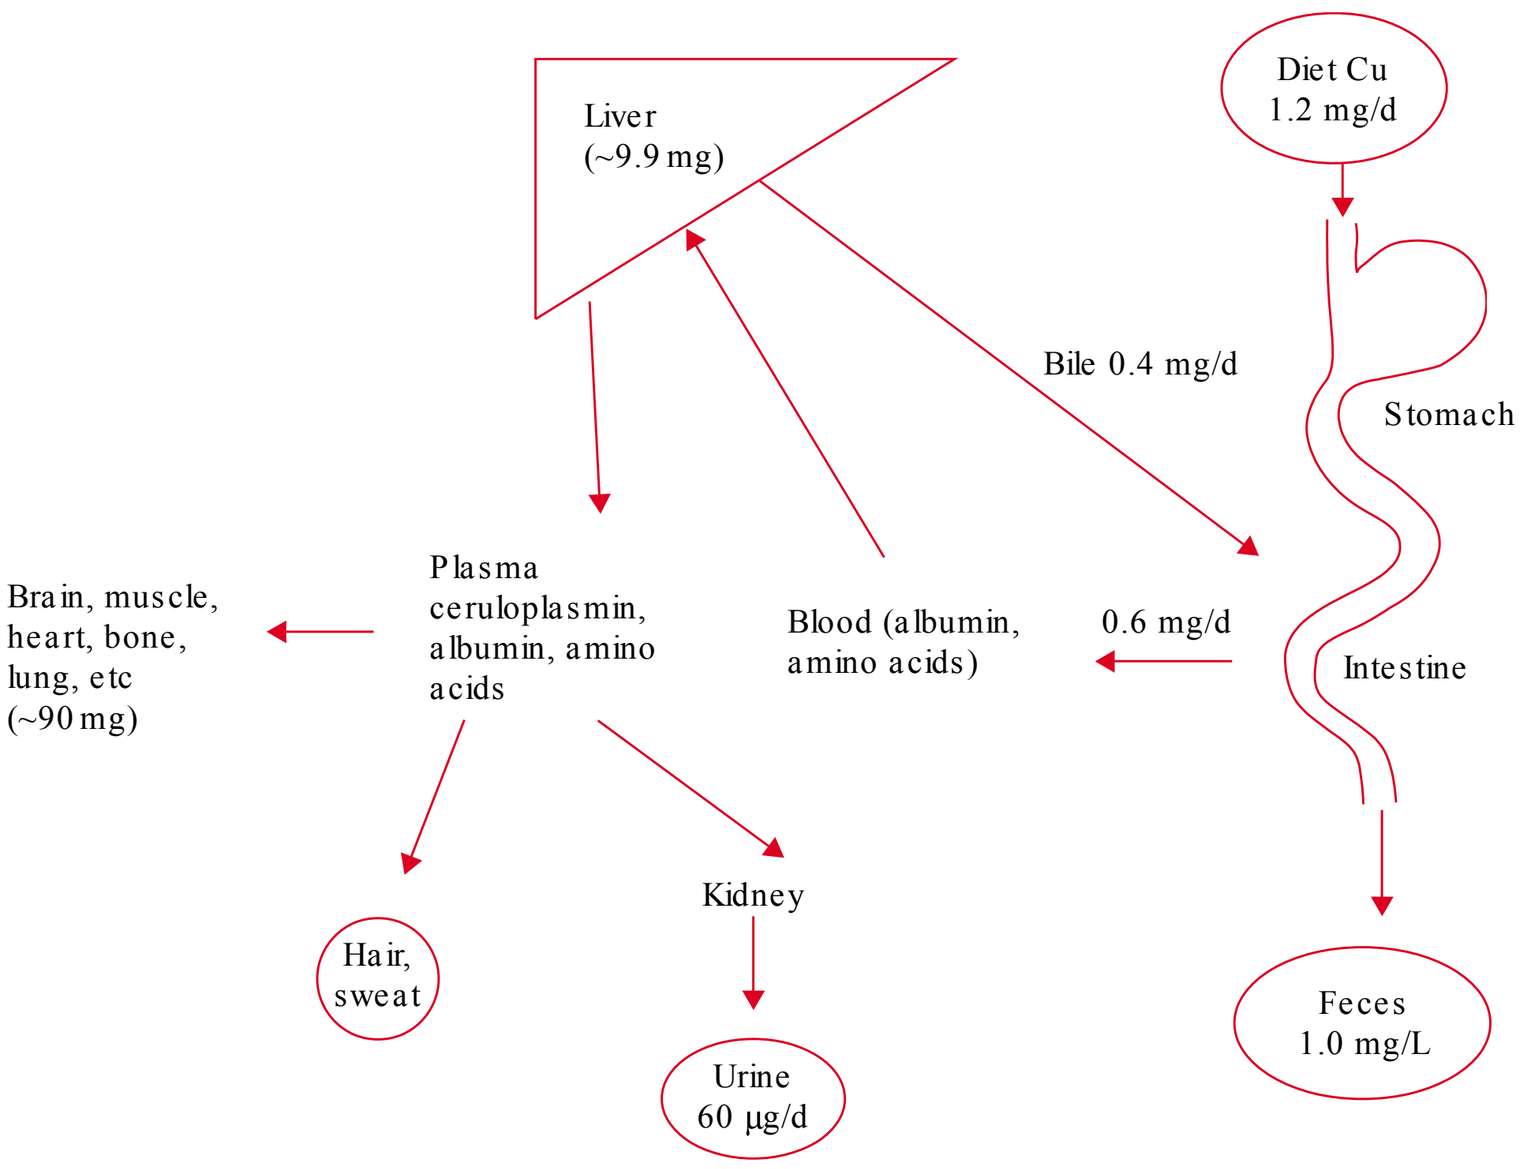

Figure 27-20 Metabolism of copper. (Modifed from Harris ED. Copper. In: O'Dell BL, Sunde RA, editors. Handbook of nutritionally essential mineral elements. New York: Marcel Dekker, 1997:231–73.)

Iron Metabolism. Copper-containing enzymes—namely, (1) ferroxidase I (ceruloplasmin), (2) ferroxidase II, and (3) hephaestin in the enterocyte—oxidize ferrous iron to ferric iron. T is allows incorporation of Fe^{3+} into transferrin and eventually into hemoglobin.

Central Nervous System. Dopamine mono-oxygenase (DMO) is an enzyme that requires copper as a cofactor and uses ascorbate as an electron donor. T is enzyme catalyzes the conversion of dopamine to norepinephrine, the important neurotransmitter. Monoamine oxidase is a copper-containing enzyme that catalyzes the degradation of serotonin in the brain.

Melanin Synthesis. Tyrosinase is a copper-containing enzyme that is present in melanocytes and catalyzes the synthesis of melanin.

Antioxidant Functions. Both intracellular and extracellular SODs are copper- and zinc-containing enzymes that are able of converting superoxide radicals to hydrogen peroxide, which is subsequently removed. Ceruloplasmin also binds copper ions, thus preventing oxidative damage from free copper ions, which generate hydroxyl radicals.

Regulation of Gene Expression and Intracellular Copper Handling. Synthesis of metallothionein is controlled by copper-responsive transcription factors, and this protein is important in regulating the intracellular distribution of copper. Additional specialized proteins act as "copper chaperones" to deliver copper to intracellular sites and prevent oxidative damage by free copper ions.

Inborn Errors of Copper Metabolism. **Menkes disease** is caused by a defective gene that regulates the metabolism of copper in the body. **Wilson disease** is inherited as an autosomal recessive trait that involves a defect in the metabolism of copper, with accumulation of copper in (1) liver, (2) brain, (3) kidney, (4) cornea, and (5) other tissue. Copper-transporting P-type ATPases, known as ATP7A and ATP7B, are essential factors in maintaining copper balance. Impaired intestinal transport of copper caused by a mutation in the ATP7A gene leads to the severe copper deficiency disease seen in Menkes disease. A defect in the ATP7B gene affects both incorporation of copper into ceruloplasmin and copper excretion via bile and serves as the basis of Wilson disease.

Requirements and Reference Nutrient Intakes[6]

T e recommended dietary intake for adults is 0.9 mg/d. T is is near the lower limit of 1.0 mg/d found in dietary surveys and has led to suggestions that marginal copper depletion could be found in the U.S. population. T e tolerable upper limit is 10 mg/d.

Def ciency

A deficiency of copper has been noted in a number of conditions.

Malnourished Infants. When malnourished infants with a history of chronic diarrhea were rehabilitated using a formula based upon cow's milk, they developed (1) iron-resistant anemia, (2) neutropenia, (3) other hematological disorders, and (4) bone lesions. Copper supplementation of milk feeds reversed these abnormalities.

Premature Infants. Most of the accumulation of copper in the fetal liver occurs in the last 3 months of pregnancy, and premature infants fed formula lacking sufficient copper are at risk of deficiency disease because they lack adequate liver copper stores. Hematological abnormalities and easily fractured brittle bones have been described.

Nutritional Support. Adults and children fed intravenously without addition of sufficient copper to the nutrient regimen develop symptomatic copper deficiency. Hematological changes of hypochromic anemia and neutropenia are reversed by copper supplementation. Similar effects have been reported during prolonged enteral feeding via jejunostomy. Children may develop the typical bone changes mentioned previously.

Menkes Disease. T is disorder typically occurs in male infants at 2 to 3 months who present with (1) loss of previously normal development, (2) hypotonia, (3) seizures, and (4) failure to thrive. Physical changes in the hair (pili torti/corkscrew hair) and in facial appearance, as well as neurological abnormalities, suggest the diagnosis. Local first-line tests would be likely to find plasma copper less than 10 μmol/L, ceruloplasmin less than 220 mg/L, and demonstration of pili torti by microscopic examination of hair.

Malabsorption Syndromes. Patients at risk include those with (1) celiac disease, (2) sprue, (3) cystic fibrosis, and (4) short bowel syndrome. In some cases, excessive intake of oral zinc supplements has caused copper deficiency by zinc induction of metallothionein in the intestinal mucosa, which then sequesters dietary copper, blocking its absorption.

Cardiovascular Disease. Animal studies show that severe copper deficiency causes cardiac damage, but the abnormality differs from that seen in human cardiovascular disease. Epidemiological surveys have shown that increased plasma copper values are a positive cardiovascular risk factor. An increase in plasma ceruloplasmin and hence plasma copper may be a nonspecific response to the inflammation of arteries seen in arteriosclerosis.

Anemia. Copper deficiency is an established cause of hematological abnormalities but is frequently misdiagnosed. Patients with copper deficiency have been known to present with a combination of hematological and neurological abnormalities that may masquerade as a myelodysplastic syndrome. Records between 1970 and 2005 of patients excluding Wilson disease with hypocupremia (mean, 0.23; range, 0 to 0.69 μg/mL; normal plasma zinc) reveal various hematological abnormalities on bone marrow examination, including (1) vacuoles in myeloid precursors, (2) iron-containing plasma cells, and (3) a decrease in granulocyte precursors and ring sideroblasts. T us copper deficiency is an uncommon but very treatable cause of hematological abnormalities.

Neuropathy. Copper deficiency is an increasingly recognized cause of gait unsteadiness. A case report of copper deficiency due to celiac disease suggested that ataxia associated with celiac disease was likely due to a copper deficiency, myeloneuropathy. Similar findings have resulted from copper deficiency due to excess zinc intake.

Toxicity

Wilson disease is a genetic disorder of copper metabolism that causes an increase in copper to toxic concentrations. The incidence of Wilson disease is estimated to be 1/30,000 live births. Because presentation is highly variable, adolescents or young adults with otherwise unexplained liver disease or neurological symptoms should be screened, especially when there is a family history of suspected Wilson disease. Initial local investigations would include measurements of plasma copper and ceruloplasmin (<50 µg/dL, 8 µmol Cu/L) and ceruloplasmin (<200 mg/L). Although the total plasma copper is decreased, the non–ceruloplasmin-bound fraction is increased, allowing deposition of copper in brain, eyes, and kidneys.

Slit lamp examination of the eye may detect copper deposits in the eye (Kayser-Fleischer rings), and abnormalities may be noted in liver function tests with increased urine copper output (>500 µg Cu/L). Liver biopsy for copper analysis is useful in suspected cases, and results showing more than 250 µg/g Cu dry weight are usually found (normal, 8 to 40 µg Cu/g dry weight). Gene tracking and mutation detection are now possible. Diagnosis often is difficult in Wilson disease cases involving acute liver failure. Greatly increased plasma copper will be found but without an increase in ceruloplasmin.

The chronic form of Wilson disease is treated with oral chelating agents, such as penicillamine and trientine, which remove excess copper from tissue and increase urine copper excretion.

Toxicity has been known to occur as the direct result of copper contamination of diet and water supplies.

Laboratory Assessment of Status[9]

Plasma copper and ceruloplasmin assays are convenient and are widely used to confirm severe copper deficiency. However, they are not sensitive indicators of marginal copper depletion.

Because about 90% of plasma copper is bound to ceruloplasmin, factors that increase the hepatic synthesis of ceruloplasmin, such as APR or the oral contraceptive pill, will increase plasma copper independently of dietary copper intake. In premature infants with liver immaturity and low ceruloplasmin synthesis, plasma copper values less than 30 µg/L (<5 µmol Cu/L) suggest the necessity for increased copper input.

The ratio of immunologically to enzymatically measured ceruloplasmin may be a useful index of marginal copper depletion. Apoceruloplasmin is increased in blood serum during copper depletion, and this contributes to the total ceruloplasmin assay, but enzymatic activity is decreased in even marginal copper depletion.

Reference Intervals

For adults, plasma copper is usually in the interval of 70 to 140 µg/dL (10 to 22 µmol/L). Values in women of child-bearing age, especially in pregnancy, are higher. Plasma copper for adults below 50 µg/dL (8 µmo/L) and for infants below 30 µg/dL (5 µmol/L) indicates probable copper depletion. Adjusting the copper concentration to account for variations in ceruloplasmin is problematic, as it depends on the accuracy of an immunoassay.

The most reliable procedure consists of using plasma ultrafiltration when a reference interval of 0 to 10 µg/dL (0 to 1.6 µmol/L) has been reported in 137 healthy adult (20 to 59 years of age) blood donors. Free copper concentrations for patients diagnosed with Wilson disease were at least sixfold greater than the reference upper limit.

Urine copper output is normally less than 60 µg/24 h (<1.0 µmol/24 h), and values above 200 µg/24 h (3 µmol/L) are found in Wilson disease. A copper concentration in a liver biopsy sample >250 µg Cu/g dry weight (normally 8 to 40 µg/g dry weight) is indicative of Wilson disease, in the absence of other causes of cholestatic disease.

Urine copper output, in response to an oral penicillamine test, greater than 25 µmol/24 h is thought to be diagnostic of Wilson disease. Evidence suggests that this test is valuable in the diagnosis of Wilson disease with active liver disease but is unreliable in excluding the diagnosis in asymptomatic siblings.

Fluoride

Fluoride (Fl) is the most widely used of the "pharmacologically beneficial trace elements" in the area of public health. Dental caries has been described as the last major epidemic of preventable bacterial disease, and dental decay leads to (1) tooth loss, (2) nutritional problems, and (3) systemic infection.

Dietary Sources

Many studies have established that addition of fluoride to drinking water reduces the incidence of tooth decay; more than 60% of the U.S. population now uses fluoridated water. Clinical studies from 1950 to 1980 in 20 different countries found that adding fluoride to community water supplies, within the interval 0.7 to 1.2 mg/L, reduced the incidence of caries by 40% to 50% in primary (infant) teeth and by 50% to 60% in permanent teeth.

Fluoride supplementation of (1) salt, (2) sugar, and (3) milk has been used in areas where fluoride is not added to water supplies.

Function

The fluoride ion is exchanged for hydroxyl in the crystal structure of apatite, a main component of skeletal bone and teeth. It is stabilizes the regenerating tooth surface. Fluoride is available from saliva and may be released from dental plaque at low pH. Initially, benefit was considered to involve solely the erupting teeth of children, but topical effects on adult teeth are now thought to reduce decay. Initial evidence from small studies suggests that pharmacological doses of fluoride may reduce the incidence of bone fracture in patients with osteoporosis.

Absorption, Transport, Metabolism, and Excretion

Fluoride ions are absorbed from both the stomach and the small intestine. Soluble salts are efficiently absorbed, and a peak increase in fluoride occurs in blood plasma within 1 hour of ingestion. Ions are rapidly cleared from plasma into tissue in exchange with anions, such as (1) hydroxyl, (2) citrate, and (3) carbonate. At least 95% of the 2.6 g of total body fluoride is located in bones and teeth. Almost 90% of excess fluoride is excreted in urine.

Toxicity

Dental fluorosis—the mottling of enamel in the erupting teeth of children—is now estimated to affect around 20% of the population. This is sometimes a disfiguring condition, and it occurs in a greater proportion of children than was thought at first. This condition is possibly caused by ingestion of fluoride-containing toothpaste by children. It is suggested that "pediatric" toothpastes with lower fluoride content should be made available in areas where the water supply is fluoridated.

Occupational exposure to inhaled fluoride dusts among cryolite workers during aluminum refining has resulted in severe bone abnormalities, but safety equipment now limits such exposure. No cases of skeletal fluorosis have been reported in areas with controlled fluoridation of water supplies. However, skeletal fluorosis may occur in areas of the world where naturally occurring drinking water has high concentrations of fluoride, such as China and the Indian subcontinent.

Laboratory Assessment of Status[3]

Laboratory analysis of drinking water may be required to detect possible fluoride excess in natural well waters and may be necessary during incidents of failure of the equipment used to treat drinking water. Determination of fluoride in urine has been used to assess exposure to different sources of fluoride. For drinking water and urine, direct determination using a fluoride-specific electrode is performed.

Reference Intervals

Concentrations of fluoride in body fluids and tissue vary widely, depending on the fluoride content of drinking water and input from diet, toothpaste, and mouth rinses. For urine, a guideline interval is 0.2 to 3.2 mg/L (10.5 to 168 μmol/L).

Manganese

Manganese is present in biological systems bound to protein in the 2^+ or 3^+ valence state. It is associated mainly with (1) formation of connective and bony tissue, (2) growth and reproductive functions, and (3) carbohydrate and lipid metabolism.

Chemistry

Manganese (atomic number 25, relative atomic mass 54.94) has 11 available oxidation states, but only Mn^{2+} and Mn^{3+} are found in biological systems, most often bound to protein.

Dietary Sources

Manganese-rich sources include (1) whole grain foods, (2) nuts, (3) leafy vegetables, (4) soy products, and (5) teas. Median intake in the United States is about 2 mg/d. Vegetarian diets containing high quantities of whole grains and nuts have been known to supply more than 10 mg/d.

Absorption, Transport, Metabolism, and Excretion

Dietary manganese is absorbed from the small intestine by mechanisms that may have a pathway common to that of iron. Manganese absorption increases at low dietary intakes and decreases at higher intakes, with tracer studies suggesting absorption efficiencies of 2% to 15%. Once absorbed, manganese is transported in portal blood to the liver bound to albumin and then is exported to other tissues bound to transferrin and possibly to α_2-macroglobulin . Excretion of manganese occurs primarily via bile into feces, and urine output is very low.

Functions

Manganese, a constituent of many important metalloenzymes, acts as a nonspecific enzyme activator. Mn^{2+} ions will replace Mg^{2+} during activation of some enzymes.

Superoxide Dismutase. Manganese-dependent **superoxide dismutase** (SOD) is a mitochondrial enzyme that is an important factor in limiting oxygen toxicity. This enzyme catalyzes the breakdown of the superoxide radical O_2^- to H_2O_2, which then is removed by catalase and glutathione peroxidase.

Pyruvate Carboxylase. SOD acts together with phosphoenol pyruvate (PEP) carboxykinase, an enzyme that is activated by manganese ions. These enzymes are required to catalyze the formation of PEP from pyruvate—a key reaction in the hepatic synthesis of glucose.

Arginase. Arginase, the terminal enzyme in the urea cycle, hydrolyzes l-arginine to urea and ornithine. The activity of arginase affects the production of nitric oxide by limiting the availability of l-arginine.

Glycosyl Transferases. These enzymes are responsible for the sequential addition of carbohydrate molecules to proteins to form proteoglycans, and ultimately connective tissue and cartilage. They are therefore important for the structural integrity of bone and skin and for healthy wound healing.

Requirements and Reference Nutrient Intakes[6]

Because of lack of information on manganese dietary requirements, the U.S. Food and Nutrition Board has set an adequate intake for adults at 2.3 mg/d for males and 1.8 mg/d for females. An area of concern is the potential toxicity of manganese for infants, whose immature hepatic development reduces the biliary excretion of excess manganese.

Deficiency

Overt manganese deficiency has not been documented in humans eating natural diets. However, in animal studies, signs of experimentally induced manganese deficiency include (1) impaired growth and reproductive function, (2) skeletal abnormalities, (3) impaired glucose tolerance, and (4) impaired cholesterol synthesis. Young men fed experimental diets low in manganese developed skin lesions and low plasma cholesterol.

Prolidase is a cytosolic dipeptidase that hydrolyzes dipeptides with proline or hydroxyproline at the carboxy terminus. Its deficiency in infants is a rare genetic disorder that is known to be associated with abnormalities of manganese biochemistry.

Toxicity

The occupational health hazard from prolonged exposure to manganese-containing dust or fumes is well recognized (see

Chapter 32). Neurological symptoms resembling Parkinson disease develop slowly over months or years.

Patients with severe liver disease may have neurological and behavioral signs of manganese neurotoxicity due to failure to excrete manganese in bile. Manganese deposition in the globus pallidus during liver failure results in magnetic resonance signal hypersensitivity.

Patients receiving manganese intravenously during TPN have shown evidence of manganese retention and deposition in the midbrain and brainstem. Typical symptoms include a parkinsonian-like tremor and abnormalities of gait.

It is now recommended that only 1 µg Mn per kg (18 nmol/kg) be administered during TPN to infants and no more than 1 µmol/d (55 µg/d) to adults. All patients requiring prolonged intravenous nutrition (IVN), especially those who have cholestasis, should be monitored for evidence of manganese retention.

Laboratory Assessment of Status

Plastic cannulae should be used for phlebotomy, and hemolysis should be prevented during sample separation. Whole blood includes about 10 times as much manganese as plasma or serum and is not as affected by contamination from steel needles during sample collection. Consequently, measurement of whole blood manganese is the most widely used method for monitoring manganese status.

Reference Intervals

T e reference interval for serum manganese is 0.5 to 1.3 µg/L (9 to 24 nmol/L). T e reference interval for whole blood manganese is 5 to 15 µg/L (90 to 270 nmol/L). Increases in serum manganese to greater than 5.4 µg/L (>30 nmol/L) or blood manganese to greater than 20 µg/L (>360 nmol/L) are indices of manganese retention.

Molybdenum

T e essential need for molybdenum by animals and humans is based on its incorporation into metalloenzymes.

Chemistry

Molybdenum (atomic number 42, relative atomic mass 95.94) is a metal that includes several oxidation states, but the most stable in biological systems is Mo^{6+}, as is found in molybdate (MoO_4^{2-}). A close parallel has been noted between the chemistries of (1) molybdenum, (2) tungsten, and (3) vanadium. Molybdenum enzymes facilitate important carbon, nitrogen, and sulfur cycles.

Dietary Sources

Good sources of molybdenum are (l) legumes, such as peas, lentils, and beans; (2) grains; and (3) nuts. In the United States, the average dietary intake for adults is 76 to 109 µg Mo per day.

Absorption, Transport, Metabolism, and Excretion

Molybdenum is efficiently absorbed over a wide range of dietary intakes, mainly as molybdate, although competitive inhibition of absorption by sulfate reduces intestinal uptake. Between 80% and 90% of molybdenum in whole blood is bound to red cell proteins. Transport of the smaller amount in blood plasma may involve α_2-macroglobulin. Urine output directly reflects the dietary intake of molybdenum.

Functions

Several important mammalian enzymes, such as (1) sulfite oxidase, (2) xanthine dehydrogenase, and (3) aldehyde oxidase, require molybdenum as a cofactor. T is organic component is a molybdopterin complex. Sulfite oxidase catalyzes the last step in the degradation of sulfur amino acids, oxidizing sulfite to sulfate and transferring electrons to cytochrome c. Xanthine dehydrogenase and aldehyde oxidase hydroxylate various heterocyclic substances, such as purines and pteridines.

Requirements and Reference Nutrient Intakes[6]

T e RDA for Mo has been set at 45 µg per day for adults, which is below the estimated average dietary intake.

Def ciency

Molybdenum deficiency has not been observed in healthy people who consume a normal dietIt is now common, especially in Europe, to include a small amount of molybdenum (19 µg/d [0.2 µmol/d]) in trace element additive mixtures.

Very rare recessive inherited diseases result from defects in the biosynthesis of molybdenum cofactor; in most cases, they lead to early childhood death. First symptoms include (1) failure to thrive and seizures; in later stages, (2) lens dislocations are noted, together with (3) cerebral atrophy. Disease-causing mutations have been identified, and the possibility of gene therapy is being investigated.

Biochemical diagnosis has been made by detection of excess sulfite in urine using the a sulfite dipstick test. Note that samples should not be evaluated until at least 10 days after birth and should be tested within 10 minutes of collection. Another type of molybdenum cofactor deficiency is confirmed by finding low plasma uric acid. Specialized centers offer biochemical prenatal diagnosis on chorionic villous samples.

Toxicity

Molybdenum compounds have low toxicity in humans. Excess molybdenum intake induces copper deficiency in ruminants by blocking copper absorption through formation of an insoluble thiomolybdate/copper complex. T is discovery has suggested the use of ammonium molybdate in the management of Wilson disease.

Laboratory Assessment of Status

Whole blood and serum or plasma molybdenum concentrations are too low to be used for the detection of deficiency. However, urinary output is responsive to increases or decreases in input. Measuring urate or sulfite in the urine is the most available means of confirming molybdenum cofactor disorders or possible molybdenum deficiency.

Reference Intervals

Approximately 0.5 µg Mo per L (5 nmol/L) is present in plasma or serum and about 1 µg Mo per L (10 nmol/L) in whole blood. Urine molybdenum values determined by ICP-MS are approximately 40 to 60 µg/L.

Selenium

Selenium (Se) is an essential element for humans and is a constituent of the enzyme glutathione peroxidase; it is believed to be closely associated with vitamin E in its functions.

Chemistry

Selenium (atomic number 34, relative atomic mass 78.96) is a nonmetal that has several chemical forms and valences and a bioinorganic chemistry that is related to sulfur. The most important biologically active compounds contain selenocysteine, in which selenium is substituted for sulfur in cysteine. Now considered to be the twenty-first amino acid, selenocysteine is incorporated into proteins by the specific codon UGA, which was previously thought to be solely a stop codon (see Chapter 18).

Ingested selenium compounds include (1) selenate, (2) selenite, (3) selenocysteine, and (4) selenomethionine, which are metabolized largely via selenide that may be associated with a chaperone protein. Selenide is then converted to selenophosphate, which is an important precursor in the synthesis of selenocysteine proteins (Figure 27-21).

Dietary Sources

Selenium enters the food chain mainly as selenomethionine from plants that take the element up from the soil but do not appear to use it. The soil content of selenium is highly variable and is usually low in volcanic soils when soluble salts are leached out by ground water. In the United States and Canada, wheat and other cereal products are a good source of selenium; average intakes in North America vary from 80 to 220 µg Se per day, whereas in the UK, dietary intake is about 30 to 60 µg/d. Intakes in China are as low as 11 µg/d and in New Zealand 28 µg/d.

Absorption, Transport, Metabolism, and Excretion

Intestinal absorption of various dietary forms of selenium is efficient but is not regulated. The inorganic salts selenite and selenate used as dietary supplements and in food fortification are almost completely absorbed, but much of the selenate ion is rapidly excreted in urine. Selenium from inorganic salts is more rapidly incorporated into glutathione peroxidase and other selenoproteins than is selenium from organic sources containing selenomethionine. However, selenium-enriched yeast containing the organic forms is considered less toxic and is widely used as a dietary supplement.

About 50% to 60% of the total plasma selenium is present as the protein selenoprotein P, a highly basic protein that includes multiple histidine residues and about 10 atoms of selenium per molecule. Approximately 30% of plasma selenium is present as glutathione peroxidase (GSHPx-3), and the remainder is incorporated into albumin as selenomethionine.

Urinary output of selenium is the major route of excretion and reflects recent dietary intake. The amounts excreted vary widely, ranging from less than 20 to more than 1000 µg Se/L, depending on the geographic origins of the food.

Functions

Thirty or more biologically active selenocysteine-containing proteins have been identified. Some of the most important ones are listed below.

Glutathione Peroxidase. This enzyme has four isoforms: (1) GSHPx-1 in red cells, (2) GSHPx-2 in gastrointestinal mucosa, (3) blood plasma GSHPx-3, and (4) the cell membrane–located GSHPx-4. These enzymes use the reducing power of glutathione to remove an oxygen atom from hydrogen peroxide and lipid hydroperoxides.

Iodothyronine Deiodinase. Type I, II, and III isoforms of this enzyme are responsible for conversion of the precursor

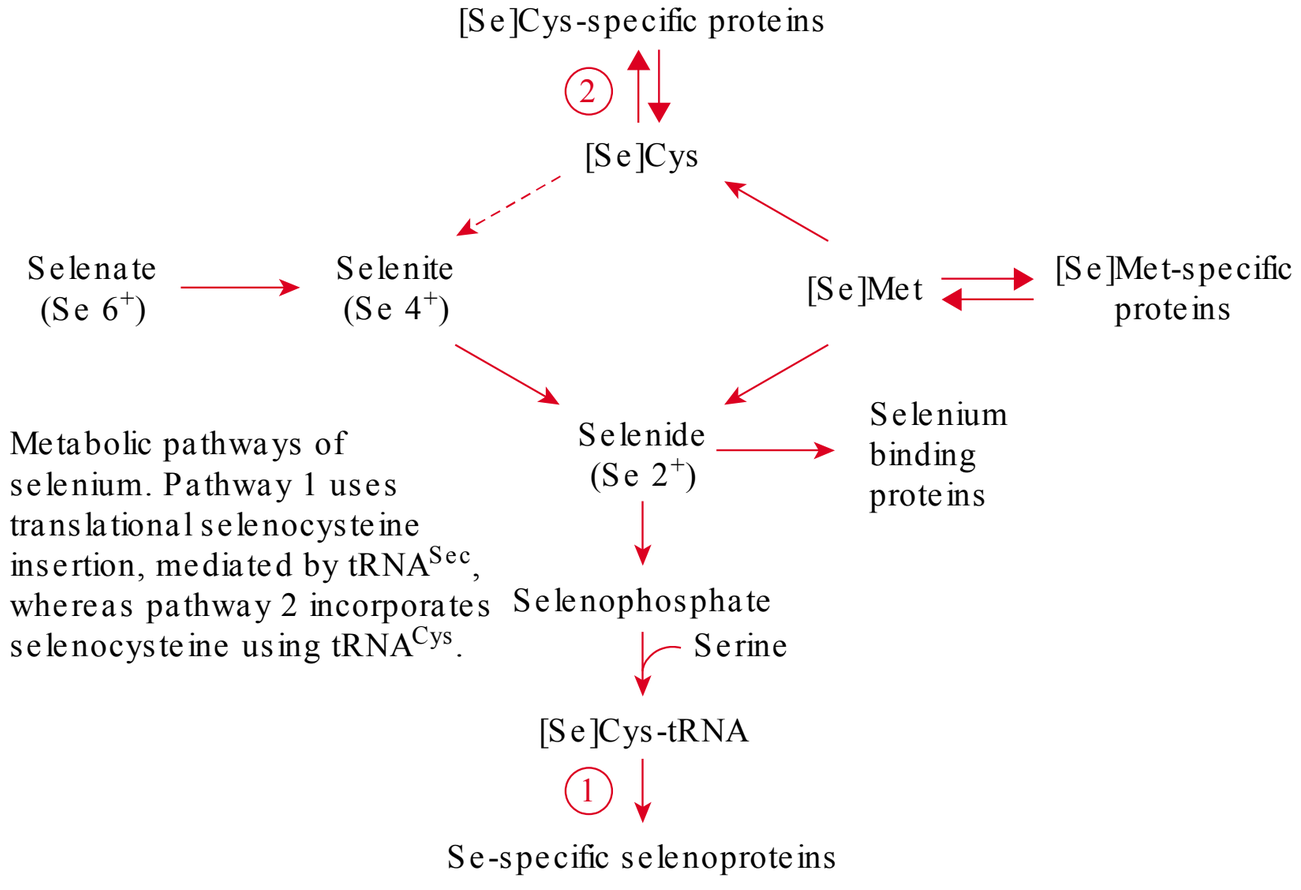

Figure 27-21 Metabolic pathways of selenium. (Adapted from Sunde.)

hormone T_4 to the active hormone T_3. Type I, thyroxine-5-deiodinase, is located in the(1) liver, (2) kidney, and (3) muscle and is responsible for more than 90% of plasma T_3 production.

T ioredoxin Reductases. T ree isoforms catalyze the NADPH-dependent reduction of thioredoxin and are important in maintaining the intracellular redox state.

Selenoprotein P. T is protein, which is the major selenium-containing protein in blood plasma, may be a transport protein for the element and has an antioxidant function.

Requirements and Reference Nutrient Intakes[1]

T e RDA for selenium is set at 55 μg/d for adults. In many countries in Europe, intakes are now close to or less than 55 μg/d, and selenium dietary provision may be suboptimal.

Def ciency

Important selenium-dependent diseases have been identified in farm animals, such as white muscle disease in sheep and cattle, and myopathy of cardiac and skeletal muscle in lambs and calves. As is discussed later, a range of deficiency states has been identified in humans.

Severe Deficiency

Keshan Disease. Conclusive evidence of a role for selenium in human nutrition came with publication of the results of large-scale trials in China that showed the protective effects of selenium supplementation on children and young adults suffering from an endemic cardiomyopathy. T is was observed in areas of the country (Keshan region (thus, **Keshan disease**)) with low soil selenium concentrations.

Kashin-Beck Disease. **Kashin-Beck disease** is type of severe arthritis is described in parts of China and neighboring areas of Russia where soil selenium is particularly low.

Artificial Nutrition. Inadequate selenium provision in specialized diets used to treat inborn errors and during long-term parenteral nutrition has led to cases of deficiency. Symptoms of severe deficiency include muscle weakness. Cases involving cardiomyopathy, which is usually fatal and resembles Keshan disease, and macrocytosis and pseudoalbinism in children have been described.

Marginal Deficiencies

T yroid Function. Selenium and other trace elements are necessary for normal thyroid function because the important deiodinase enzymes are selenoproteins. Endemic thyroid disease in Zaire may be related to the combined depletion of iodine and selenium. Care must be taken in giving selenium supplementation under such circumstances because stimulation of thyroid hormone metabolism may induce hypothyroidism.

Immune Function. Deficiency of selenium is accompanied by loss of immunocompetence and this is related to the reduction of selenoproteins in the liver, spleen, and lymph nodes. Both cell-mediated immunity and B-cell function are impaired.

Reproductive Disorders. Adequate selenium supply is necessary for successful reproduction in a variety of farm animals. Male fertility in man may be affected by selenium depletion because selenium is necessary for testosterone synthesis and for maintenance of sperm viability.

Mood Disorders. Marginal selenium depletion has been associated with (1) anxiety, (2) confusion, and (3) hostility, and improvements have been claimed following supplementation.

Inf ammatory Conditions. Many conditions associated with inflammation and increased oxidative stress may be influenced by selenium status. Positive effects have been reported following supplementation in arthritis, in pancreatitis, and in intensive care.

Viral Virulence. An unusually virulent strain of the Coxsackie virus is probably part of the cause of cardiomyopathy in selenium-depleted regions of China. T is is consistent with seasonal variations in the incidence of disease. In laboratory studies, a nonlethal form of Coxsackie B (CVB 3/O) mutated to a virulent strain when inoculated into selenium-deficient mice, probably as a result of oxidative stress. Further animal studies have demonstrated that a mild strain of influenza virus exhibits increased virulence when given to selenium-deficient mice. T e relevance of these study findings for humans needs to be established.

Cancer Chemoprevention. Epidemiological surveys have found a link between cancer incidence and soil selenium content, suggesting a higher incidence of certain cancers in individuals with low selenium intake. Large-scale trials in China on people at high risk for viral hepatitis B and liver cancer demonstrated that selenium-enriched table salt led to a reduced incidence of liver cancer of 35%.

For some years, it was hoped that selenium supplementation above the minimum dietary requirement may have a role in cancer prevention, particularly in relation to prostatic cancer. However, the large selenium and vitamin E cancer prevention study known as the Selenium and Vitamin E Cancer Prevention Trial (SELECT) reported and concluded that selenium or vitamin E, alone or in combination at the doses and formulations used, did not prevent prostate cancer in this population of relatively healthy men.

Toxicity

Soil in areas of China and the United States includes large amounts of selenium, and locally produced food contains excess selenium. Clinical signs of selenosis are (1) garlic odor in the breath, (2) hair loss, and (3) nail damage. T e tolerable upper limit has been set at 400 μg/d for adults and less for children.

Laboratory Assessment of Status[1]

Carbon furnace atomic absorption spectroscopy (CFAAS) is widely used to measure plasma and/or serum selenium, although ICP-MS, without the need for dynamic cell reaction to remove polyatomic interference from argon mass 80, is probably the preferred procedure in routine laboratories.

T e main components of plasma selenium are extracellular GSHPx-3 and selenoprotein P. Red cell GSHPx-1 and plasma GSHPx-3 are assayed by enzymatic methods, and tertiary-butyl peroxide is a commonly used substrate because it is not as affected by catalase as is hydrogen peroxide.

After 1 year on TPN without selenium supplements, patients have low plasma selenium and red cell GSHPx. With

replacement of selenium as selenious acid, a rapid increase in GSHPx-3 is seen within the first 24 hours, and normal concentrations are reached within 1 to 2 weeks. Red cell GSHPx takes 3 to 4 months to recover, consistent with the need for formation of these cells in the presence of selenium.

The major selenium-containing plasma protein selenoprotein P is determined by immunological methods. Selenoprotein P concentration in plasma responds rapidly to supplementation.

Plasma selenoprotein P, plasma GSHPx-3, and total plasma selenium concentrations are all lowered by the SIRS to injury or infection. This effect should be considered when plasma selenium values in postoperative patients or those with infection or inflammatory disease are considered.

Urine selenium output is mainly a reflection of recent dietary input and has not been extensively employed in population surveys. Hair and nail selenium analysis has been used as a measure of long-term dietary selenium intake.

In practice, measurements of plasma selenium and GSHPx provide a good estimate of status, in particular the adequacy of recent intake, provided they are interpreted with knowledge of changes in the SIRS, with red cell GSHPx providing an index of long-term intake.

Reference Intervals

The reference interval for selenium in (1) whole blood, (2) plasma, (3) serum, (4) hair, and (5) nails should be established locally because these indices are affected by dietary selenium intake. Plasma selenium adult values lie in the interval from 63 to 160 µg/L (0.8 to 2.0 µmol/L). Values less than 40 µg Se/L (0.5 µmol/L) indicate probable selenium depletion.

Values in children are lower and in the United Kingdom are as follows: 16 to 71 µg/L (0.2 to 0.9 µmol/L) for those younger than 2 years old; 40 to 103 µg/L (0.5 to 1.3 µmol/L) for 2- to 4-year-olds; and 55 to 134 µg/L (0.7 to 1.7 µmol/L) for 4- to 16-year-olds. Cut-off values less than 8 µg/L (0.1 µmol/L) in neonates are strongly suggestive of selenium depletion. Increased plasma values are found in suspected selenium toxicity, and results greater than 5 µmol/L (400 µg/L) indicate excessive intake.

In cases of toxicity (selenosis), serum concentrations were as high as 1400 µg/L with no obvious effects, and acute fatal poisonings were seen with selenium at up to 30,000 µg/L. However, the nature of the selenium compound is important, as most reports that describe acute selenium poisoning involve ingestion of inorganic compounds such as selenious acid, which is found in gun-bluing agents, and fatalities that occur within the first day are associated with postmortem blood selenium concentrations greater than 1400 µg/L.

Red cell GSHPx-1 activity in adults ranges from 13 to 25 U/g Hb, whereas values in children are slightly lower. Local age-related reference intervals are again required.

Zinc

The discovery of a variety of zinc-related clinical disorders has directly demonstrated the importance of zinc in human nutrition. It is second to iron as the most abundant trace element in the body.

Chemistry

Zinc (atomic number 30, relative atomic mass 65.39) is a particularly stable ion. Zinc is a good electron acceptor (strong Lewis acid) that has no redox reactions. It has been hypothesized that zinc ions, present in the cytoplasm at 10^{-11} mol/L and in equilibrium with numerous zinc metalloenzymes and transcription factors, act as a "master hormone," particularly in relation to cell division and growth.

Dietary Sources

Zinc is widely distributed in food, mainly bound to proteins. The bioavailability of dietary zinc is dependent upon digestion of these proteins to release zinc and allow it to bind to (1) peptides, (2) amino acids, (3) phosphate, and (4) other ligands within the intestinal tract. The most available dietary sources of zinc are red meat and fish. Wheat germ and whole bran are good sources, but their zinc content is reduced by milling and food processing. The median intake for men in the United States is about 14 mg/d and for women 9 mg/d.

Absorption, Transport, Metabolism, and Excretion

The net intestinal uptake of zinc is regulated by control of absorption efficiency and varies from 20% to 50% of the dietary content. At an intake of 12.2 mg Zn per day, the fractional absorption is 26%, but at the very low intake of 0.23 mg Zn per day, this has been shown to increase to 100%. Interaction with other dietary constituents, such as (1) phytate, (2) fiber, (3) calcium, and (4) iron, reduces the net absorption of zinc.

Iron at supplemental dosages (up to 65 mg/d) may decrease zinc absorption, so that pregnant and lactating women taking iron may require zinc supplementation.

New insights into mammalian zinc metabolism have been acquired through the identification and characterization of zinc transporters. All of these proteins have transmembrane domains and are encoded by two solute-linked carrier (SLC) gene families: ZnT (SLC30) and Zip (SLC39). At least 9 ZnT and 15 Zip transporters are present in human cells. They appear to have opposite roles in cellular zinc homeostasis. ZnT transporters reduce intracellular zinc availability by promoting zinc efflux from cells or into intracellular vesicles; Zip transporters increase intracellular zinc availability by promoting extracellular zinc uptake and, perhaps, vesicular zinc release into the cytoplasm.

Both ZnT and Zip transporter families exhibit (1) unique tissue-specific expression, (2) differential responsiveness to dietary zinc deficiency and excess, and (3) differential responsiveness to physiological stimuli via hormones and cytokines.

Absorbed zinc is transported to the liver, where active incorporation into metalloenzymes and plasma proteins occurs. About 80% of plasma zinc is associated with albumin, and most of the rest is tightly bound in α_2-macroglobulin. Zinc is present on albumin in equilibrium with plasma amino acids (mostly histidine and cysteine), and this small (<1%) ultrafilterable fraction may be important in cellular uptake mechanisms (Figure 27-22).

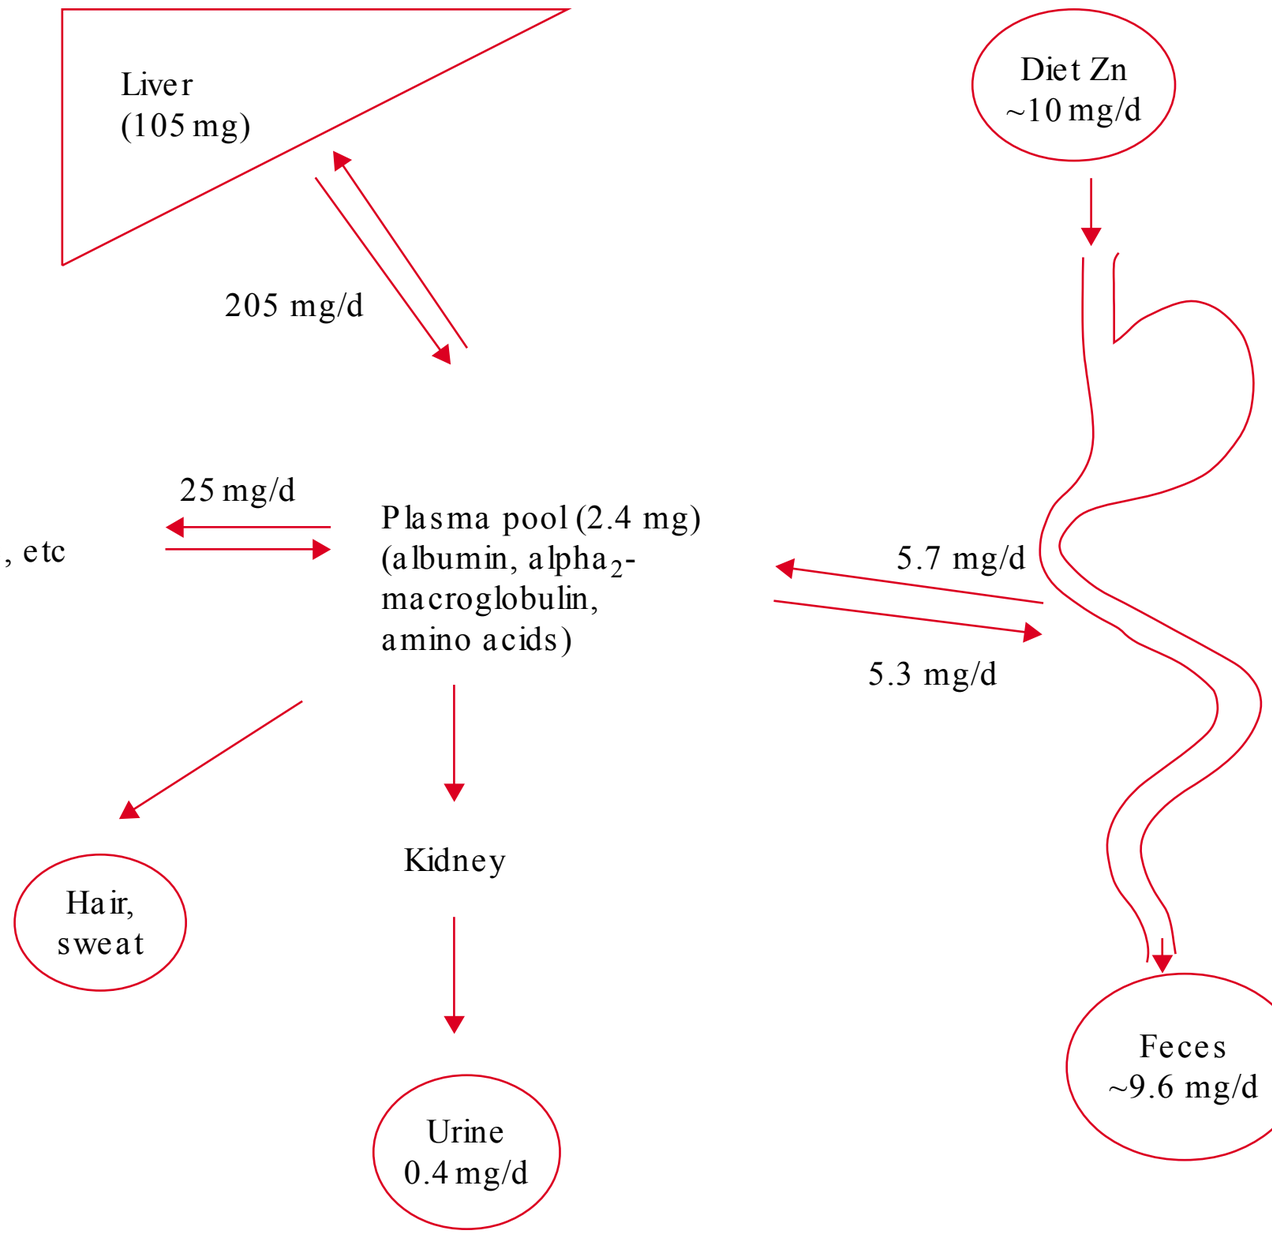

Figure 27-22 Summary of zinc metabolism.

Total adult body content of zinc is about 2 to 2.5 g, and the metal is present in the cells of all metabolically active tissues and organs. About 55% of the total is found in muscle, and approximately 30% in bone. Red cell zinc concentration is about 10 times higher than in plasma because of the large amounts of carbonic anhydrase.

Zinc binding to the metal-regulatory transcription factor 1 (MTF1) activates metallothionein (Mt) expression. T is multifunctional, protein (9000 to 10,000 Da) has a high content of cysteine and reversibly binds zinc. Mt is important in intracellular zinc trafficking and helps to maintain intracellular zinc concentrations. Hepatic synthesis of Mt is induced by interleukin-1, interleukin-6, and glucocorticoids in response to (1) infection, (2) trauma, and (3) other stressors.

Fecal excretion includes both unabsorbed dietary zinc and zinc resecreted into the gut. Urine output of zinc is normally only about 0.5 mg/d but increases greatly during catabolic illness and ketosis. Release of intracellular contents from skeletal muscle has been established as the source of excess urinary zinc.

Functions

More than 300 zinc metalloenzymes are present in all six categories of enzyme systems. Important examples in human tissue include (1) carbonic anhydrase, (2) alkaline phosphatase, (3) RNA and DNA polymerases, (4) thymidine kinase carboxypeptidases, and (5) alcohol dehydrogenase. T e key role of zinc in protein and nucleic acid synthesis explains the failure of growth and impaired wound healing observed in individuals with zinc deficiency.

Proteins form domains that are able to bind tetrahedral zinc atoms by coordination with histidine and cysteine to form folded structures known as "**zinc fingers**." T ese have important roles in gene expression by acting as DNA-binding transcription factors and play a key role in developmental biology and in the regulation of (1) steroid, (2) thyroid, and (3) other hormone synthesis.

Prostate Function. Secretion by the prostate of large amounts of zinc (resultant concentration, 1 to 2 mmol/L) is key to the function of sperm, maintaining both vitality and an antibacterial environment. T e mechanism of this aspect of zinc function is regulation of motility through interaction of Zn^{2+} ions with semenogelin (Sg1) during semen coagulum formation at ejaculation, as well as during liquefaction of the coagulum in the female reproductive tract. Studies have implicated seminal Zn with parameters of semen quality, in that decreased seminal Zn is considered a risk factor for sperm abnormality and idiopathic male infertility, and smokers in particular are susceptible to Zn deficiency in their seminal fluid. Poor Zn nutrition may therefore be a risk factor for low quality of sperm and idiopathic male infertility. Routine determination of Zn concentrations during infertility investigation is recommended.

Seminal plasma zinc concentrations are normal in chronic prostatitis and adenoma, whereas with prostatic neoplasm, a highly significant decrease (100-fold) in zinc secretion has been noted. Prostate cancer cells do not secrete zinc because they have a reduced capacity for accumulation of intracellular zinc caused by the decrease in ZIP1 protein expression and the intracellular redistribution of intracellular transporter ZIP3.

T ese neoplastic cells are extremely sensitive to the Zn^{2+} ion; direct tumor injection causes marked cell death and therefore may represent a possible chemoprevention therapy.

Requirements and Reference Nutrient Intakes[6]

In the United States, the dietary reference intake (DRI) for zinc is 11 mg/d for men and 8 mg/d for women. Infants and young children need smaller amounts. Strict vegetarians may need as much as 50% more zinc per day because of the increased phytic acid and fiber in their diet.

Clinical Def ciency

As might be expected from the multiple biochemical functions of zinc, the clinical presentation of deficiency disease is (1) varied, (2) nonspecific, and (3) related to the degree and duration of depletion. Signs and symptoms include (1) depressed growth with stunting; (2) increased incidence of infection, possibly related to alterations in immune function; (3) diarrhea; (4) skin lesions; and (5) alopecia.

Ef ects on Growth. Dietary zinc deficiency is prevalent in countries worldwide where a cereal-based diet high in phytate and fiber, but low in animal protein, is common. In children, reduced growth and other developmental abnormalities are reversible by zinc supplementation. Zinc in human breast milk is efficiently absorbed because of the presence of factors such as picolinate and citrate.

Acrodermatitis Enteropathica. Acrodermatitis enteropathica (AE) is characterized by (1) periorificial and acral dermatitis, (2) alopecia, and (3) diarrhea; symptoms are reversed by oral zinc supplementation. T is formerly fatal condition is an autosomal recessive inborn error that affects zinc absorption from the intestinal mucosa via mutation of the SLC39a4 gene on chromosome 8 q24.3, which encodes a transporter for zinc uptake.

Parenteral Nutrition. Some patients who require intravenous feeding after surgery are likely to be significantly zinc depleted because of poor oral intake before and after surgery. T ey may have increased zinc losses from the intestinal tract via diarrhea and in the urine from catabolism of muscle during periods of negative nitrogen balance. Other problems include (1) diarrhea, (2) mental depression, (3) dermatitis, (4) delayed wound healing, and (5) alopecia that may be seen during the anabolic period of weight regain, when zinc in the nutritional regimen is insufficient to support tissue repair. Provision of adequate zinc intravenously to achieve a positive zinc balance is associated with improvement in nitrogen balance.

Infectious Disease. Zinc depletion impairs immunity and has a direct effect on the gastrointestinal tract, which increases the severity of enteric infections. A review of controlled trials of zinc supplementation for children in low-income countries found significant clinical benefit in cases of persistent diarrhea and respiratory disease. Interaction with vitamin A is important because in populations at risk of zinc and vitamin A deficiency, provision of zinc alone increases the incidence of respiratory infection, but when vitamin A is added, respiratory infections are decreased.

Subclinical Effects of Def ciency

When zinc deficiency is not severe enough to cause clinical signs and symptoms, it may still have a subclinical effect on (1) immune function, (2) synthesis and action of hormones, and (3) neurological function.

Immune Function. Patients in the Middle East with zinc deficiency were known to die before the age of 25 because of various infections and parasitic diseases. With zinc deficiency, a reduction is seen in the activity of serum thymulin, the thymus-specific hormone that is involved in T-cell function, and an imbalance develops between Th1 and Th2 helper cells. The lytic activity of natural killer cells also decreases. These complex changes result in impairment of cell-mediated immunity.

Hormones. Zinc has a role in the synthesis and actions of many hormones via zinc transcription factors. Zinc depletion is associated with low circulating concentrations of (1) testosterone, (2) free T_4, (3) insulin-like growth factor (IGF)-1, and (4) thymulin. Both plasma IGF-1 and growth velocity are increased in zinc-supplemented children.

Neurological Ef ects. Severe zinc deficiency is known to affect mental well-being; varying degrees of confusion and depression are consistent with the important activity of zinc enzymes in brain development and function.

Zinc has been shown to be a neurosecretory product or cofactor and is highly concentrated in the synaptic vesicles of a specific contingent of neurons, called zinc-containing neurons. Zinc in the vesicles probably exceeds 1 mmol/L in concentration and is only weakly coordinated with any endogenous ligand. Zinc-containing neurons are found almost exclusively in the forebrain, where in mammals they have evolved into a complex and elaborate associational network that interconnects most of the cerebral cortices and limbic structures. Alterations in zinc homeostasis may be associated with brain dysfunction, including brain inflammatory status. Zinc ion dyshomeostasis may play a role in the aging neuron through deterioration of synapses.

Toxicity

Clinical effects of ingestion of a zinc-contaminated diet include (1) abdominal pain, (2) diarrhea, (3) nausea, and (4) vomiting. More than 60 mg Zn per day has been known to result in copper depletion by causing blockade of intestinal absorption.

Laboratory Assessment of Status

Although plasma zinc determination is insensitive to dietary zinc intake and subject to a variety of influences, it remains the most widely used laboratory test to confirm severe deficiency. It is also used to monitor adequacy of zinc provision, especially when interpreted together with changes in serum albumin and the SIRS. No laboratory procedures have been established to clearly identify populations with marginal zinc depletion. Clinical and biochemical responses to zinc supplementation are therefore used to postulate a marginally zinc-depleted state.

Plasma Zinc. Plasma samples are preferred to serum samples for zinc analysis because of possible zinc contamination

from (1) erythrocytes, (2) platelets, and (3) leukocytes during clotting and centrifugation. Plasma zinc concentrations are most commonly measured by CFAAS.

Care has to be taken in controlling preanalytical factors that will lower plasma zinc independently of dietary intake. T ese include collection of sample in relation to (1) meals, (2) time of day, and (3) use of steroid-based medications, such as the contraceptive pill. Any cause of hypoalbuminemia will lower plasma zinc. Plasma albumin is a negative acute-phase protein that is redistributed into interstitial spaces from the plasma pool (1) during infection, (2) after trauma, and (3) in chronic disease. Induction of hepatic Mt synthesis during the SIRS and subsequent sequestering of zinc further lower the plasma concentration. It is therefore essential to consider plasma zinc results along with plasma albumin and plasma CRP or another marker of the SIRS.

Blood Cell Zinc. It has been suggested that the zinc content of white cells and platelets better reflects tissue zinc. T e zinc content of (1) neutrophils, (2) lymphocytes, and (3) platelets has been shown to decline more rapidly than plasma zinc in experimental studies of zinc depletion in humans. However, the relatively large volume of blood required and problems with contamination make application to patients in the hospital or to population surveys difficult.

Zinc in Hair. Low hair zinc has been associated with poor growth in children. However, variables such as hair growth rate and external contamination from hair dyes and cosmetics have caused inconsistent results.

Zinc-Dependent Enzymes. Despite the large number of zinc metalloenzymes that have been identified, no single enzyme assay has yet found acceptance as an indicator of zinc status.

Urine Zinc. A slight fall in the urinary excretion of zinc has been noted during dietary deficiency. Difficulties of sample contamination during collection limit the practical value of this information.

Zinc Speciation

Relatively few studies have explored the actual chemical species present in physiological fluids. However, studies on wound fluids regarded as an important site of zinc wound healing have revealed complex interactions. Most Zn ions were present as charged species, and the major species was a citrate complex.

Reference Intervals

Serum zinc concentrations are generally 5% to 15% higher than those of plasma because of osmotic fluid shifts from the blood cells when anticoagulants are used. Concentrations are decreased after food and are higher in the morning than in the evening. A guidance reference interval is 80 to 120 μg/dL (12 to 18 μmol/L).

Other Possibly Essential Elements

More than 15 additional trace elements are considered to have a potentially important role in human medicine.

Other trace metals to consider include (1) lead, (2) cadmium, (3) arsenic, (4) aluminum, and (5) nickel, primarily as toxic elements (see Chapter 32). Others, such as (6) lithium and (7) fluoride, are classified as pharmacologically beneficial, and monitoring of dosage may be required. Some elements are considered "nutritionally beneficial" and are reported to produce "restorative health effects" at lower dosages. Evidence is derived mainly from animal studies, when dietary depletion of the element is combined with other metabolic, hormonal, or physiological "stressors."

For (8) boron, (9) silicon, and (10) vanadium, measurable responses in humans have been observed during variations in the dietary intake of these elements. T ese and other elements have been promoted by the supplement industry, and the clinical chemist may be asked for advice and possibly for monitoring of dosage in cases of suspected toxicity. AAS, ICP-OES, and ICP-MS methods have been used to measure most of these elements in biological samples.

Contamination of TPN solutions by small quantities of metals, such as Al, Pb, Cd, and Ni, could be a problem, as could the lack of others, such as Si, B, and V, when very long-term nutritional support is required.

Boron

Boron (B) has not been officially designated as essential to human health, although it is considered an essential macronutrient for plants.

Function

Boron normally present in living organisms as the borate ion (BO_3^{3-}) does have essential properties in plants that affect cell wall integrity. However, it still is not known to have any specific physiological function in humans, although various studies have suggested that it may be a beneficial bioactive element.

Dietary Sources

It is thought that the acceptable safe range of boron intake is from 1 to 13 mg/d, and evidence suggests that some people are consuming less than 1 mg/d. Plant foods, especially (1) fruits, (2) leafy vegetables, (3) nuts, and (4) legumes, are good sources, whereas meat, fish, and dairy products are not. Average daily intakes of dietary boron in the United Kingdom are variable (2.8 ± 1.5 mg), and intakes are higher than in the United States (1.5 ± 0.4 mg).

Absorption, Transport, Metabolism, and Excretion

Dietary boron is efficiently absorbed as boric acid—$B(OH)_3$—and is efficiently excreted into urine, with about 85% to 100% of an oral dose of borate appearing in urine over a 5- to 7-day period. T e oral toxicity of boron is relatively low; it has been estimated that safe population mean intakes are <13 mg/d, and that individuals are at risk of toxicity when intakes continually exceed 100 mg/d for up to 6 days. T e richest food sources of boron are nuts and dried fruits (15 to 30 mg/kg) and wine (8.5 mg/L). T e use of boric acid food additives is now prohibited, except for caviar, at 4000 mg/kg.

Laboratory Assessment of Status

Problems with contamination and loss of volatile boron compounds during sample preparation have limited the

reliable documentation of boron concentrations in human tissue and body fluids. A complex technique involving a porous graphite column—inductively coupled plasma–atomic emission spectrophotometry (ICP-AES)—and an ICP time-of-flight mass spectrometer (TOF-MS) has been developed for investigation of boron neutron capture in cancer therapy.

Normal concentrations in plasma of less than 30 µg/L were established by ICP-AES—the recommended procedure for assay because of the low atomic mass (10) of boron. Excretion in urine is normally less than 1 mg/d and up to 5 mg/L with boron intake of 0.33 to 3.33 mg/d.

Silicon

Silicon (Si) is a nonmetallic element that has an atomic weight of 28; it is a member of group IV C, Si, Ge, etc. Similar to elements in this group, it forms tetrahedral types of complexes and a multitude of polymer types. Silica is the term used to refer to the naturally occurring materials composed principally of silicon dioxide. The term silicone refers to any of a large group of siloxane polymers that do not occur naturally and are based on the structure of alternating oxygen and silicon (…-Si-O-Si-O-Si-O-…), with organic side groups attached to the four-coordinate silicon atoms. In some cases, organic side groups are used to link two or more of these -Si-O- backbones. Through variations in -Si-O- chain lengths, side groups, and cross-linking, silicones with a wide variety of properties and compositions have been synthesized. These compounds have a variety of uses from parchment coatings to sealant and breast implants.

Dietary Sources

Soluble silica (orthosilicic acid) is ubiquitous in the diet (20 to 50 mg Si/d) and in natural waters (0.8 to 44 mg Si/L), and, unlike crystalline silica (quartz), has no associated toxicity. Silicon is widely distributed in plants and is an essential element for structural integrity. Amorphous silica is incorporated as an anticaking agent at concentrations up to 2% in a variety of foods. Beer can also be rich in silicon with content up to 20 mg/L. No values have been suggested for the recommended intake of silicon.

Absorption, Transport, Metabolism, and Excretion

Absorption of silicon seems to be dependent on its polymeric nature; the smaller the molecule (i.e., monomeric orthosilicic acid), the more effective is absorption, whereas the larger polymer forms are poorly absorbed. The efficiency of absorption is up to 60% of an ingested load, with most excreted renally within 24 hours of exposure. As yet, little evidence suggests retention in any tissue-specific site.

Function and Clinical Significance

In veterinary and laboratory animals, silicon has been shown to be important in the synthesis of collagen and bone. The few supplementation studies in humans have reported associated increases in trabecular bone volume and bone mineral density.

Laboratory Assessment of Status

Healthy fasting plasma concentrations of silicon are less than 12 µmol/L. These concentrations are elevated in renal failure, particularly in patients on hemodialysis, to above 150 µmol/L and higher, depending on the content of dialysis water. Urine silicon excretion depends on intake and varies from 100 to 1000 µmol/24 h. Toxicity from silicon has never been reported, although increased concentrations (>3 mmol/L) have resulted in the formation of silica stones.

Vanadium

Vanadium, a group V trace element that belongs to the first transition series of elements, is ubiquitously distributed. It exists in four valency states—2, 3, 4, and 5; thus, its chemistry is complex. Vanadium is found in neutral solutions as metavanadate (V_3^-), the predominant species in body fluids, and enters cells through an anion transport system. Exogenously administered vanadyl sulfate and ammonium vanadate have been found to bind serum transferrin tightly, indicating that this protein may serve as a vanadium transporter. Although the vanadium requirement of some organisms has been established, its essential value in humans remains to be proved.

Although most foods contain low concentrations of vanadium (<1 ng/g), food is the major source of exposure to vanadium for the general population; however, absorption of vanadium salts from the gastrointestinal tract is poor. Excretion of vanadium by the kidneys is rapid, with its biological half-life of 20 to 40 hours. Estimated daily intake of the U.S. population ranges from 10 to 60 µg. Vanadyl sulfate is a supplement that is commonly used to enhance weight training in athletes at doses up to 60 mg/d. Most of the toxic effects of vanadium compounds result from local irritation of the eyes and upper respiratory tract, rather than from systemic toxicity.

Functional Aspects

Vanadium plays a limited role in biology. Nevertheless a vanadium-containing nitrogenase is used by some nitrogen-fixing microorganisms. Clinical interest in the vanadate compounds involves their potential role in the treatment of diabetes. Various studies have suggested that these compounds reduce the requirement for insulin by activating the cellular response without the presence of insulin, in effect mimicking its action.

Amounts given in such trials are much greater than suggested normal intake, indicating that vanadium compounds are more likely to work as alternative therapies, rather than revealing the essential function of the element. The possibility of using vanadium compounds is focused on cytotoxicity and cancer treatment.

Assessment of Laboratory Status

Plasma and urine concentrations are usually measured by GF-AAS or ICP-AES. Use of ICP-MS revealed a number of urinary vanadium compounds of 1 to 10 µg/L in healthy volunteers. Detection of the vanadate ion using size exclusion chromatography coupled with ICP-MS with a dynamic reaction cell yielded normal serum concentrations less than 0.05 µg/L. Studies on

high-resolution ICP-MS also showed whole blood concentrations close to the detection limit of less than 0.05 µg/L, indicating that careful sampling techniques are required for confident use of analyzed concentrations.

Review Questions

Match the vitamin in column A with its correct function in column B.

A	B
1. Ascorbic acid	a. red blood cell protection
2. Folic acid	b. antihemorrhagic activity
3. Phylloquinone	c. coenzyme activity
4. Tocopherol	d. nucleic acid synthesis
5. Niacin	e. collagen synthesis

6. Thiamine:
   a. is considered a fat-soluble vitamin.
   b. deficiency is referred to as pellagra.
   c. functions in oxidative decarboxylation reactions.
   d. is also referred to as vitamin B_{12}.
7. A vitamer:
   a. is an essential organic micronutrient that must be supplied exogenously.
   b. is any of a number of compounds that possess a given vitamin activity.
   c. is a natural reactant, usually either a metal ion or a coenzyme, that is required in an enzyme-catalyzed reaction.
   d. is an inorganic molecule that is found in human and animal tissues in milligram per kilogram amounts.

Match the trace element in column A with its correct function listed in column B. Answers may be used once, more than once, or not at all.

A	B
8. Molybdenum	a. role in glucose tolerance
9. Cobalt	b. structural component of vitamin B_{12}
10. Zinc	c. cofactor in electron transfer reactions
11. Chromium	d. normal growth and development
12. Manganese	

13. Ultratrace elements:
   a. are those elements found in ng/dL concentrations in body fluids and in µg/kg concentrations in tissue.
   b. include retinol, iron, and chromium, for example.
   c. are inorganic molecules found in human and animal tissues in mg/kg amounts or less.
   d. are organic micronutrients that must be supplied exogenously.
14. Fat-soluble vitamins include:
   a. B and C vitamins only.
   b. vitamin B_{12} and folic acid.
   c. vitamins D and E only.
   d. vitamins A, D, E, and K.
15. Selenium:
   a. is a constituent of glutathione peroxidase that is associated with vitamin E.
   b. excess will induce copper deficiency by blocking copper absorption.
   c. toxicity results in neurological symptoms resembling Parkinson disease.
   d. stabilizes the regenerating tooth surface by binding the tooth enamel.

CHAPTER 28

Hemoglobin, Iron, and Bilirubin*

Trefor Higgins, F.C.A.C.B., John H. Eckfeldt, M.D., Ph.D., James C. Barton, M.D., and Basil T. Doumas, Ph.D.

Objectives

1. Define the following:
   - Bilirubin
   - Conjugated (direct) bilirubin
   - Ferritin
   - Hemochromatosis
   - Hemoglobin
   - Hemoglobinopathy
   - Hemosiderin
   - Hemosiderosis
   - Jaundice
   - Kernicterus
   - Thalassemia
   - Transferrin
   - Unconjugated (indirect) bilirubin
   - Urobilinogen
2. Describe the structure and physiological role of hemoglobin.
3. State the function of hemoglobin and its significance in health and disease.
4. List four different types of hemoglobin and state the makeup of the globin chains in each.
5. State the specific changes in the globin chain in deletional, insertion, deletion/insertion, and elongation hemoglobin variants.
6. List four different types of thalassemia and state the globin deficiency and genetic defect in each.
7. Compare the differences between hemoglobinopathy and thalassemia with regard to causes and laboratory values.
8. List five analytical methods used to assess the presence of a hemoglobinopathy or thalassemia.
9. Describe the principle of the cyanmethemoglobin method of hemoglobin determination.
10. Contrast ferritin with hemosiderin with regard to structure and solubility.
11. State how iron is transported in blood.
12. State how the regulation of body iron is achieved.
13. List three proteins that affect iron homeostasis and the effects of a deficiency of each of these.
14. State the two major disorders of iron metabolism.
15. List two causes of iron deficiency anemia in children and adults; list two causes of increased serum iron.
16. Compare the causes of primary, secondary, and juvenile hemochromatosis.
17. State the principle of chromogenic serum iron determination and the clinical significance of the results.
18. Define total iron-binding capacity (TIBC) and state how TIBC value is determined.
19. State and, given appropriate data, solve the formula used to calculate transferrin saturation (Tsat).
20. List three analytical methods used to assess serum ferritin and state the clinical significance of the results of these.
21. Compare the laboratory results of serum iron, TIBC and Tsat in the following conditions: ingestion of oral contraceptives, hepatitis, inflammation, iron deficiency, and hemochromatosis; describe how serum iron is affected by diurnal variation.
22. Describe the biochemistry of bilirubin including transport in blood, conjugation in the hepatocyte, and hydrolysis in the intestine.
23. List two inherited disorders of bilirubin metabolism and state the bilirubin alteration.
24. List and describe three causes of unconjugated hyperbilirubinemia in the neonate and two causes of conjugated hyperbilirubinemia in the neonate.
25. State the principle of the diazo method of total bilirubin analysis; state what is required in this reaction to measure direct bilirubin.

*The authors gratefully acknowledge the original contributions of Drs. Virgil F. Fairbanks and George G. Klee (hemoglobin and iron) and Drs. Keith G. Tolman and Robert Rej (bilirubin), on which portions of this chapter are based.

Key Words and Definitions

Biliary atresia A condition characterized by failure of a fetus to develop an adequate pathway for bile to drain from the liver to the intestine.

Bilirubin A yellow bile pigment that is a breakdown product of heme mainly formed from the degradation of erythrocyte hemoglobin in reticuloendothelial cells.

Carboxyhemoglobin A form of hemoglobin in which the sites usually bound to oxygen are bound to carbon monoxide.

Complete blood count (CBC) The determination of the quantity of each type of blood cell in a mL of blood, often including the amount of hemoglobin, the hematocrit, and the proportions of various white cells.

Conjugated bilirubin Bilirubin that has been taken up by the liver cells and conjugated to form the water-soluble bilirubin diglucuronide.

Crigler-Najjar syndrome An autosomal recessive form of nonhemolytic jaundice due to the absence of the hepatic enzyme glucuronosyltransferase.

Direct bilirubin The fraction of bilirubin that reacts with the diazo reagent in the absence of alcohol.

Dubin-Johnson syndrome An autosomal recessive disorder that causes an increase of conjugated bilirubin in the serum.

Ferritin The iron/apoferritin complex, which is one of the chief forms in which iron is stored in the body; it occurs in the (1) gastrointestinal mucosa, (2) liver, (3) spleen, (4) bone marrow, and (5) reticuloendothelial cells.

Gilbert syndrome An inborn error of bilirubin metabolism,

Heme Any quadridentate chelate of iron with the four pyrrole groups of a porphyrin, further distinguished as ferroheme or ferriheme, referring to the chelates of Fe(II) and Fe(III), respectively.

Hemin A porphyrin chelate of Fe^{3+} derived from red blood cells.

Hemochromatosis A rare genetic disorder caused by deposition of hemosiderin in the parenchymal cells, resulting in tissue damage and dysfunction of the liver, pancreas, heart, and pituitary. Also called iron overload disease.

Hemoglobin The oxygen-carrying pigment of the erythrocytes, formed by the developing erythrocyte in bone marrow. It is a conjugated protein containing four heme groups and globin, with the property of reversible oxygenation.

Hemoglobinopathy Any inherited disorder caused by abnormalities of hemoglobin, resulting in conditions such as sickle cell anemia, hemolytic anemia, or thalassemia.

Hemosiderin An intracellular storage form of iron; the granules consist of an ill-defined complex of ferric hydroxides, polysaccharides, and proteins having an iron content of about 33% by weight.

Hemosiderosis A focal or general increase in tissue iron stores without associated tissue damage. Hepatic and pulmonary forms of hemosiderosis are characterized by abnormal quantities of hemosiderin in the liver and lungs, respectively.

Hereditary hemochromatosis A genetically heterogeneous group of inherited disorders of iron metabolism characterized by failure to prevent excessive amounts of iron from entering the circulatory pool and accumulating in the tissues.

Hereditary persistence of fetal hemoglobin A condition characterized by continued production of fetal hemoglobin beyond the point when it is normally replaced by hemoglobin A

Hyperbilirubinemia Excessive concentrations of bilirubin in the blood, which may lead to jaundice; the hyperbilirubinemias are classified as conjugated or unconjugated, according to the predominant form of bilirubin in the blood.

Icterus A condition characterized by hyperbilirubinemia and deposition of bile pigments in the skin, mucous membranes, and sclera, with resulting yellow appearance of the patient; called also jaundice.

Indirect bilirubin Free bilirubin that has not been conjugated with glucuronic acid.

Jaundice A condition characterized by hyperbilirubinemia and deposition of bile pigment in the skin, mucous membranes, and sclera, with resulting yellow appearance of the patient; also called icterus.

Kernicterus A clinical syndrome of the neonate resulting from high concentrations of unconjugated bilirubin that passes the immature blood-brain barrier of the newborn and causes degeneration of cells of the basal ganglia and hippocampus.

Ligandin An hepatic transport protein; measurement of it in serum and urine may be a means of estimating the severity of hepatocellular necrosis.

Lucey-Driscoll syndrome A potentially fatal disorder characterized by severe hyperbilirubinemia present at birth, which accumulates in the brain.

Methemoglobin A form of hemoglobin where its iron atom is changed from the ferrous to the ferric state.

Myoglobin A heme-containing protein found in red skeletal muscle.

Rotor syndrome A type of chronic familial nonhemolytic jaundice that differs from Dubin-Johnson syndrome in the lack of liver pigmentation.

Sickle cell anemia An autosomal dominant type of hemolytic anemia that is caused by the presence of hemoglobin S with abnormal sickle-shaped erythrocytes (sickle cells).

Thalassemia A heterogeneous group of hereditary hemolytic anemias having a decreased rate of synthesis of one or more hemoglobin polypeptide chains and classified according to the chain involved (α, β, δ); the two major categories are α- and β-thalassemia.

Thalassemia major The homozygous form of β-thalassemia, a severe condition evident from the neonatal period with complete absence of hemoglobin A

Thalassemia minor The heterozygous form of β-thalassemia; it is usually asymptomatic, although hemoglobin A synthesis may be retarded and there is sometimes moderate anemia and splenomegaly.

Transferrin A beta globulin that carries iron in the blood.

Unconjugated bilirubin Free bilirubin that has not been conjugated with glucuronic acid.

Urobilinogen A colorless compound formed in the intestines by the reduction of bilirubin.

Hemoglobin (Hb), iron, and **bilirubin** are analytes that collectively may be viewed in terms of a manufacturing process in which the raw material (iron) is incorporated with other raw materials in a multistage complex process leading to a finished product (Hb).[16] The finished product has a limited life span, after which degradation into the waste product (bilirubin) occurs. Within this process, many exquisite (1) biochemical control, (2) conservation, and (3) synthesis mechanisms are found. For example, this process may be disrupted by (1) a deficiency in the supply of raw material, (2) lack of control or synthesis mechanisms, (3) excessive loss of finished product, or (4) excessive conversion to or deficiency in the elimination of waste products. These disruptions are manifest in the clinical disorders of (1) **hemoglobinopathies**, (2) **thalassemias**, (3) iron deficiency anemias, (4) liver disease, and (5) various genetic diseases.

Hemoglobin

Hemoglobin is the oxygen-carrying pigment of the erythrocytes that is formed by the developing erythrocyte in bone marrow. It is a conjugated protein containing four **heme** groups and globin (Figure 28-1), having the property of reversible oxygenation.

Chemistry

Hemoglobin is a hemoprotein, globular in shape with a diameter of 6.4 nm and a molecular weight of approximately 64,500 Da. The heme portion is an iron-containing chelate with the globin portion consisting of two pairs of polypeptide globin chains, designated α and non-α. The four globin chains form a thick-walled globular shell surrounding a central cavity, in which the heme portion, attached by interaction of the histidine residues of the globin chains to the iron in heme, is suspended (see Figure 28-1). The heme iron is normally in the ferrous (2^+) oxidation state.

The two pairs of globin chains in normal hemoglobin (HbA) are called α and β. The α-chain contains 141 amino acid residues and the β-chain 146 amino acid residues. In fetal hemoglobin, HbF, the α-chain is the same as that found in HbA, but the non-α chain is the γ-chain that has the same number of amino acid residues and substantial structural homology to the β-chain. HbA_2 has the usual α-chain, but the non-α chain is the δ-chain. By convention, the α-chain is always written first in abbreviations of hemoglobin structure. For example, HbA is written as $\alpha_2\beta_2$, HbF as $\alpha_2\gamma_2$, and HbA_2 as $\alpha_2\delta_2$. In normal adults, HbA forms about 85% to 95% of the total hemoglobin, HbF is less than 1%, and HbA_2 is less than 3.5%. Changes in the amino acid residue sequence of the globin chains (a qualitative change) lead to hemoglobinopathies, whereas decreases in globin chain production (a quantitative change) lead to thalassemias.

Chemically Modified Hemoglobins

Hemoglobin may be modified by attachment of chemicals to form chemically modified hemoglobins. Some of these chemically modified hemoglobins compromise the structural stability and/or functionality of hemoglobin. Carbon monoxide, for example, preferentially replaces oxygen from heme to form **carboxyhemoglobin**, compromising the oxygen-carrying ability of hemoglobin; in extreme cases, death results from the deprivation of oxygen to the tissue. **Methemoglobin** is formed as the result of a change in oxidation state of the iron atom in heme from the normal ferrous oxidation state (2^+) to the ferric (3^+) state, resulting in notably decreased oxygen-carrying ability. The presence of nitrate in well water has been known to cause methemoglobinemia. Sulfhemoglobin, commonly resulting from exposure to certain drugs, is formed when one or more oxygen atoms in the porphyrin rings of heme is replaced by sulfur. Removal of the source of the chemical leads to restoration of normal hemoglobin.

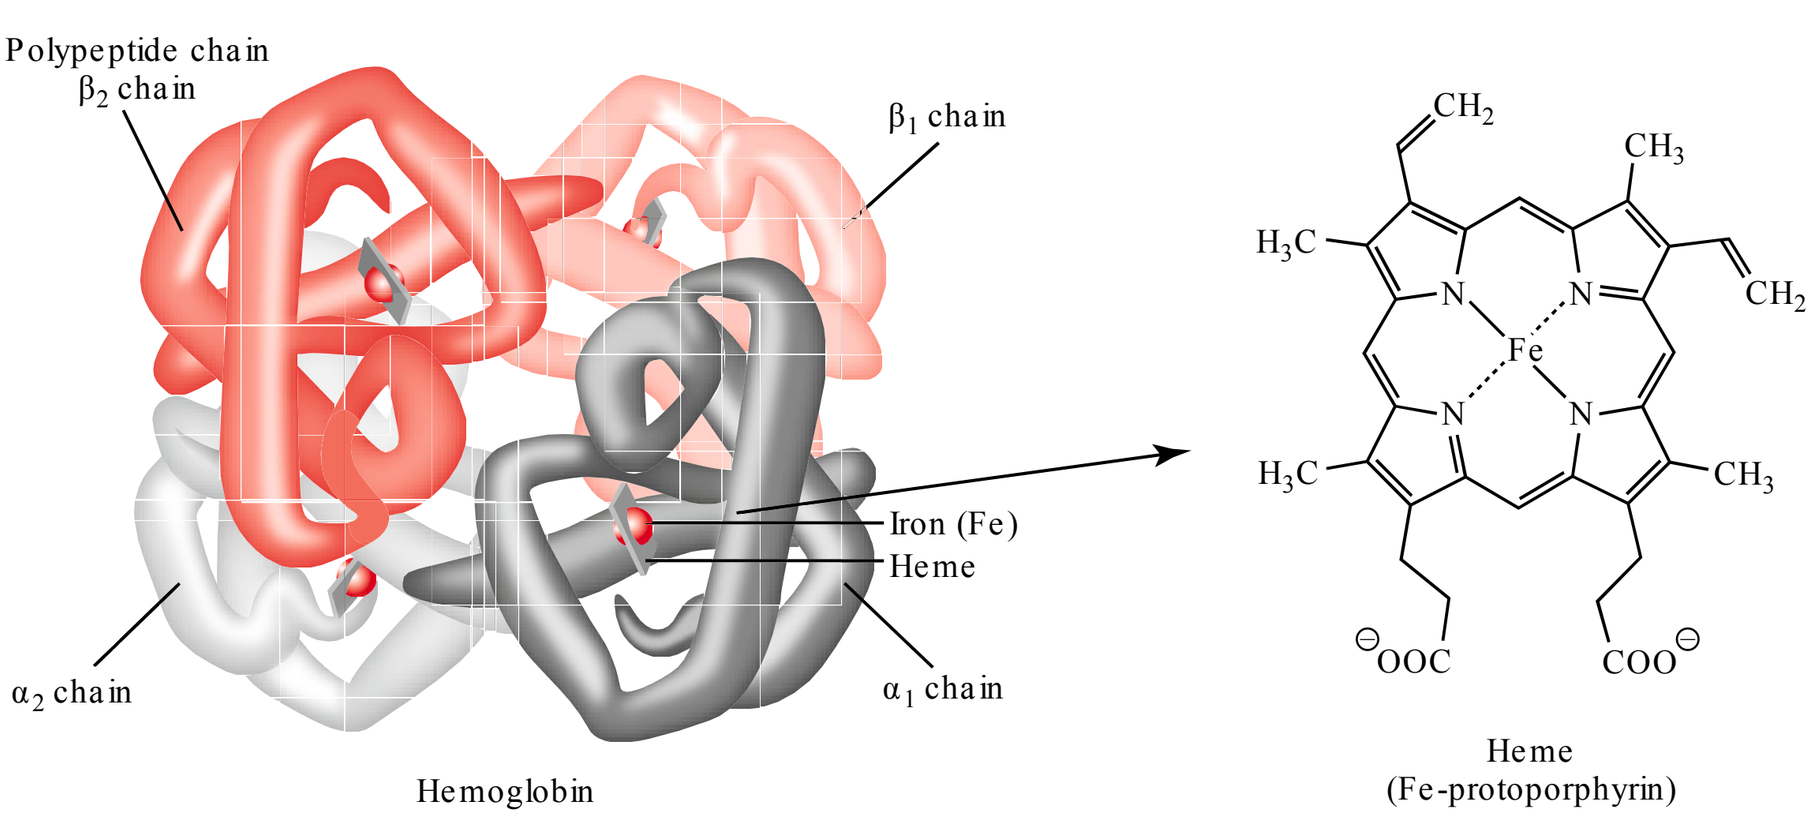

Figure 28-1 Model of the Hb tetramer with the α-chain subunits facing the reader. Each subunit contains a molecule of heme attached to an atom of iron.

Adduct hemoglobins are formed by the attachment of a molecule to the globin chains most commonly at the N-terminal amino acid, although it may occur anywhere along the globin chain. Carbamylated hemoglobin, seen in patients with end-stage renal disease, is formed by the attachment of urea, and glycated hemoglobin is formed by the attachment of glucose to the N terminus of the β-globin chain. The glycated hemoglobin adduct, HbA_{1c}, is important clinically in diagnosis and monitoring of glycemic control in patients with diabetes mellitus (see Chapter 33). Fetal hemoglobin (HbF, $\alpha_2\gamma_2$) is unique in that it may form an acetylated adduct. Heme, ferrous protoporphyrin IX, consists of four pyrrole rings surrounding an iron atom, with four of the six electron pairs of iron attached to the nitrogen atoms in the pyrrole rings (see Chapter 29).

Hemin results from the relatively easy oxidation of the iron of heme from the ferrous to the ferric state. To remain electrically neutral, a halide molecule, usually chloride, becomes attached to hemin. In alkaline solution, hematin is formed by replacement of the halide atom of hemin by a hydroxyl group.

Biochemistry

Heme is biosynthesized primarily in the bone marrow and the liver (see Chapter 29).

It is an eight-step process, with each step involving a different genetically controlled enzyme. The first and last three steps take place in the mitochondria of the erythroblasts and reticulocytes of the bone marrow. The middle four stages take place in the cytosol.

In common with all genes, the globin genes consist of exons (coding sequences) and introns (intervening noncoding sequences) with codons (triplets of nucleotides) coding for specific amino acids. The globin genes have three exons and two introns, with a promoter region (specific for the globin chain) at the 5′ end of each gene. The transcription and translation processes are the same as in any other synthesis of amino acid chains.

Physiological Role

The iron in heme is normally in the ferrous state (2^+) and is able to act as the major oxygen-carrying entity by combining reversibly with oxygen. Cooperativity is the term used to describe the interaction of globin chains in such a way that oxygenation of one heme group enhances the probability of oxygenation of another or all heme groups. The Bohr effect refers to the reduction in oxygen affinity to heme with a decrease in pH. This effect is particularly important in exercising muscle, where the products of anaerobic metabolism, CO_2, and carbonic acid lower the pH to 6, and release of the oxygen attached to heme is facilitated.

Clinical Significance

Thalassemias and hemoglobinopathies form two distinct disease groups of genetic origin.[9] Thalassemias originate from insufficient globin chain production. The name is derived from the Greek word for sea, thalasa, because all early cases of β-thalassemia were described in children of Mediterranean origin. Hemoglobinopathies, collectively, are structural hemoglobin variants arising from mutations in the globin genes and resulting in disruptions in the normal amino acid sequence in one, or more, of the globin chains of hemoglobin. They are the most common single gene disorder in the world.

Thalassemias

Thalassemias are identified according to the globin chain in which there is a production deficiency. For example, α-thalassemias arise from defective α-globin chain production, β-thalassemias from deficient β-globin chain production, and δβ-thalassemia from deficiencies in production of both δ- and β-globin chains. Thalassemias are further classified by the extent of the reduction in globin chain production and resultant anemia. Four globin genes control the production of α-globin, and deletions or point mutations in any of these genes result in α-thalassemia. The severity of the anemia is a reflection of the number of gene deletions. The diagnosis of α-thalassemia is often one of exclusion, with the presence of thalassemic indices in the **complete blood count (CBC)** and the absence of an elevation in the HbA_2 forming the basis for presumptive diagnosis of α-thalassemia. Confirmation by DNA testing is required for definitive diagnosis.

A single gene deletion written as (αα/α-), sometimes called silent α-thalassemia, is usually clinically silent and has no significant hematological feature other than occasionally marginally decreased mean corpuscular volume (MCV).

The two gene deletions, sometimes called α-thalassemia trait or α-thalassemia minor (written as αα/- or α-/α-), have significant clinical and hematological features. Indices that are all decreased include (1) MCV, (2) mean corpuscular hemoglobin (MCH), and (3) Mentzer index (MCV/red blood count). The peripheral blood smear shows a microcytic, hypochromic anemia. No abnormal peaks are noted on high-performance liquid chromatography (HPLC) or capillary electrophoresis, and no unusual bands on conventional electrophoresis. The deletion is said to be a cis deletion when the two deletions are found on the same gene locus (αα/-), and a trans deletion when they are on opposite gene loci (α-/α-).

A three α-gene deletion (-/αα-) results in HbH disease. However, a nondeletion HbH disease is seen, which is more severe in clinical presentation than the more typical deletion HbH disease. Patients with HbH disease have (1) low hemoglobin concentration, (2) decreased MCV, (3) decreased MCH, (4) a slightly raised red blood cell count, and (5) increased RDW. Iron studies are normal. The HPLC chromatogram, shown in Figure 28-2, shows the presence of sharp bands close to the injection point. HbH is noted as a distinct peak on capillary electrophoresis.

The four α-gene deletion, commonly called Hb Bart's hydrops *f*etalis, is incompatible with life without massive intrauterine and postnatal transfusion. Typically, mothers carrying a fetus with Hb Bart's present at about weeks 20 to 25 of gestation with manifestation of polyhydramnios. The hemoglobin concentration of the cord blood is greatly decreased for age, and hypoalbuminemia is present. HPLC analysis of cord blood, shown in Figure 28-2, shows a single sharp band at the

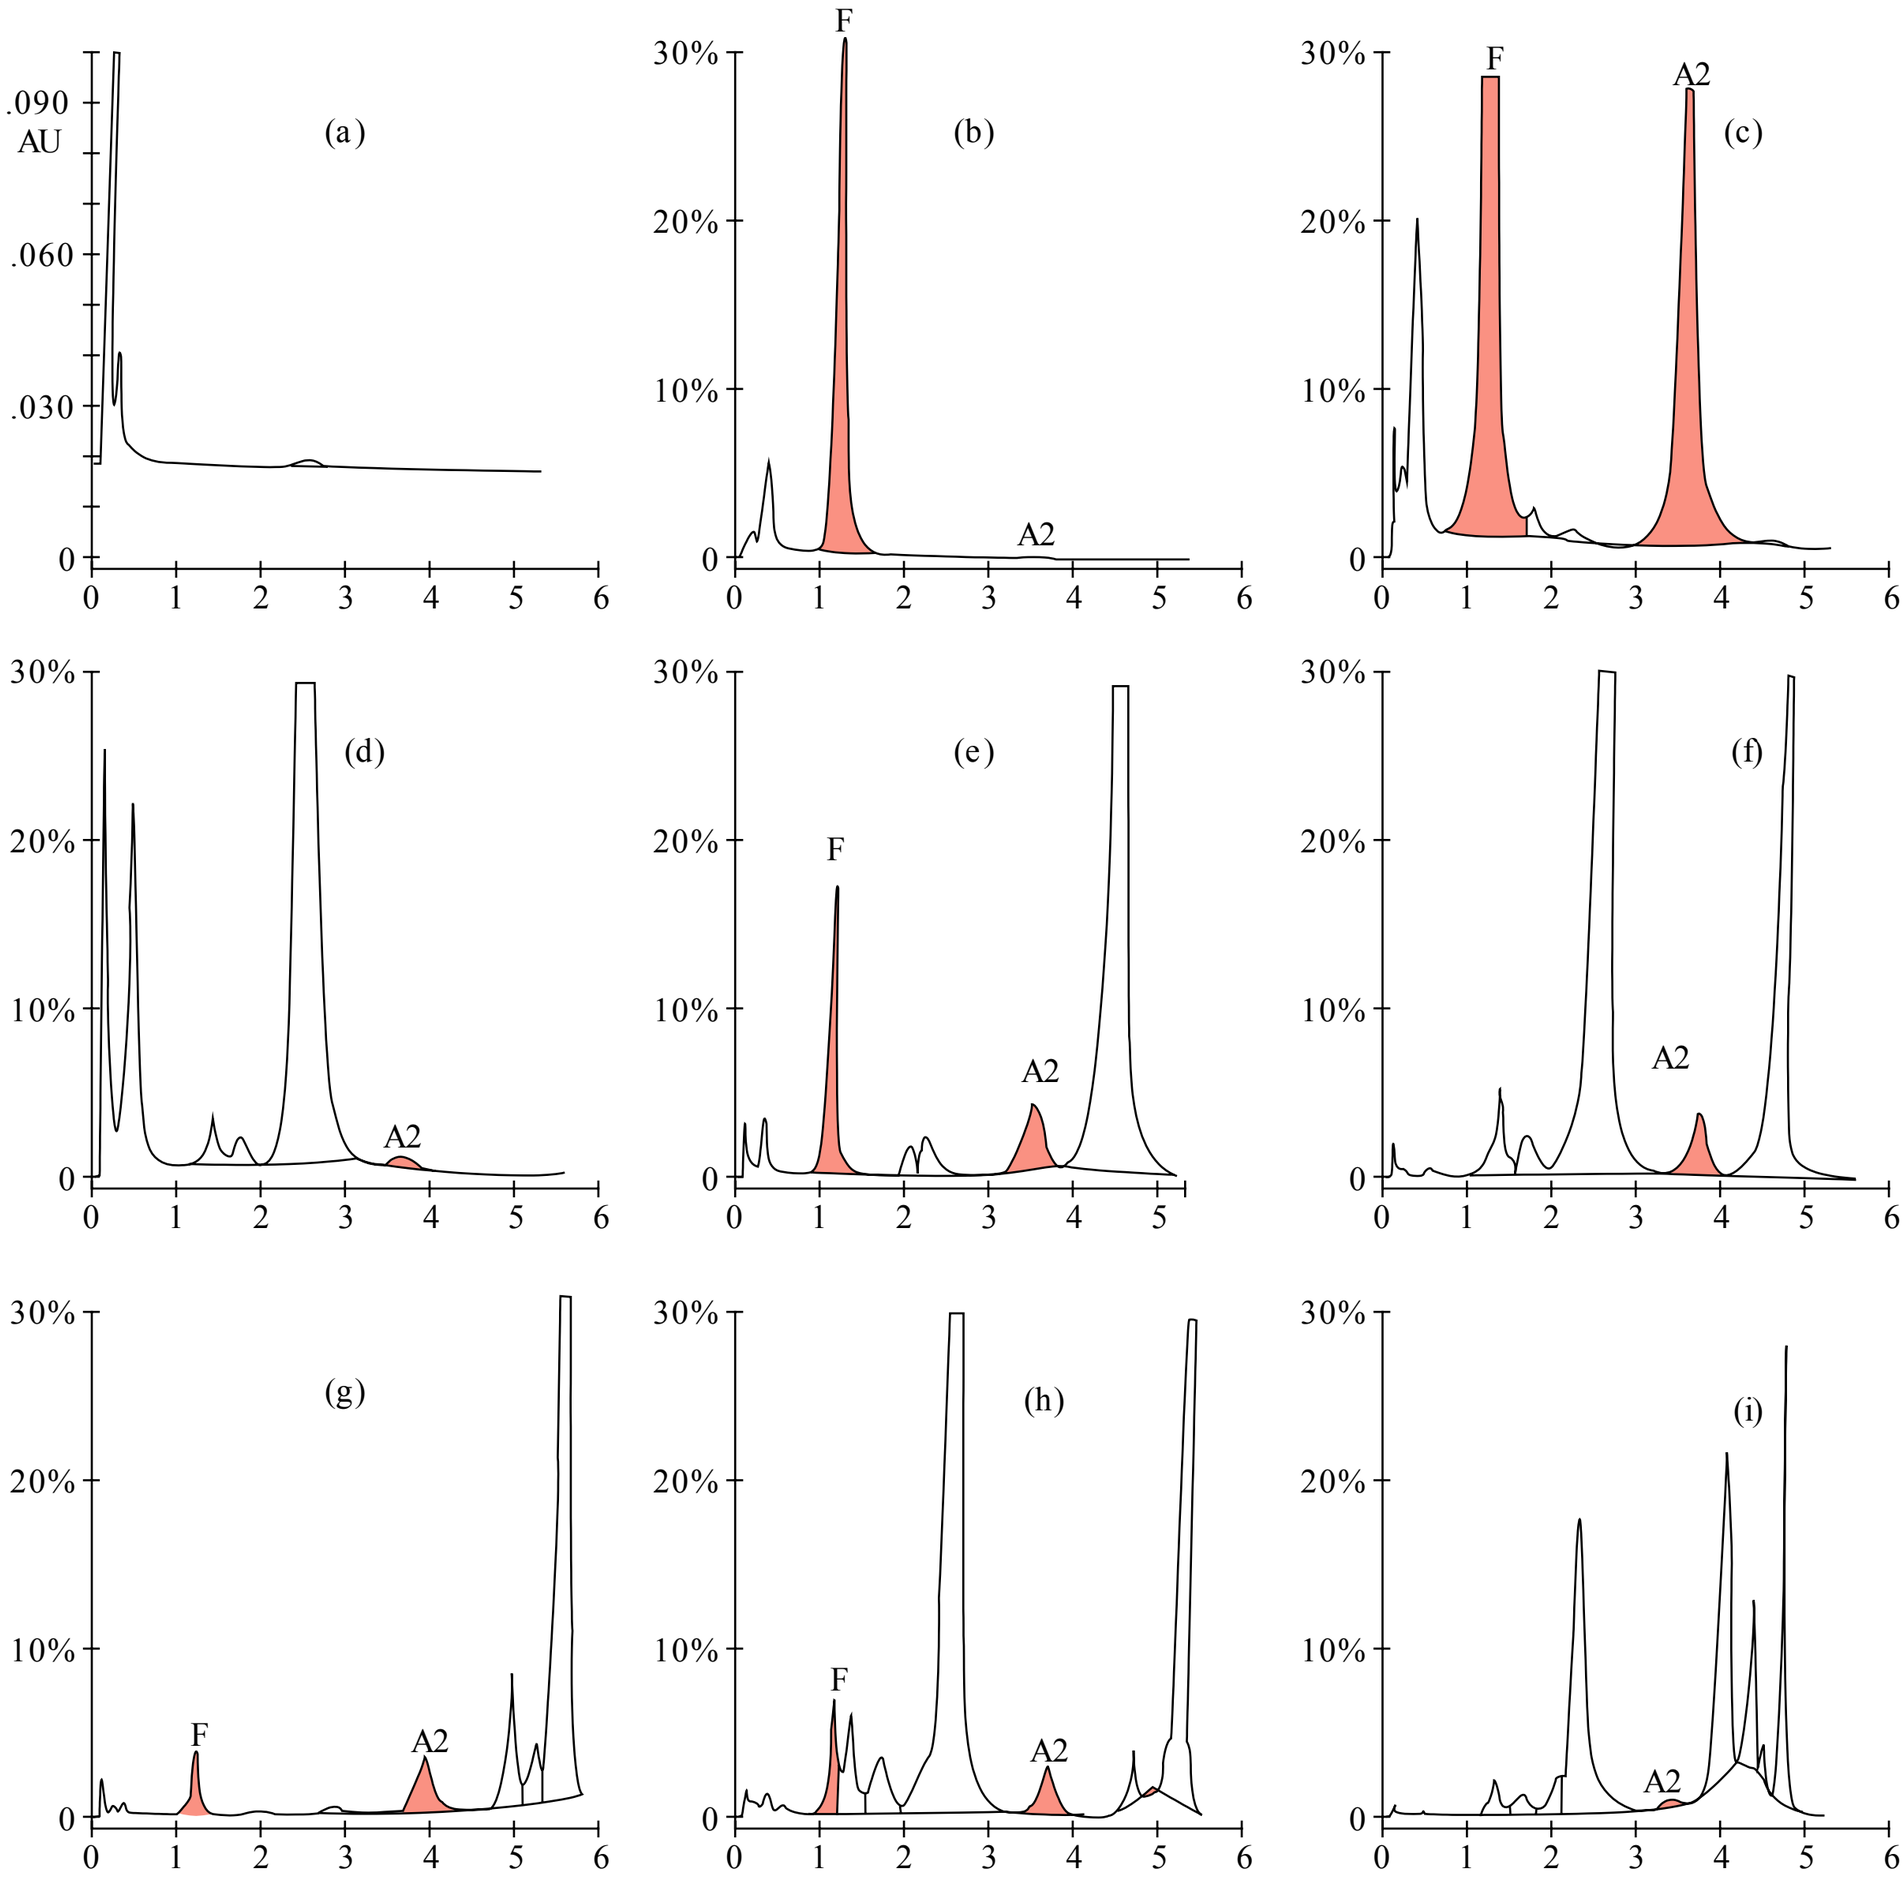

Figure 28-2 HPLC chromatograms obtained from a variety of variants. a, Hb Bart's; b, β^0-thalassemia major; c, β^0-thalassemia homozygous E; d, HbH; e, homozygous S; f, S trait; g, homozygous C; h, C trait; i, HbS-HbG Philadelphia. (From Clarke GM, Trefor N, Higgins TN. Laboratory investigation of hemoglobinopathies and thalassemias: review and update. Clin Chem 2000;46:1284-90.)

injection point of the chromatogram. Electrophoresis at alkaline pH shows a fast migrating band. In Figure 28-3, HPLC and electrophoresis patterns at alkaline pH of cord blood from a normal 26-week-old fetus and a fetus of similar gestational age with Hb Bart's are shown. T e HPLC of the Hb Bart's fetus shows the characteristic single peak at the point of injection, whereas the HPLC from the normal fetus shows HbF (both acetylated and normal) with some HbA. Screening, with appropriate follow-up counseling, is provided for all prospective parents in some parts of the world, where two cis α-gene deletions are common.

Beta (β)-thalassemias result from a decrease in synthesis of β-globin chain. T ese are common in areas surrounding (1) the Mediterranean, (2) the southern provinces of China, and (3) the Indian subcontinent. Scrreening programs are in place[2] in several of these locations.

β-T alassemia is further classified as (1) **thalassemia major**, (2) T alassemia intermediate, or (3) **thalassemia minor**. δβ-T alassemia is also a thalassemic condition.

β^0-Thalassemia (β-Thalassemia Major)

Sometimes called Cooley's anemia, β-thalassemia major is evident when individuals (1) have frequent infections, (2) appear pale, (3) are malnourished, and (4) exhibit splenomegaly with facial bone changes. T ese manifestations primarily reflect the degree of bone expansion associated with ineffective

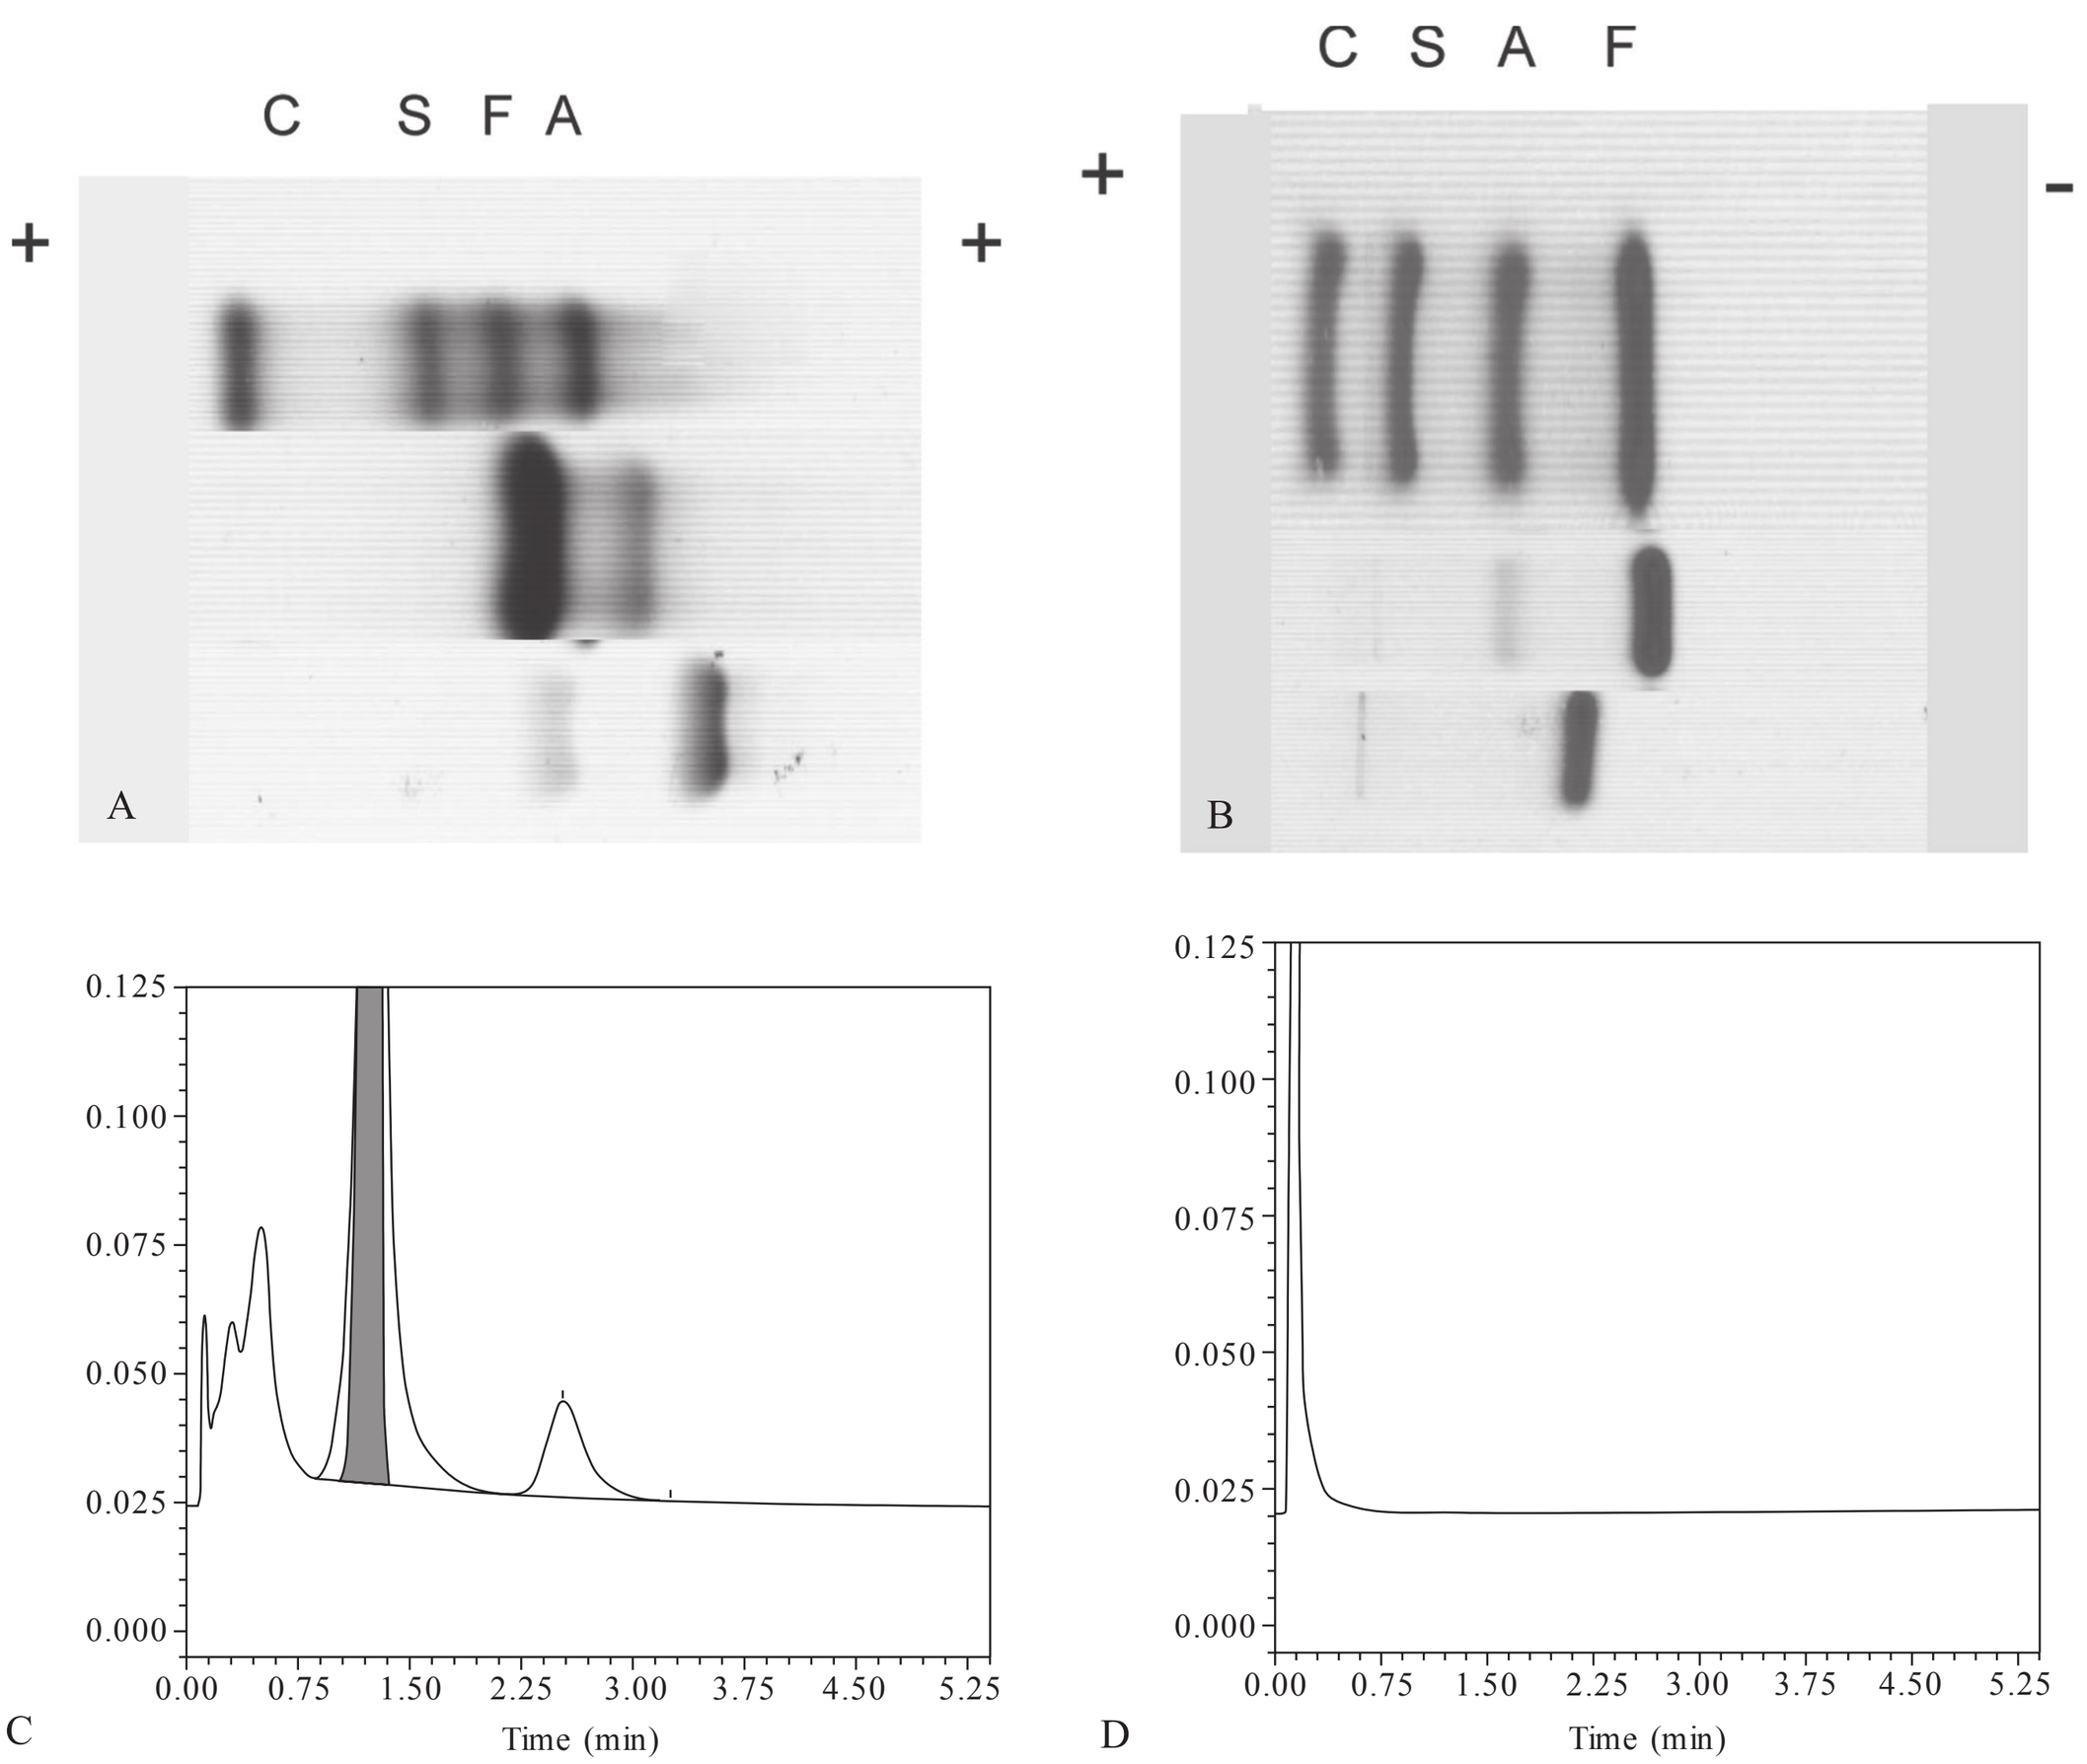

Figure 28-3 Hemoglobin electrophoresis at alkaline pH (A) and acid pH (B) of a normal 26 weeks' gestational age fetus (lane 2) and an Hb Bart's fetus of similar gestational age (lane 3). HPLC chromatograms of the same normal fetus (C) and Hb Bart's fetus (D).

erythropoiesis. β^0-Thalassemia results from mutations that interfere with translation or are involved in (1) initiation, (2) elongation, or (3) termination of β-globin chain synthesis.

Clinical presentation usually occurs before 1 year of age with features that include (1) small size for age, (2) abdominal girth expansion, and (3) failure to thrive. Physical examination of the patient may reveal (1) frontal bossing (a rounded eminence on the forehead) caused by thickening of the cranial bones, (2) pallor, and (3) prominence of the cheek bones. In older children, this obscures the base of the nose and exposes the teeth.

Typical CBC results include severe anemia, with the hemoglobin concentration between 30 and 65 g/L, MCV 48 to 72 fL, and mean corpuscular hemoglobin concentration (MCHC) of 230 to 320 g/L. On the peripheral blood smear, a characteristic abnormal red blood cell (RBC) morphology is noted that includes (1) a large number of microcytes, (2) numerous target cells, which may have a bridge joining the central and peripheral pigment zones, (3) polychromasia, (4) occasional spherocytes, (5) schistocytes, and (6) nucleated red cells. T e **ferritin** is within its reference interval. A family study[1] should always be performed on a family with a child with β-thalassemia major. Hemoglobinopathy investigation of blood from children with β-thalassemia major shows a large HbF peak with no HbA peak and a small or absent HbA_2 peak (for an HPLC chromatogram, see Figure 28-2). Sometimes a small sharp band at the point of injection is seen that has been called pseudo Hb Bart's but is, in fact, bilirubin. Co-inheritance of β^0-thalassemia with a β-chain hemoglobin variant, for example, HbE/β^0-thalassemia, produces a severe anemia.

Lifelong transfusions together with chelation therapy are the primary therapies. Bone marrow transplantation has also been effective.

β⁺-Thalassemia (β-Thalassemia Intermedia)

β⁺-Thalassemia intermedia is attributed to a wide variety of genotypes, but all have in common a significant reduction in production of the β-globin chain, with subsequent reduction in the quantity of HbA present. A reduction in the severity of clinical features is seen with the co-inheritance of α-thalassemia. β⁺-Thalassemia is found in Mediterranean countries, especially in countries in the Eastern Mediterranean.

Clinical presentation varies from symptoms similar to β^0-thalassemia through to those associated with β-thalassemia trait. Transfusions usually are not necessary, and hydroxyurea therapy is frequently used to increase the production of hemoglobin F and mitigate disease symptoms. The CBC shows decreased hemoglobin, with (1) anisocytosis, (2) hypochromia, (3) basophilic stippling, (4) target cells, and (5) nucleated RBCs observed on the peripheral blood smear.

Co-inheritance of β⁺-thalassemia with a β-chain haemoglobin variant, HbE/β⁺-thalassemia, for example, produces a severe anemia.

β-Thalassemia Minor

Patients with β-thalassemia minor, sometimes called β-thalassemia trait, are often asymptomatic, except at times of hematopoietic stress, such as infection or pregnancy, when they may require blood transfusions because of the development of anemia. The CBC on patients with β-thalassemia trait shows low normal or decreased hemoglobin and hematocrit, decreased MCV (<74 fL) and MCH (<27 pg), and a normal or mildly increased RBC distribution width (RDW). However, for patients with liver disease and β-thalassemia, MCV and MCH may be increased to the low end of the reference interval.

The peripheral blood smear shows microcytic RBCs with occasional (1) hypochromia, (2) poikilocytosis, and (3) target cells. The diagnosis of β-thalassemia minor may be made when the HbA_2 is greater than 4% if the patient is iron replete, with appropriate thalassemic indices such as (1) low MCV, (2) high RBC count, and (3) normal or acceptably close to normal RDW in the CBC. Individuals with iron deficiency (Hb <8.0 g/L) should become iron replete before a definitive diagnosis of β-thalassemia is made, as the HbA_2 may be falsely decreased (up to 0.5%) with iron depletion. HPLC is the preferred method for this quantification. In 30% to 40% of all cases of β-thalassemia minor, HbF will also be raised (>1.0%). In β-thalassemia minor, the life span of the RBC may be reduced, and patients with diabetes may show a lower HbA_{1c} compared with normal individuals with equivalent glycemic control. The β-thalassemia mutation may be identified by Southern blot electrophoresis using mutation-specific probes or a sequence-specific polymerase chain reaction (PCR).

δβ-Thalassemia

Deletion of both δ- and β-genes results in δβ-thalassemia, with both heterozygous and homozygous conditions described. The condition is found in a variety of ethnic groups but is most prevalent in countries of the Eastern Mediterranean, especially Greece and Italy. CBC analysis shows reduced hemoglobin (80 to 135 g/L) with low normal or marginally reduced MCV and MCH. HPLC analysis shows an HbA peak with reduced HbA_2 concentration and raised HbF concentration. However, in the Sardinian type of δβ-thalassemia, thalassemic indices are present on the CBC (low MCV and MCH, normal RDW) with a normal HbA_2 concentration and an HbF concentration between 15% and 20%.

Hereditary Persistence of Fetal Hemoglobin

The term **hereditary persistence of fetal hemoglobin** (HPFH) is used to describe a group of genetic conditions in which the concentration of HbF is increased above the reference interval with reduction of β-globin synthesis and a compensatory increase in γ-globin synthesis. Two major classes, of HPFH have been described—heterocellular and deletional. Several deletional variants of HPFH have been described that include (1) Greek, (2) Indian, (3) Italian, (4) Corfu, and (5) Black variants. In these deletional HPFH variants, the HbF concentration may be as high as 36%.

Nondeletional HPFH, sometimes called heterocellular HPFH, describes a group of disorders in which the increase in HbF is distributed heterogeneously among the red cells of otherwise hematologically normal individuals. The HbF concentration varies between 1% and 13% of the total hemoglobin in heterozygotes and from 19% to 21% in homozygotes.

Hemoglobinopathies

More than 950 hemoglobinopathies have been described (http://globin.cse.psu.edu/; accessed October 15, 2013); however, only a few have clinical significance. Identification of hemoglobin variants in areas with previously low incidence (Northern Europe, South America, and Canada) has increased in recent years because of immigration from areas of high incidence of hemoglobinopathies (Africa, Southeast Asia). Screening of neonates for hemoglobinopathies is common in the United States and in Northern European countries.

Nomenclature

Hemoglobin variants have been named by using (1) letters (S, C, D, E), (2) the family name of the index case (Hb Lepore), (3) the place of discovery of the variant, or (4) the hometown or river flowing through the town of the propositus (person immediately concerned about or affected by an action). In some cases, both a letter and a secondary name are used, for example, HbG Coushatta, indicating that the variant has electrophoretic mobility similar to other hemoglobin Gs, and that the variant was originally found in the Coushatta Indian tribe in the Southern United States. The term AS trait (sometimes abbreviated to S trait) is used to describe the heterozygous HbS state, with the term SS used to describe the homozygous HbS state. The homozygous HbS state is known as **sickle cell anemia** or sickle cell disease because of the sickle-shaped cells that appear in the blood of afflicted individuals.

A systematic nomenclature system is now used alongside the variant name to describe (1) the affected chain, (2) the chain location, and (3) the amino acid substitution. As an example, Hb Spanish Town ($\alpha 27[B8]^{Glu \rightarrow Val}$) is a hemoglobin variant named after a district in Kingston, Jamaica, and found

TABLE 28-1 Parameters That Constitute a Complete Blood Count (CBC)

Parameter	Definition
White blood cell count (WBC)	The number of white blood cells in the blood
WBC differential count (neutrophils, lymphocytes, basophils, eosinophils, and monocytes)	The number (or percentage) of each type of WBC present in the blood
Red blood cell count (RBC)	The number of red blood cells in the blood
Hematocrit (Hct)	The proportion of blood volume that is occupied by red blood cells
Hemoglobin (Hb)	The protein molecule in RBCs that carries oxygen
Mean cell volume (MCV)	The average volume of an RBC
Mean cell hemoglobin (MCH)	The average amount of hemoglobin in the average RBC
Mean cell hemoglobin concentration (MCHC)	The average concentration of hemoglobin in a given volume of blood
Red cell distribution width (RCDW)	A measurement of the variability of red blood cell size
Platelet count	Number of platelets in a volume of blood

in Jamaicans of African descent; it arises from a substitution of valine for glutamic acid in position 27 of the α-globin chain, which is located in position 8 of the B helix of the α-chain.

Classification of Hemoglobin Variants

Hemoglobin variants are classified according to type of mutation. Single-point mutations in a globin chain give rise to a substitution of one amino acid residue [e.g., Hb San Diego ($\beta 109[G11]^{Val \rightarrow Met}$)]. Hemoglobin C Harlem is an example of a hemoglobin variant in which two amino acid residues are substituted, namely, valine replacing glutamic acid at position 6 and asparagine replacing aspartic acid at position 73 of the β-chain.

Types of hemoglobin variants include (1) deletional, (2) insertion, (3) deletion/insertion, (4) elongation, and (5) hybrid/fusion/crossover hemoglobins. Deletional hemoglobin variants arise from the deletion of one to five amino acid residues in the globin chain. Insertion hemoglobins are seen with insertion of one to three amino acid residues into the globin chain. Deletion/insertion hemoglobins are caused by the deletion of a portion of the normal amino acid residue sequence and the insertion of another sequence, with resultant lengthening or shortening of the globin chain. Elongation hemoglobins result from a single base pair mutation or frameshift at the 3′ end of exon 3 or at the 5′ end of exon 1 of the α_2- or β-globin chain. Hybrid/*f*usion/crossover hemoglobins result from the fusion of an α- or β-globin chain with a portion of another globin chain.

Analytical Methodology

Hemoglobin and related compounds are measured by several different types of methods. In addition, several technologies provide information leading to the diagnosis of thalassemias and hemoglobinopathies. Methods used for this purpose are divided into (1) those that provide a presumptive identification and (2) those that provide definitive identification. Examples of tests that provide presumptive identification include CBC, HPLC, and electrophoresis. DNA sequencing or mass spectroscopy provides definitive information. The preferred sample for investigation of hemoglobins and thalassemias is a fresh ethylenediaminetetraacetic acid (EDTA) anticoagulated blood sample. Storage for longer than 5 days at 4 °C may compromise sample integrity.

Measurement of Hemoglobin in Whole Blood

Measurement of hemoglobin concentration in venous or capillary blood is typically performed using the cyanmethemoglobin method. The principle of the method is based upon oxidation of the Fe^{2+} of hemoglobin to the Fe^{3+} of methemoglobin by ferricyanide, with methemoglobin then converted into stable cyanmethemoglobin by the addition of potassium cyanide (KCN):

$$HbFe^{2+} + Fe^{3+}(CN)_6^{3-} \rightarrow HbFe^{3+} + Fe^{2+}(CN)_6^{4-}$$

$$HbFe^{3+} + CN^- \rightarrow HbFe^{3+}CN$$

where $HbFe^{2+}$ represents a hemoglobin monomer, $HbFe^{3+}$ a methemoglobin monomer, and $HbFe^{3+}CN$ a monomer of cyanmethemoglobin. The absorbance of cyanmethemoglobin is measured at 540 nm and is used to calculate the concentration of hemoglobin.

Complete Blood Count

A complete blood count is a test (Table 28-1) that evaluates the cells that circulate in blood; it is also known as a full blood count (FBC), full blood exam (FBE), or blood panel. It consists of (1) counts of cells such as RBCs (erythrocytes), white blood cells (leukocytes), and platelets; (2) a measure of Hb; (3) estimates of the volume of red cells; and (4) an estimation of white blood cell subtypes (neutrophils, lymphocytes, basophils, eosinophils, and monocytes).

As a CBC provides the first indication of a thalassemia or hemoglobinopathy, it is essential to perform a CBC as a part of any investigation of hemoglobinopathies and thalassemias. In thalassemias, values for the MCV and MCH are below the reference interval. Hemoglobin may be below or within the reference interval. MCV is sometimes quite notably low, with the RBC count in the upper half of or elevated above the reference interval. The RDW is within the reference interval or is marginally above it. The blood smear should show a microcytic, hypochromic pattern. In hemoglobinopathies, the CBC is very often normal. On the peripheral blood smear, however, changes may be noted that are associated with a particular hemoglobin variant, such as the presence of sickle red cells in sickle cell disease (homozygous HbS) or target cells in homozygous HbE.

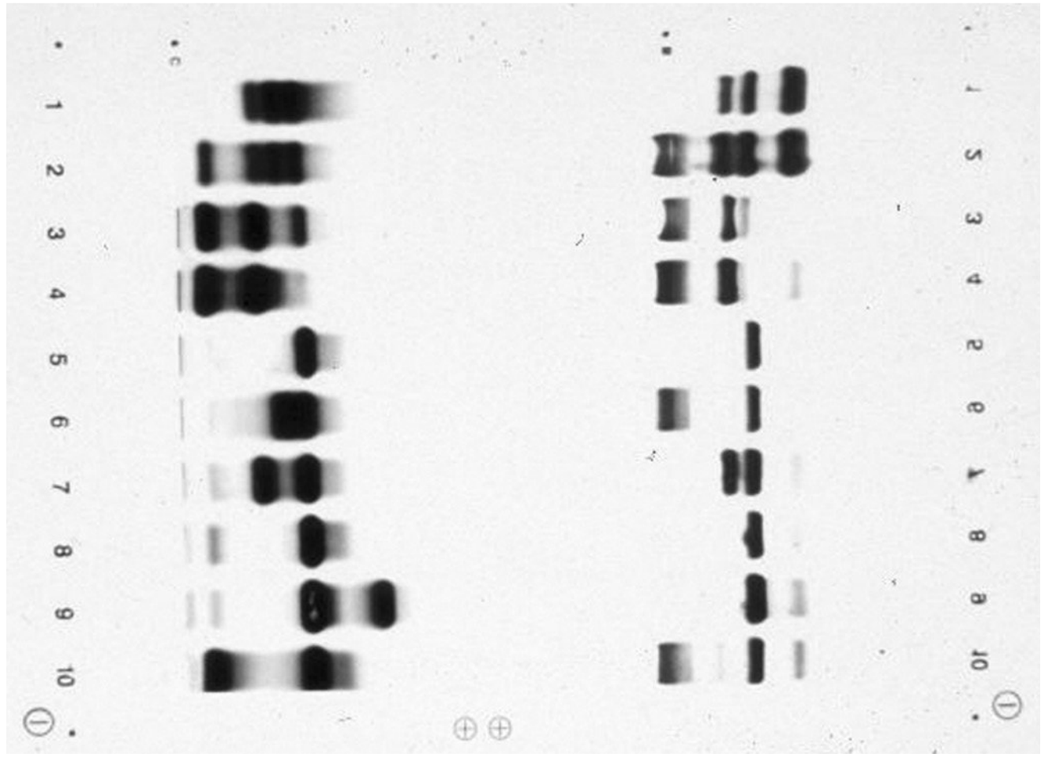

Figure 28-4 Alkaline and acid electrophoresis of various hemoglobinopathies. Lane 1, HbS, HbFA control. Lane 2, HbS, HbF, HbCA control. Lane 3, Transfused SC disease. Lane 4, SC disease. Lane 5, Hb A (normal). Lane 6, Hb Presbyterian. Lane 7, HbS. Lane 8, Raised HbA_2 (β-thalassemia trait). Lane 9, HbJ Baltimore. Lane 10, HbC.

Several formulas derived from parameters in the CBC have been recommended to determine whether the patient has thalassemia. One study proposes that MCV less than 72 fL (reference interval ≈80 to 100 fL)[20] is suggestive of thalassemia, and that this single parameter is the best discriminator of thalassemia. The Mentzer index (MI) has been proposed as a screening parameter for β-thalassemia,[9] with values less than or equal to 14.69 indicative of thalassemia.

CBC parameters and associated calculations or the peripheral blood smear, however, is unable to provide a definitive diagnosis of thalassemia or hemoglobinopathies. It is also crucial to know the iron status of the patient, as iron deficiency may mimic or blunt the features of an underlying thalassemia. In practice, the measurement of ferritin is the most popular test for determining iron status but has limitations.

Electrophoresis

The most common initial test for hemoglobinopathy or thalassemia screening is electrophoresis using agarose gel and a pH 9.2 barbital buffer. Although this method is commonly used, it has several limitations. First, the HbA_2 cannot be accurately quantified, and second, many hemoglobin variants comigrate, making identification difficult. After electrophoresis (Figure 28-4), the hemoglobins are visualized using Ponceau S (reddish staining) or preferably Amido Black (dark blue to black staining).

Variations of electrophoretic techniques that have been used in the identification of hemoglobin variants include isoelectric focusing and capillary isoelectric focusing electrophoresis (see Chapter 11).

HPLC

HPLC using a column packed with cation exchange resin provides in a single analysis quantification of HbA_2 and HbF and initial identification of any hemoglobin variant present (see Figure 28-2). Extensive lists of the retention times of hemoglobin variants on both commercial and laboratory developed methods have been published.[17,23] Advantages of HPLC over electrophoresis include (1) superior resolution of hemoglobin variants, (2) rapid assay time, and (3) accurate quantification of hemoglobin fractions, including HbA_2 and HbF.

BOX 28-1 Uses of DNA Analysis for Investigating Hemoglobinopathies and Thalassemias

- Diagnose and characterize α-thalassemias
- Investigate potentially life-threatening disorders of hemoglobin synthesis in the fetus and perform before 10 weeks' gestation on chorionic villous samples
- Characterize the β-thalassemia genotype
- Screen at-risk populations for clinically significant hemoglobin variants
- Distinguish between conditions that have similar clinical and laboratory presentations but are due to different genetic conditions

Capillary Electrophoresis

Capillary electrophoresis systems are now commercially available and used in clinical laboratories to assay for hemoglobin variants. Separation in an alkaline buffer using high voltages is based on (1) charge differences, (2) electrolyte pH, and (3) electro-osmotic flow. Extra manual manipulation is needed to correctly analyze a sample with a homozygous hemoglobin variant. However, several advantages of capillary electrophoresis over HPLC have been noted, including the quantification of HbA_2 in the presence of HbE.

Electrospray Mass Spectroscopy

Electrospray mass spectroscopy has become the method of choice for the characterization of hemoglobin variants and hemoglobin adducts. This technique establishes very quickly (1) whether the variant is an α- or β-chain variant, (2) the location and identity of the amino acid residue substitution, and (3) the quantity of variants present. It requires, however, several preparative steps and a mass spectrometer.

DNA Analysis

The primary role of DNA analysis in the investigation of hemoglobinopathies and thalassemias is to identify, in populations with a known high incidence of disease, those specific individuals at risk who may benefit from genetic counseling. The uses of DNA analysis for this purpose are listed in Box 28-1.

Tests for Specific Hemoglobin Variants

HbS Solubility Test

Hemoglobin S, when deoxygenated, is insoluble in concentrated phosphate buffer and produces visible turbidity. Almost all other hemoglobins, including hemoglobins (1) A, (2) F, (3) C, (4) E, and (5) D, are soluble in such solutions. Thus, this test quickly identifies specimens of blood that contain HbS. A reducing substance, sodium hydrosulfite ($Na_2S_2O_4$, sodium dithionite), is used to deoxygenate the hemoglobin, and saponin is used to lyse the RBCs. Increased turbidity in

a sample with HbS is noted by viewing a lined card (Figure 28-5) through the treated sample, with decreased clarity of the lined card indicating the presence of HbS. False-positive results are found in samples with (1) Heinz bodies, (2) high concentrations of monoclonal protein, or (3) cold agglutinins. False-negative results are obtained on anemic patients (hemoglobin <80 g/L) or on samples with hematocrit less than 15%. Other hemoglobin variants, including HbC Harlem, Hb Memphis, and HbC Ziguinchor, also yield positive results. Interpretation of the test is highly subjective.

HbH Test

HbH, beta 4 (β_4), is an insoluble tetramer found in patients with α-thalassemia. HbH punctate inclusions, usually described as looking like "golf balls," are found in the RBCs of a peripheral blood smear from a patient with α-thalassemia that has been treated with new methylene blue or brilliant cresyl blue at 37 °C. The method is laborious and is highly subjective. Many such inclusions are present in individuals with HbH disease, whereas cells containing inclusions are rare among individuals with thalassemia trait.

Tests for Unstable Hemoglobins

Treatment of the blood sample with heat at 55 °C to 60 °C or with isopropanol is used to detect the presence of unstable hemoglobins. For example, unstable hemoglobins precipitate under these conditions and are detected by an increase in turbidity or complete precipitation in the sample after treatment. Normal HbA takes about 40 minutes to precipitate, but unstable hemoglobins precipitate in 3 to 4 minutes.

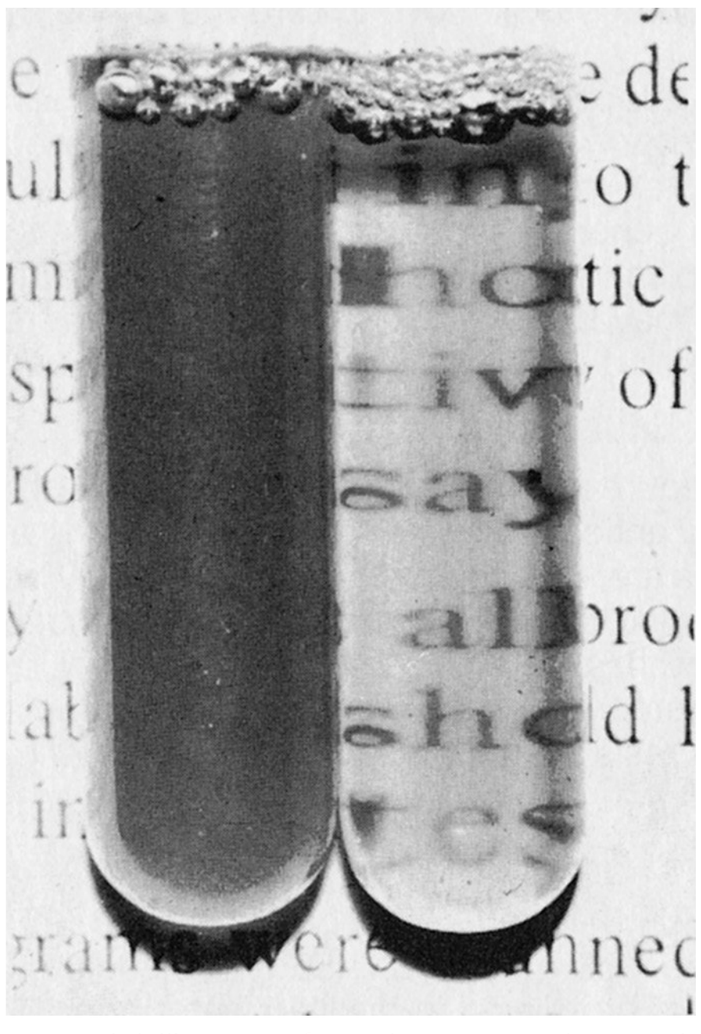

Figure 28-5 Solubility test for HbS. Deoxyhemoglobin S (left tube) is insoluble in 2.3 mol/L phosphate buffer. By contrast, normal hemolysate (right tube) is sufficiently transparent that print can easily be read through it.

Iron

In health, very small quantities of iron are present in (1) most cells of the body, (2) plasma, and (3) other extracellular fluids. Less than 0.1% of the body iron content is lost daily, mostly in desquamated cells or menses. Body iron stores are replenished daily by controlled absorption.

Distribution of Iron in the Body

Body iron is distributed into these compartments: (1) hemoglobin, (2) storage iron (ferritin and **hemosiderin**), (3) myoglobin, (4) a labile iron pool, (5) other tissue iron, and (6) transport iron (**transferrin** and apotransferrin). An estimate of the amount of iron in each compartment is listed in Table 28-2.

Hemoglobin

The erythrocyte volume in a 70-kg man is about 2 L. Each mL contains approximately 1 mg of iron which is equivalent to the body containing ≈2 g of hemoglobin iron.

Storage Iron

Iron is stored in the form of ferritin and hemosiderin.

Ferritin

Ferritin consists of a protein shell surrounding an iron core. Ferritin consists of an apoferritin shell composed of 24 subunits that are either L (light) or H (heavy) ferritin chains, and an interior ferric oxyhydroxide $(FeOOH)_x$ crystalline core (Figure 28-6).

Ferritin occurs in nearly all body cells and stores iron in a form that is shielded from body fluids and is therefore unable to cause oxidative damage. Ferritin in hepatocytes and macrophages provides a reserve of iron that is available for synthesis of hemoglobin and other heme proteins. In healthy men, ≈800 mg of storage iron is present, mostly as ferritin. In healthy women, storage iron ranges up to ≈200 mg. Minute quantities of ferritin are also present in serum in concentrations roughly proportional to total body iron stores. Relatively large amounts of ferritin, much of it without stored iron, may be released into plasma as the result of liver injury and diverse other pathological conditions.

Hemosiderin

Hemosiderin, a terminus of the intracellular storage iron pathway, is formed when ferritin is aggregated and partially

TABLE 28-2 Average Iron Content of Compartments in an Average 70-kg Male

Compartment	Iron Content, mg	Total Body Iron, %
Hemoglobin iron	2000	67
Storage iron (ferritin, hemosiderin)	1000	27
Myoglobin iron	130	3.5
Labile pool	80	2.2
Other tissue iron	8	0.2
Transport iron	3	0.08

deproteinized in secondary lysosomes. Like ferritin, hemosiderin is usually found predominantly in cells of the (1) liver, (2) spleen, and (3) bone marrow. Unlike ferritin, hemosiderin is insoluble in aqueous solutions.

Tissue Iron

Numerous cellular enzymes and coenzymes require iron as an integral part of the molecule or as a cofactor. These include peroxidases and cytochromes, all of which are heme proteins, like hemoglobin. Other enzymes, such as aconitase and ferredoxin, contain iron that is coordinated with sulfur in a so-called iron-sulfur cluster. These enzymes and coenzymes occur in all nucleated cells of the body and form the tissue iron compartment, normally ≈8 mg of iron.

Myoglobin

Myoglobin very closely resembles a single hemoglobin subunit and contains a single heme per molecule.

The Labile Iron Pool

The labile pool contains ≈80 mg of iron. This compartment has no clear anatomical location and is a concept derived from kinetic measurements with radiolabeled iron.[18]

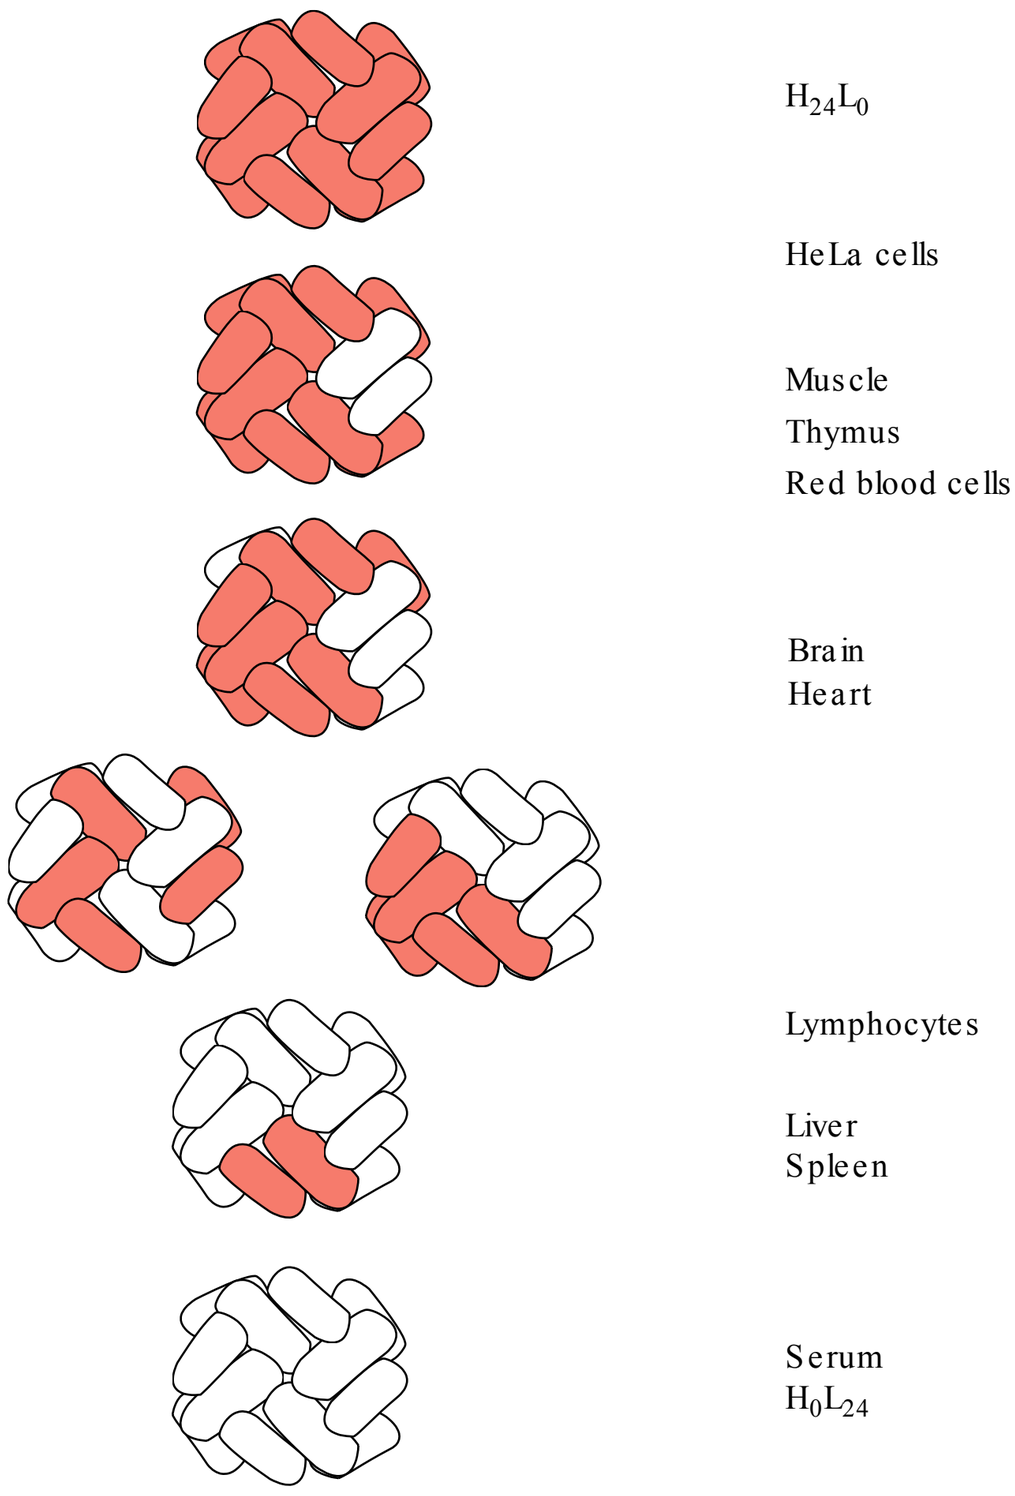

Figure 28-6 Schematic representation of the subunit structure of ferritins from various tissues. (From Harrison PM, Arosio P. The ferritins: molecular properties, iron storage function and cellular regulation. Biochim Biophys Acta 1996;1275:161-203.)

Iron Transport

Iron is transported from one organ to another in the plasma by the transport protein apotransferrin. The apotransferrin/Fe^{3+} complex is called transferrin. Normally, ≈2.5 mg of iron is present in plasma. When transferrin binds to the transferrin receptor of cells, the transferrin/receptor complex is internalized into an endosome that becomes acidified, releasing the iron from transferrin and reducing it to ferrous iron (Fe^{2+}). This is transported into the cell via the divalent metal transporter, DMT1. The apotransferrin is then transported back to the cell surface, ready to transport another transferrin molecule to the interior of the cell. This series of reactions has been designated the transferrin cycle.

Regulation of Iron Homeostasis

Regulation of body iron content in healthy persons is achieved predominantly by controlling the amount of iron absorbed from the upper intestinal tract to that lost.[14] Hepcidin, a peptide hormone produced by the liver, is the central regulator of iron absorption. The amount of unavoidable iron loss in healthy persons depends only minimally upon the iron burden.

Normal Iron Balance

The average daily American diet contains 10 to 15 mg of iron, much of it in the form of (1) heme proteins, (2) hemoglobin, and (3) myoglobin in meat. Normally, ≈1 mg of iron is absorbed each day, mostly by the duodenum. To be absorbed, inorganic iron must be in the ferrous state (Fe^{2+}). Heme is absorbed directly through a specific receptor.[25]

Proteins That Affect Iron Homeostasis

Many proteins influence iron homeostasis. Mutations in genes that encode these proteins may cause iron overload or iron deficiency. Table 28-3 summarizes the effects of some of these proteins on iron homeostasis.

Clinical Significance

Iron deficiency and iron overload are the major disorders of iron metabolism. Abnormal distribution of iron or abnormal production of iron-related proteins may play a primary or secondary role in other heritable or acquired disorders. The latter include (1) hereditary hyperferritinemia–cataract syndrome, (2) aceruloplasminemia, (3) GRACILE (growth retardation, aminoaciduria, cholestasis, iron overload, lactic acidosis, and early death) syndrome, (4) neuroferritinopathy, (5) pantothenate kinase–associated neurodegeneration (formerly Hallervorden-Spatz disease), (6) atransferrinemia, and possibly (7) neurodegenerative disorders such as Parkinsonism, Alzheimer disease, and amyotrophic lateral sclerosis (Lou Gehrig's disease).

Iron Deficiency

Iron deficiency is a a common disorder of humans and especially affects (1) children, (2) young women, and (3) older persons, but it can occur in people of all ages and social strata. In children, iron deficiency is frequently caused by dietary deficiency because milk has low iron content, and iron

TABLE 28-3 Proteins That Affect Iron Homeostasis

Protein	Putative Function	Effect of Deficiency	Comments
HFE*	May transmit signal that upregulates hepcidin	Increased Fe	Most patients with hereditary hemochromatosis are homozygous for the 845 A→G (C282Y) mutation of this gene
Hemojuvelin	Helps regulate hepcidin	Increased Fe absorption	Mutations cause early age of onset of hemochromatosis
β_2-Microglobulin	Transports HFE to the cell membrane	Increased Fe absorption	Deficiency known to cause iron overload in mice only
Transferrin	Transports iron in the plasma	Increased Fe absorption	
Transferrin receptor-1	Binds and internalizes transferrin at the membrane	Lethal. Increased CNS Fe	
Transferrin receptor-2	May transmit signal that upregulates hepcidin	Increased Fe absorption	Mutations cause rare forms of severe hemochromatosis
Ferroportin (SLC40A1)	Transmembrane iron transport protein that acts as a receptor for hepcidin	Increased Fe absorption	Dominant inheritance of iron overload
Hephaestin	Oxidizes ferrous iron to ferric iron at the intestinal abluminal membrane	Fe deficiency	Encoded by a sex-linked gene. Deletion is cause of sla mouse
DMT1	Transports ferrous iron across membranes	Fe deficiency in rodents; iron overload in humans	The naturally occurring mutations found in the mk mouse and the Belgrade rat are the same
Ceruloplasmin		Fe increased in brain, liver	Brain accumulation and neurological disease
Hepcidin	Central regulator of iron absorption; produced in liver	Increased Fe absorption, hemochromatosis	Rare mutations cause hemochromatosis
Steap3		Fe deficiency	

HFE, Human hemochromatosis protein.

requirements for growth and development are high. In adults, iron deficiency is almost always the result of chronic blood loss or childbearing.[15]

Many different measurements have been advocated for the diagnosis of iron deficiency. Originally, emphasis was placed upon RBC indices. Today, measurements of (1) serum iron, (2) iron-binding capacity, (3) serum ferritin, (4) stainable iron in the bone marrow, and (5) erythrocyte protoporphyrin are used extensively to diagnose iron deficiency. Circulating transferrin receptor and reticulocyte hemoglobin measurements also have diagnostic utility. DNA analyses are necessary to confirm diagnoses in unusual cases. For example, iron-refractory iron deficiency is caused by mutations in the TMPRSS6 gene. Neuroferritinopathy caused by mutations in the ferritin light chain gene (FTL) mimics iron deficiency because affected persons typically have low serum ferritin levels.

Although most methods readily identify severe, uncomplicated iron deficiency, the large number of tests that have been advocated for the diagnosis of iron deficiency reflects the fact that none by itself is sufficient to detect mild iron deficiency or iron deficiency in a clinically complex setting. No one method is superior, and various studies differ in the conclusions that they draw regarding advantages of one method over another.[3]

Iron Overload

Hemochromatosis and types of anemia associated with ineffective erythropoiesis cause increased iron absorption and iron overload that affect the (1) liver, (2) heart, (3) pancreas, and (4) joints. The increased absorption is mediated by subnormal or inappropriately low action of hepcidin. Other heritable disorders such as (1) aceruloplasminemia, (2) neuroferritinopathy, or (3) Friedreich's ataxia cause harmful brain iron overload. **Hemosiderosis** and siderosis are terms best used to describe iron overload at the tissue level. Examples include relatively harmless iron deposits at sites of bleeding or inflammation and the life-threatening heart iron overload seen in some persons with hemochromatosis or severe β-thalassemia. Hyperferritinemia without iron overload is usually due to (1) common liver disorders, (2) inflammation, (3) neoplasms, and (4) hereditary hyperferritinemia–cataract syndrome. In general native Africans, African Americans, and Asians have higher mean levels of serum ferritin.

Hereditary Hemochromatosis

Hereditary hemochromatosis is a group of heritable disorders[24] that increase the susceptibility to develop iron overload due to increased iron absorption.[5] Some severely affected persons have (1) bronzing of the skin, (2) cirrhosis, (3) diabetes mellitus, (4) joint disease, (5) hypogonadotrophic hypogonadism, and (6) cardiomyopathy. The term juvenile hemochromatosis is used to describe rare severe forms of hemochromatosis and severe iron overload that affect (1) children, (2) adolescents, and (3) young adults. Specific types of hemochromatosis are best designated by the name of the gene in which causative mutations have been detected.

HFE Hemochromatosis. This is the most prevalent type of hemochromatosis worldwide. It occurs predominantly in Caucasians of European descent. Transmitted as an autosomal recessive trait, this disorder is usually caused by inheritance of two copies of the HFE mutation designated as C282Y

(nt.845G→A).[4] Approximately 1 in 200 European Caucasians are C282Y homozygotes (two abnormal gene copies). A high proportion of C282Y homozygotes diagnosed in nonscreening settings have moderate or severe iron overload. More than 50% of untreated homozygotes have elevated transferrin saturation or serum ferritin concentrations, and ≈10% have elevated levels of serum alanine aminotransferase. In C282Y homozygotes discovered in screening programs, severe iron overload (serum ferritin >1000 μg/L) is uncommon. HFE H63D and S65C are common mutations that are infrequently associated with severe iron overload.

Hemojuvelin (HJV) Hemochromatosis. This disorder is characterized by early age of onset and severe multiorgan iron overload. Most reported patients have European ancestry. Manifestations of iron overload are more prevalent and more severe in HJV than in HFE hemochromatosis. Heart failure and arrhythmia are the predominant causes of death. Untreated patients have (1) high transferrin saturation, (2) severe hyperferritinemia, and (3) elevated liver transaminase levels. HJV hemochromatosis is transmitted as an autosomal recessive disorder. Worldwide, the most common deleterious HJV mutation is G320V (nt.959G→T). A major attribute of HJV hemochromatosis is dysregulation of hepcidin.

Transferrin Receptor-2 (TFR2) Hemochromatosis. TFR2 hemochromatosis is a rare autosomal recessive disorder characterized by (1) elevated serum transferrin saturation, (2) elevated ferritin levels, and (3) liver iron overload. Most patients are of European or Asian ancestry. In some kinships, severe iron overload occurs in children or young adults. Many patients are compound heterozygotes for two different TFR2 mutations. The TFR2 gene encodes transferrin receptor-2, a protein that continues to mediate uptake of transferrin-bound iron by the liver after the classical transferrin receptor is downregulated by iron overload. Increased iron absorption in TFR2 hemochromatosis is due to hepcidin dysregulation.

Ferroportin (SLC40A1) Hemochromatosis. Ferroportin, the receptor for hepcidin, occurs on the surfaces of cells responsible for gathering and recycling iron, including macrophages and absorptive cells of the small intestine and placenta. Mutations in the SLC40A1 gene cause an uncommon, heterogeneous group of iron overload disorders characterized by an autosomal dominant pattern of inheritance. Ferroportin hemochromatosis has been described worldwide in a variety of race/ethnicity groups. In some kinships, (1) serum iron measures are minimally abnormal, (2) mild anemia is often present, and (3) complications of iron overload are uncommon. In other kinships, ferroportin mutations cause a serious disorder that resembles HFE or HJV hemochromatosis.

African Iron Overload and African American Iron Overload. African iron overload occurs in 14% to 18% of Bantu-speaking Natives in many sub-Saharan Africa countries. This disorder is due primarily to the ingestion of large quantities of iron contained in traditional beer, although an African iron overload gene(s) may also exist. Some patients develop harmful iron deposits in the (1) liver, (2) spleen, (3) pancreas, and (4) other organs, predominantly in macrophages. Affected persons have normal or elevated transferrin saturation and elevated serum ferritin levels. A similar disorder occurs in African Americans, but iron overload is typically less severe than in African Natives. Some cases in African Americans are due to (1) HFE genotypes typical of Caucasian hemochromatosis, (2) rare mutations of other hemochromatosis-associated genes, or (3) types of hemoglobinopathy or thalassemia.

Iron Overload Due to Anemia With Ineffective Erythropoiesis

Some types of heritable and acquired anemia cause ineffective erythropoiesis and increased GDF15 (growth/differentiation factor-15) production by erythroblasts. This downregulates hepcidin expression and thus increases iron absorption. Transferrin saturation and serum ferritin levels are elevated in untreated patients. These types of anemia include (1) β-thalassemia major, pyruvate kinase deficiency, (2) congenital dyserythropoietic anemia, and (3) refractory anemia with ringed sideroblasts due to myelodysplasia. Increased GDF15 expression probably also occurs in patients with X-linked sideroblastic anemia. Chronic erythrocyte transfusion may exacerbate iron overload due to increased absorption in persons with these types of anemia.

Secondary Iron Overload

Chronic erythrocyte transfusion is the most common cause of this group of disorders.[8] Transfusion iron overload is common in patients with severe β-thalassemia major and sickle cell disease. Transfusion iron overload also occurs in persons with (1) severe aplastic anemia, (2) Blackfan-Diamond syndrome, (3) Fanconi's anemia, (4) acute leukemia, (5) autoimmune hemolytic anemias, and (6) myelodysplasia with refractory anemia.

Daily consumption of traditional beer that contains large amounts of iron is the major cause of African iron overload. Rarely, iron overload develops in persons who ingest large quantities of supplemental iron. Hematite miners and other workers chronically exposed to iron ore dust may develop iron overload of the lungs and adjacent lymph nodes, but serum iron measures are usually normal.

Analytical Methodology

Several methods are used to measure iron and related analytes.[7] These include methods for (1) serum iron, (2) iron-binding capacity, (3) transferrin saturation, and (4) serum ferritin.

Methods for the Determination of Serum Iron, Iron-Binding Capacity, and Transferrin Saturation

Iron is released from transferrin by decreasing the pH of the serum. It is reduced from Fe^{3+} to Fe^{2+} and then is complexed with a chromogen such as bathophenanthroline or ferrozine. Such iron/chromogen complexes have an extremely high absorbance at the applicable wavelength, which is proportional to the iron concentration.

Serum unsaturated iron-binding capacity and total iron-binding capacity (TIBC) are determined by the addition of sufficient Fe^{3+} to saturate iron-binding sites on transferrin. Excess Fe^{3+} is removed (e.g., by adsorption with [1] light magnesium carbonate [$MgCO_3$] powder, [2] a silica column, or

[3] an ion exchange resin], and the assay for iron content is then repeated. From this second measurement, the TIBC is obtained.

$$\text{Transferrin saturation (\%)} = (100 \times \text{serum iron})/\text{TIBC}$$

Many automated chemistry analyzers now measure unsaturated iron-binding capacity (UIBC) and calculate TIBC, rather than measure it directly. UIBC is measured by adding a known excess concentration of iron to serum. By leaving the pH near neutral, only the iron that did not bind to transferrin is measured upon addition of an iron-binding chromogen. TIBC is calculated by adding the UIBC to the serum iron level.

Reference Intervals

Reference intervals for serum iron differ by as much as 35% between commercial methods. Therefore, a generic reference interval is not valid. If an automated commercial method is used, a laboratory should independently define its own reference intervals based on race/ethnicity samples appropriate for the laboratory's clientele.

Clinical Relevance

The serum iron concentration refers to the Fe^{3+} bound to serum transferrin and does not include the iron contained in serum as free hemoglobin. The serum iron concentration is decreased in many, but not all, patients with iron deficiency anemia and with chronic inflammatory disorders, such as (1) acute infection, (2) immunization, and (3) myocardial infarction (Table 28-4). Other conditions that decrease serum iron concentration include (4) blood donation, (5) hemorrhage, and (6) menstruation.

Elevated serum iron levels occur (1) in iron-loading disorders such as hemochromatosis,[22] (2) in patients with aplastic anemia, (3) in children with acute iron poisoning, (4) after oral or parenteral iron use, (5) as the result of acute liver injury, and (6) with the use of hormonal contraceptives.

Because only about one-third of the iron-binding sites of transferrin are occupied by Fe^{3+} in healthy individuals, serum transferrin has much reserve iron-binding capacity (UIBC). TIBC is a measurement of the maximum concentration of iron that transferrin binds. TIBC is increased in many persons with iron deficiency and is decreased in those with chronic inflammatory disorders or malignancies. In many persons with untreated hemochromatosis, TIBC is slightly decreased.

Comments and Precautions

1. Except when atomic absorption spectroscopy is used, hemolysis has very little effect on serum iron assay results because hemoglobin iron is not released from heme by acid treatment. Markedly hemolyzed specimens should be rejected for analysis.
2. Many factors influence serum iron concentration and TIBC. Conditions that affect these measures are listed in Table 28-4. Day-to-day variation is great in many healthy people. Diurnal variation in serum iron concentrations also occurs. Values are lower in the afternoon than in the morning and are very low in the evening (as low as 10 to 20 µg/dL [2 to 4 µmol/L] in healthy individuals). Because many causes of low serum iron levels are known, results must be interpreted with caution. Furthermore, values of serum iron concentration and TIBC are normal in many people with mild iron deficiency.

TABLE 28-4 Conditions Known to Affect Serum Iron Concentration, Total Iron-Binding Capacity, and Transferrin Saturation

Condition	Effect
Diurnal variation	Normal values in morning; low values in midafternoon; very low values near midnight
Menstrual cycle	Premenstrually, elevated values (SI increased by 10%-30%); at menstruation, low values (SI decreased by 10%-30%)
Pregnancy	May elevate SI owing to increased progesterone; may lower SI owing to iron deficiency
Ingestion of iron (including iron-fortified vitamins)	High values; may raise SI by +54 µmol/L (+300 µg/dL) and Tsat to 100%
Oral contraceptives (progesterone-like)	High values; may raise SI to >36 µmol/L (>200 µg/dL) and Tsat to 75%; also elevates TIBC
Iron contamination of syringe, Vacutainer tube, or other glassware (phenomenon may be rare, sporadic, very difficult to prove)	High values; e.g., SI >30 µmol/L (>170 µg/dL); Tsat 75%-100%
Iron dextran injection	Very high values; SI may be >180 µmol/L (>1000 µg/dL), Tsat 100%, probably from circulating iron dextran; effect may persist for several weeks
Hepatitis	Very high values; SI may be >180 µmol/L (>1000 µg/dL) owing to hyperferritinemia from hepatocyte injury
Acute inflammation (respiratory infection), abscess, immunization, myocardial infarction	Low or normal SI; normal or low Tsat
Chronic inflammation or malignancy	Low or normal SI; normal or low Tsat
Iron deficiency	Low or normal SI; low or normal Tsat; increased TIBC
Iron overload (hemochromatosis)	High SI; high Tsat; normal or low TIBC

From Fairbanks VF. Laboratory testing for iron status. Hosp Pract 1991;26:19.
SI, Serum iron concentration; TIBC, total iron-binding capacity; Tsat, transferrin saturation.

3. Because iron is ubiquitous, scrupulous care is necessary to ensure that glassware, water, and reagents do not become contaminated with extraneous iron.
4. Transferrin saturation (Tsat) may be estimated from the TIBC by the following relationship:

$$\text{Serum transferrin (g/L)} = 0.007 \times \text{TIBC (}\mu\text{g/dL)}$$

Note that the relationship is not entirely linear as a small portion of iron in serum is bound to proteins other than transferrin. Therefore, calculated TIBC values are slightly greater than the amount of transferrin-bound iron. However, these small differences are of no practical consequence. Immunoassays are available for assay of serum transferrin concentration. Results of immunological measurements of transferrin concentration correlate with those of the TIBC assay, but the clinical utility of transferrin measurement is very limited. A slight advantage for the immunoassay of transferrin is that the required volume per specimen is much smaller.

Methods for the Determination of Serum Ferritin

Serum ferritin assay may be performed by any of several methods, including (1) immunoradiometric assay, (2) enzyme-linked immunosorbent assay (ELISA), (3) immunochemiluminescence assays, and (4) immunofluorometric methods. Reagents for these assays are available in kit form and for automated immunoassay instruments from several manufacturers.

Reference Intervals

Reference intervals for serum ferritin concentrations are summarized in Table 28-5. Much variation is seen with different methods for serum ferritin and purposes of testing and test populations. Reference intervals must be determined for each laboratory.

Clinical Significance

Ferritin is present in the blood in very low concentration. Although it is an acute-phase protein, under normal conditions serum ferritin levels are usually proportional to the body iron content. The circulating protein is largely apoferritin. It is iron-poor and largely consists of iron-poor, glycosylated l-chains. The plasma ferritin concentration declines very early in the development of iron deficiency—long before changes are observed in (1) blood hemoglobin concentration, (2) RBC size, or (3) serum iron concentration. Thus measurement of serum ferritin concentration is used as a highly sensitive indicator of iron deficiency that is uncomplicated by other concurrent disease. Alternatively, many chronic diseases cause increased serum ferritin levels (see Table 28-4). Most persons with elevated serum ferritin levels do not have hemochromatosis and other iron overload disorders. In persons with proven hemochromatosis or iron overload, serum ferritin measurements are useful gauges to the progress of phlebotomy therapy in achieving iron depletion.

TABLE 28-5 Reference Intervals for Serum Ferritin

	ng/mL	μg/L
Newborn	25-200	25-200
1 mo	200-600	200-600
2 to 5 mo	50-200	50-200
6 mo to 15 y	7-140	7-140
Adult man	20-250	20-250
Adult woman	20-200	20-200
Iron overload		
• Adult male	>400	>400
• Adult female	>200	>200

Method for Red Cell Volume and Hemoglobin Content

MCV and mean corpuscular hemoglobin concentration (MCHC) are indices that are included in the CBC test. One of their uses is to characterize the blood of patients with anemia. Low values of MCV and MCHC are indicators of iron deficiency. The diagnostic utility of MCV and MCHC in detecting iron deficiency is limited in patients with MCV values greater than 100 fL. Values of MCV are elevated in many persons with other chronic medical conditions, including untreated HFE hemochromatosis. Common heritable traits may increase or decrease MCV and MCHC.

Method for the Determination of the Serum Transferrin Receptor

The cell membranes of developing erythroid cells in bone marrow are rich in transferrin receptors to which the iron/transferrin complex binds as a normal attribute of the transferrin cycle. The number of transferrin receptors increases in the presence of iron deficiency and decreases in iron excess. These variations in the quantity of transferrin receptors in erythropoietic tissue are reflected in changes in soluble serum transferrin receptor, which are measured by a variety of standard immunoassay techniques. To a large extent, serum transferrin receptor concentrations reflect the rate of erythropoietic activity, regardless of the iron status of the patient.

Bilirubin

Bilirubin is the orange-yellow pigment derived mainly from senescent (aging) red blood cells. It is extracted and metabolized mainly in the liver and is excreted in bile and urine. The (1) chemistry, (2) biochemistry, (3) clinical significance, and (4) analytical methods for bilirubin are reviewed in this section.

Chemistry

Bilirubin was discovered in blood in 1849 by Virchow, who called the yellow pigment "hematoidin." The term bilirubin was coined by Stadeler in 1864, and in 1874 Tarchanoff demonstrated the direct association of bile pigments with hemoglobin. In 1942, Fisher and Plieninger synthesized bilirubin IXα and proposed the structure shown in the upper portion of Figure 28-7. This is linear tetrapyrrolic structure of the bilirubin molecule was accepted for longer than 30 years. However, the insolubility of the bilirubin molecule in water and its solubility in a variety of nonpolar, lipid solvents are not predicted

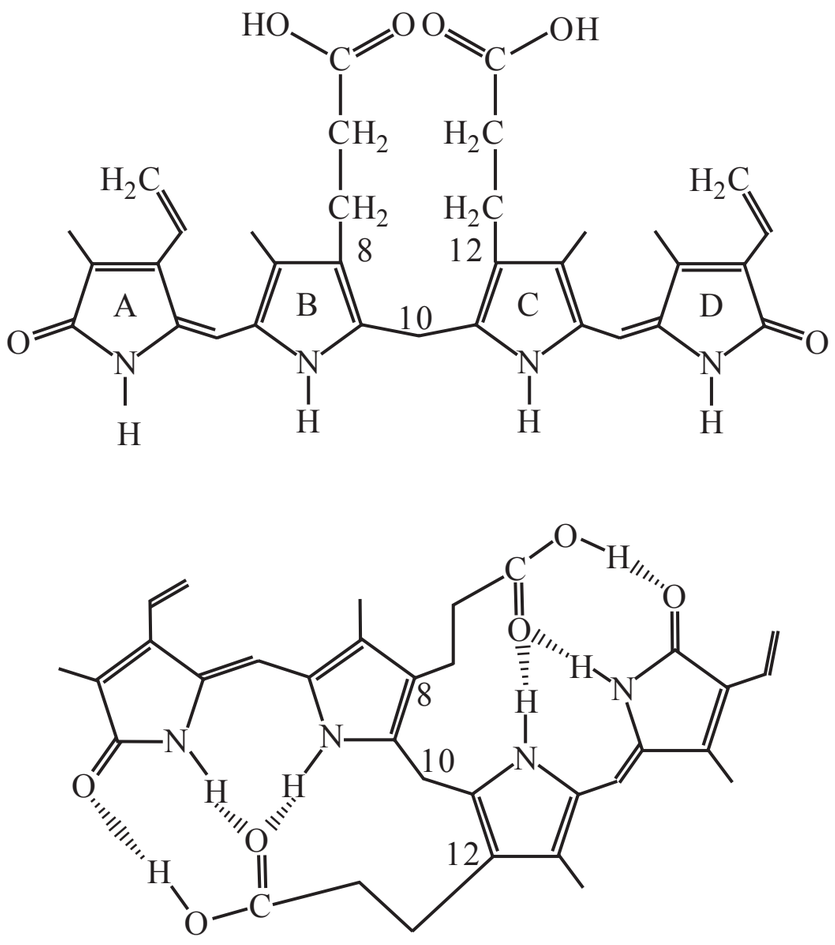

Figure 28-7 Bilirubin IXα structure. Top, A linear molecular representation of unconjugated bilirubin. Bottom, The preferred structure of unconjugated bilirubin IXα, Z-Z confguration. The folded ridge-tile structure is stabilized by six hydrogen bonds formed between the two carboxyl groups of the sidechains and the two carbonyl- and four imino- groups. The "ridge" involves carbon atoms 8 through 12.

from this linear tetrapyrrole structure; the two propionic acid sidechains would be expected to make the bilirubin molecule highly polar and therefore water soluble.

T e overall chemical structure of bilirubin was established by X-ray crystallography. Crystalline bilirubin assumes a ridge-tiled configuration, stabilized by six intramolecular hydrogen bonds. T is Z-Z (trans) conformation, in which the propionic acid–carboxylic acid groups are hydrogen-bonded to the nitrogen atoms of the pyrrole rings (see Figure 28-7), prevents the interaction of bilirubin with polar groups in aqueous media. When exposed to light, the Z-Z (trans) configuration is converted by rupture of the intramolecular double bonds to the E-E (cis) conformation, which is more water soluble than the Z-Z conformation. T us light-exposed forms of bilirubin are more water soluble and are readily excreted in the bile. T is is the rationale for irradiating jaundiced newborns with 450 nm light.

Bio che mis try

Bilirubin IXα is produced from the catabolism of protoporphyrin IX by a microsomal heme oxygenase (Figure 28-8). T e tetrapyrrolic product of the ring opening at the α-methene bridge is the green pigment biliverdin, which is subsequently reduced to bilirubin by the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH)-dependent, cytosolic enzyme biliverdin reductase. For each mole of heme catabolized by this pathway, one mole each of (1) carbon monoxide, (2) bilirubin, and (3) ferric iron is produced. Daily bilirubin production from all sources in humans averages from 250 to 300 mg. Approximately 85% of the total bilirubin produced is

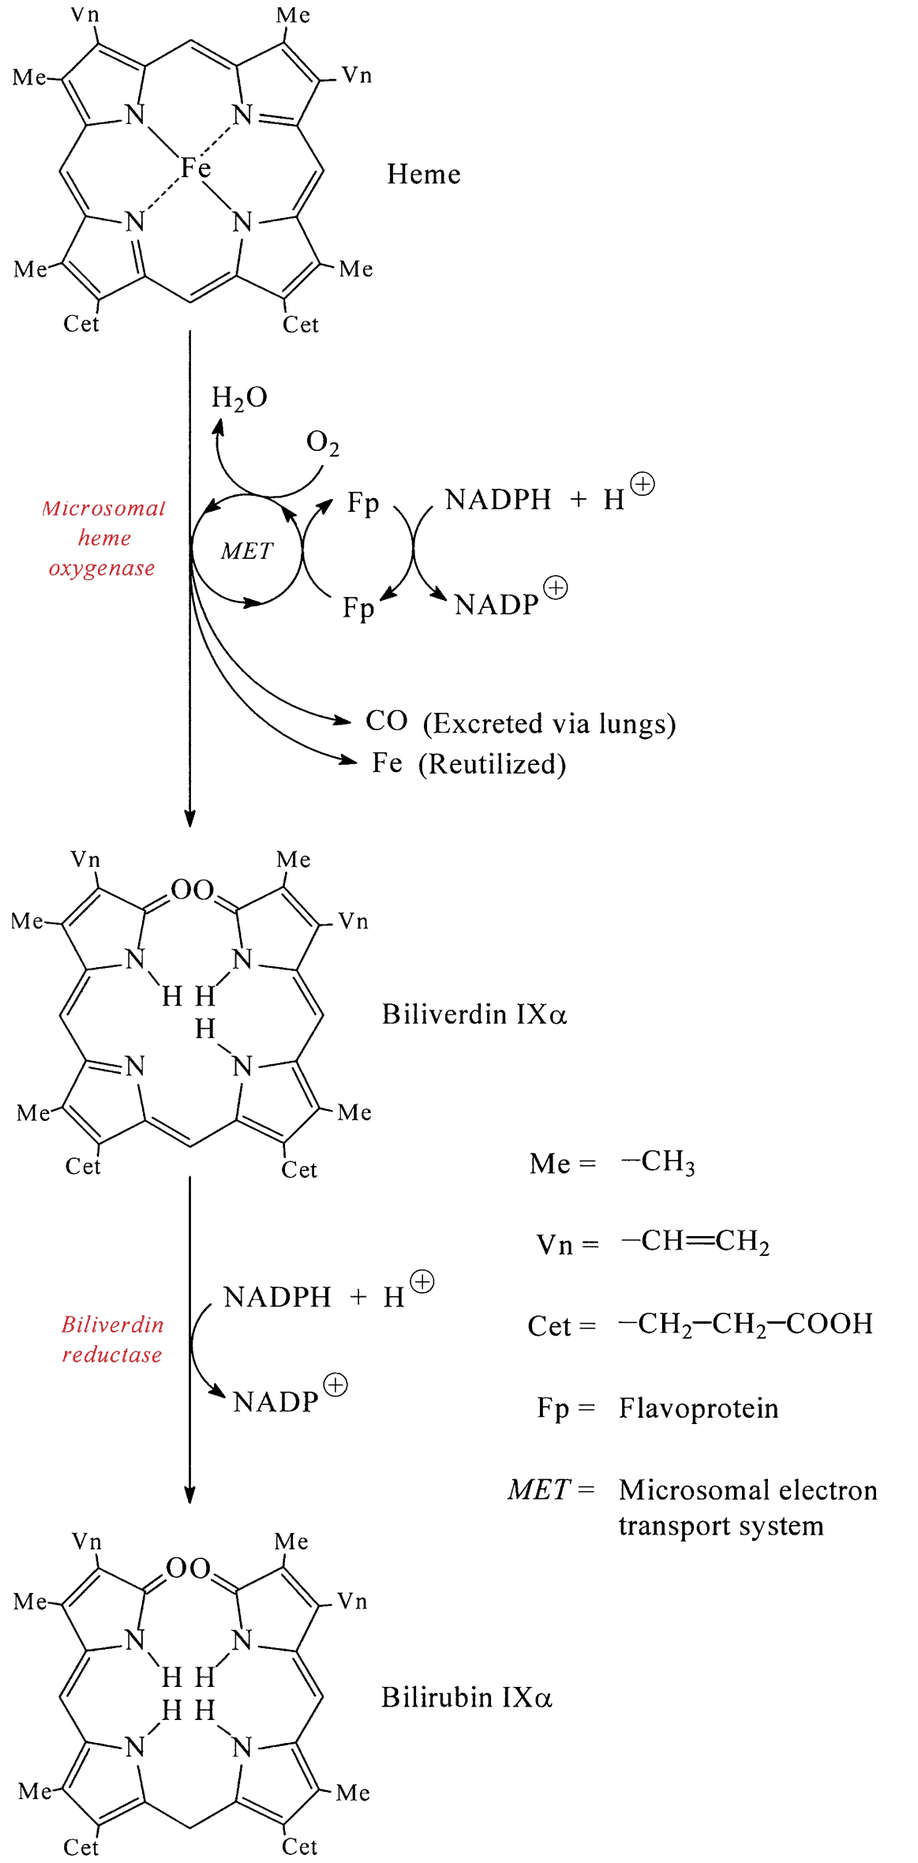

Figure 28-8 Catabolism of heme to bilirubin IXα. (From Berlin NI, Berk PD. Quantitative aspects of bilirubin metabolism for hematologists. Blood 1981:57:983-99.)

derived from the heme moiety of hemoglobin released from senescent erythrocytes that are destroyed in the reticuloendothelial cells of the (1) liver, (2) spleen, and (3) bone marrow. T e remaining 15% is produced from red blood cell precursors destroyed in the bone marrow (so-called ineffective erythropoiesis) and from the catabolism of other heme-containing proteins, such as (1) myoglobin, (2) cytochromes, and (3) peroxidases.

In blood, bilirubin is bound to albumin and is transported to the liver. It dissociates from albumin at the membrane of the hepatocyte and is transported across the membrane into the liver (Figure 28-9). Inside the liver cells, bilirubin is reversibly bound to soluble proteins known as **ligandins** or protein Y. Ligandin also binds a variety of other compounds, such as (1) steroids, (2) bromsulphthalein (BSP), (3) indocyanine green, and (4) some carcinogens. Inside the hepatocytes, bilirubin

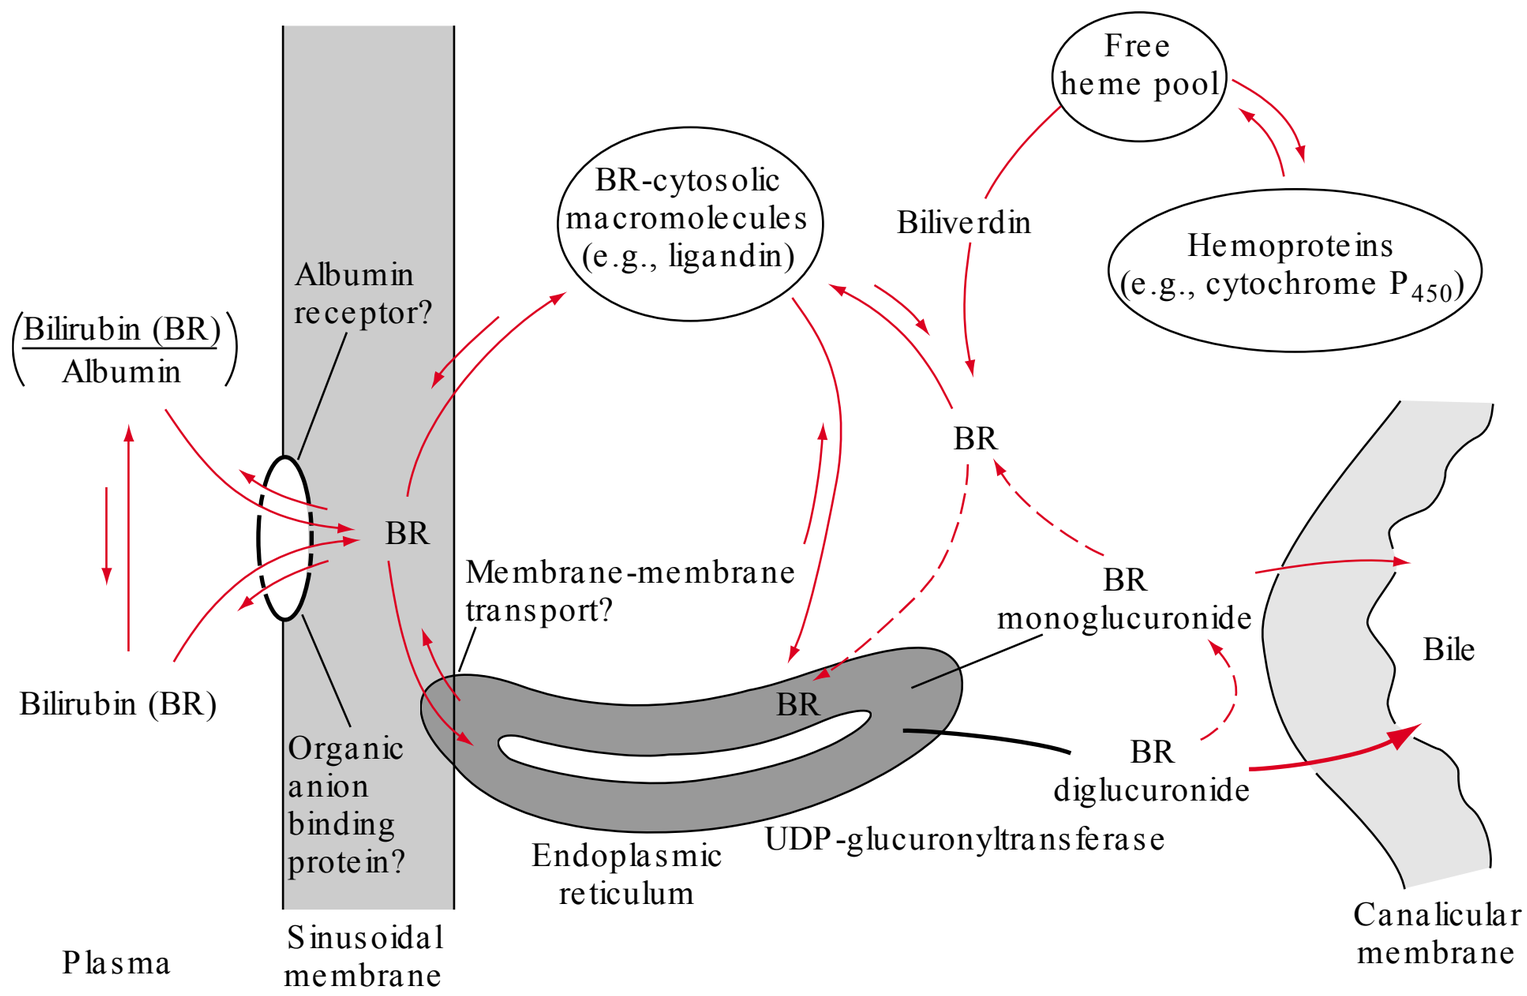

Figure 28-9 Bilirubin uptake, metabolism, and transport in the hepatocyte. (From Gollan JL, Schmid R. Bilirubin metabolism. In: Popper H, Schaffner F, eds. Progress in liver diseases, vol 7, Chapter 15. Philadelphia: WB Saunders, 1982.)

is rapidly conjugated with glucuronic acid to produce bilirubin monoglucuronide and diglucuronide, which then are excreted into bile (see Figure 28-9). The microsomal enzyme bilirubin uridine diphosphate (UDP)–glucuronyltransferase (EC 2.4.1.17) catalyzes the formation of bilirubin monoglucuronide. It is not certain whether conversion of the monoglucuronide to the diglucuronide is catalyzed by the same enzyme or by another enzyme located in or near the canaliculus. In adults, virtually all bilirubin excreted in bile is in the form of glycosidic conjugates.

In the intestine, bilirubin glucuronides are hydrolyzed by the catalytic action of β-glucuronidase from the (1) liver, (2) intestinal epithelial cells, and (3) bacteria. The **unconjugated bilirubin** is then reduced by anaerobic intestinal microbial flora to form a group of three colorless tetrapyrroles collectively called **urobilinogens**. The urobilinogens differ from one another in the degree of hydrogenation; they contain 6, 8, or 12 more hydrogen atoms than does bilirubin and are named (1) stercobilinogen, (2) mesobilinogen, or (3) urobilinogen, respectively. In the lower intestinal tract, the three urobilinogens are spontaneously oxidized at the middle methylene bridge to produce the corresponding bile pigments (1) stercobilin, (2) mesobilin, and (3) urobilin, which are orange-brown and the major pigments of stool.

Clinical Significance

Jaundice is a condition characterized by **hyperbilirubinemia** and deposition of bile pigment in the (1) skin, (2) mucous membranes, and (3) sclera, with a resulting yellow appearance of the patient; it is also called **icterus**. Defects in bilirubin metabolism resulting in jaundice occur at each step of the metabolic pathway (see Figure 28-9). The disorders are usually classified as (1) inherited disorders of bilirubin metabolism or (2) jaundice of the newborn. All of these disorders are characterized by elevations in conjugated or unconjugated bilirubin

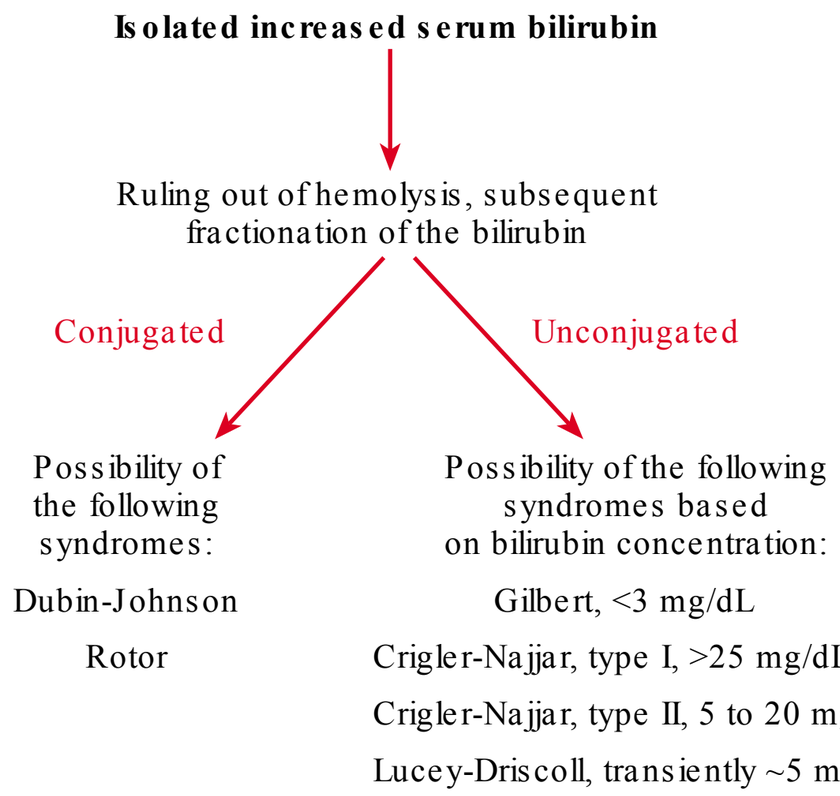

Figure 28-10 Algorithm for differentiating the familial causes of hyperbilirubinemia.

in the absence of other abnormal liver tests. It is only in these disorders that bilirubin fractionation is clinically useful.

Patients are occasionally seen with isolated elevations in bilirubin concentration. In most cases, this is due to (1) inherited disorders of bilirubin metabolism, (2) familial hyperbilirubinemia, or (3) hemolysis. An algorithm for differentiating familial causes of hyperbilirubinemia is presented in Figure 28-10.

Inherited Disorders of Bilirubin Metabolism

Inherited disorders of bilirubin metabolism include (1) **Gilbert**, **Crigler-Najjar** (Types I and II), (2) **Lucey-Driscoll**, (3) **Dubin-Johnson**, and (4) **Rotor syndromes**.

Gilbert Syndrome

Gilbert syndrome is a benign condition manifested by mild unconjugated hyperbilirubinemia. This abnormality, which

affects 3% to 5% of the population, is probably inherited as an autosomal recessive trait; it is clinically important because is often misdiagnosed as chronic hepatitis. (Gilbert syndrome is easily distinguished from chronic hepatitis by the absence of anemia and bilirubin in urine and by normal liver function test results.)

With this syndrome, the serum concentration of bilirubin fluctuates between 1.5 and 3 mg/dL (26 and 51 µmol/L) and tends to increase with fasting. The cause of jaundice is low hepatic glucuronyltransferase activity.

Patients with Gilbert syndrome may be predisposed to acetaminophen toxicity because acetaminophen is primarily metabolized by glucuronidation. No treatment is needed, but patients must be reassured that they do not have liver disease.

Crigler-Najjar Syndrome (Type I)

Crigler-Najjar syndrome type I, a rare disorder caused by complete absence of UDP-glucuronyltransferase, is manifested by very high concentrations of unconjugated bilirubin, often exceeding 25 mg/dL (428 µmol/L). It is inherited as an autosomal recessive trait. Most patients die of severe brain damage caused by kernicterus (encephalopathy related to increased serum bilirubin that leads to permanent brain damage) within the first year of life. Phlebotomy and plasmapheresis reduce the serum bilirubin, but encephalopathy usually develops. Early liver transplantation is the only effective therapy.

Crigler-Najjar Syndrome (Type II)

This is rare autosomal dominant disorder is characterized by a partial deficiency of UDP-glucuronyltransferase. Unconjugated bilirubin is usually 5 to 20 mg/dL (85 to 340 µmol/L). Unlike Crigler-Najjar syndrome type I, type II responds dramatically to phenobarbital, and a normal life is expected.

Lucey-Driscoll Syndrome

Lucey-Driscoll syndrome is a familial form of unconjugated hyperbilirubinemia caused by a circulating inhibitor of bilirubin conjugation. The hyperbilirubinemia is mild and lasts for the first 2 to 3 weeks of life.

Dubin-Johnson and Rotor Syndromes

Dubin-Johnson syndrome is due to a rare autosomal recessive disorder and is characterized by jaundice with predominantly elevated **conjugated bilirubin** and a minor elevation of unconjugated bilirubin. Rotor syndrome is similar to Dubin-Johnson syndrome, but without black pigment in the liver. Both conditions are benign.

Jaundice in the Neonate

Disorders that cause jaundice in the neonate are classified as unconjugated or conjugated hyperbilirubinemia (Box 28-2).

BOX 28-2 Physiological Classification of Jaundice

Unconjugated Hyperbilirubinemia
Increased Production of Unconjugated Bilirubin from Heme
Hemolysis
- Hereditary
- Acquired

Ineffective erythropoiesis
Rapid turnover of increased RBC mass (in the neonate)

Decreased Delivery of Unconjugated Bilirubin (in Plasma) to Hepatocyte
Right-sided congestive heart failure
Portacaval shunt

Decreased Uptake of Unconjugated Bilirubin Across Hepatocyte Membrane
Competitive inhibition
- Drugs
- Others

Gilbert syndrome
Sepsis, fasting

Decreased Storage of Unconjugated Bilirubin in Cytosol (Decreased Y and Z Proteins)
Competitive inhibition
Fever

Decreased Biotransformation (Conjugation)
Neonatal jaundice (physiological)
Inhibition (drugs)
Hereditary (Crigler-Najjar)
- Type I (complete enzyme deficiency)
- Type II (partial deficiency)

Hepatocellular dysfunction
Gilbert syndrome

Conjugated Hyperbilirubinemia (Cholestasis)
Decreased Secretion of Conjugated Bilirubin into Canaliculi
Hepatocellular disease
- Hepatitis
- Cholestasis (intrahepatic)

Dubin-Johnson and Rotor syndromes
Drugs (estradiol)

Decreased Drainage
Extrahepatic obstruction
- Stones
- Carcinoma
- Stricture
- Atresia

Sclerosing cholangitis
Intrahepatic obstruction
- Drugs
- Granulomas
- Primary biliary cirrhosis
- Bile duct paucity
- Tumors

Unconjugated Hyperbilirubinemia

Unconjugated hyperbilirubinemia poses a risk for development of **kernicterus** (acute bilirubin encephalopathy), especially in low birth weight infants. Kernicterus refers to a neurological syndrome that results in brain damage owing to deposition of bilirubin in the basal ganglia and brainstem nuclei. In term infants, early symptoms of kernicterus include (1) poor feeding, (2) lethargy, and (3) vomiting; later, (4) opisthotonos (backward arching of the trunk), (5) seizures, and (6) death may follow. Seventy percent of affected infants die

within the first week, and those remaining have severe brain damage. It is possible to prevent this syndrome by phototherapy and exchange transfusion in infants with elevated unconjugated bilirubin concentrations.

Causes of unconjugated hyperbilirubinemia in the neonate are (1) physiological jaundice of the newborn, (2) hemolytic (3) disease owing to Rh or ABO incompatibility, and (4) breast milk hyperbilirubinemia.

Guidelines for Assessing Risk. In 2004, the Subcommittee on Hyperbilirubinemia of the American Academy of Pediatrics issued new guidelines for management of jaundice in the neonate. These guidelines became necessary because newborns are currently discharged between 36 and 72 hours after birth, and severe hyperbilirubinemia may not be present at discharge. The time-honored bilirubin concentration of 20 mg/dL (340 μmol/L), which was considered critical and required action (e.g., phototherapy, exchange transfusion), has now been abandoned and replaced by monitoring the increase in bilirubin concentration from time of birth until time of discharge from the hospital[6]; it is now recommended that a plot of bilirubin concentration (mg/dL) versus time (hours) should be constructed and compared with the similar plot found in Figure 2 of reference 6.

Physiological Jaundice of the Newborn. Babies frequently become jaundiced within a few days of birth; this condition is known as physiological jaundice *of* the newborn. Unconjugated bilirubin concentrations reach a peak within 3 to 5 days of birth and remain elevated for less than 2 weeks. Factors contributing to physiological jaundice include (1) increased bilirubin load in the newborn caused by the shortened life span of red blood cells; (2) decreased conjugation of bilirubin resulting from relative lack of glucuronyltransferase (conjugating enzyme) in the first few days after birth; and (3) exposure of breast-feeding infants to pregnanediol, nonesterified fatty acids, and other inhibitors of bilirubin conjugation present in breast milk.

Physiological jaundice of the newborn is treated with phototherapy; the infant is exposed to light of approximately 450 nm that disrupts intramolecular hydrogen bonds in the bilirubin molecule and yields several photoisomers that are more water soluble than the Z-Z-isomer and thus are excreted in the bile. Exchange transfusions are rarely necessary.

Hemolytic Disease. Hemolytic disease of the newborn results from maternal-fetal incompatibility of Rhesus blood factors, in which the maternal Rh-negative blood becomes sensitized by a previous pregnancy with an Rh-positive fetus or an Rh-positive blood transfusion. The infant becomes jaundiced with unconjugated bilirubin in the first or second day of life and is susceptible to kernicterus. The diagnosis is confirmed by Coombs' test with Rh-positive blood in the infant and Rh-negative blood in the mother.

Breast Milk Hyperbilirubinemia. This type of hyperbilirubinemia affects about 30% of breast-fed newborns. It is due to the presence of α-glucuronidase in breast milk, which hydrolyzes conjugated bilirubin in the intestine. The unconjugated bilirubin, being more lipophilic, is passively absorbed. The condition lasts for a few weeks and is treated by discontinuation of breast-feeding.

Conjugated Hyperbilirubinemias

These syndromes are characterized by hyperbilirubinemia in which conjugated bilirubin exceeds 1.5 mg/dL (26 μmol/L). The most important of these stndromes are idiopathic neonatal hepatitis and biliary atresia. Conjugated hyperbilirubinemia is seen fairly often in the newborn as a complication of parenteral nutrition.

Biliary Atresia

Biliary atresia is a condition in which the bile ducts either fail to develop or develop abnormally. It occurs in one in 10,000 births, and females are more frequently affected.

Having no exit to the intestine, bile accumulates inside the liver and eventually escapes into the blood, causing mixed hyperbilirubinemia. Other possible causes include (1) cytomegalovirus, (2) reovirus III, (3) Epstein-Barr virus, (4) rubella virus, (5) α_1-antitrypsin deficiency, and (6) trisomy 17 or 18.

Extrahepatic biliary atresia, more common than the intrahepatic type, may involve all or part of the extrahepatic biliary tree. If jaundice persists beyond 14 days of age, a direct or conjugated bilirubin measurement must be performed to exclude biliary atresia. If bilirubin is elevated, the urine should be tested for bile. Early identification of this condition is essential if these infants are to benefit from the operation of portoenterostomy, which should be performed no later than 60 days after birth. If portoenterostomy is not successful, liver transplantation is the treatment of choice. Children rarely live beyond 3 years unless the lesion is surgically correctable.

Intrahepatic biliary atresia is characterized by lack of intrahepatic bile ducts. Jaundice usually appears within the first few days of life. Serum bilirubin is elevated, and serum cholesterol may be very high, leading to the formation of xanthomas.

Analytical Methdology

Several analytical techniques are used to measure bilirubin in serum and urine.

Serum Bilirubin

Bilirubin is measured in body fluids by (1) spectrophotometric (diazo—chemical, direct spectrophotometric, enzymatic, and transcutaneous) or (2) chromatographic methods.

Diazo Methods

The reaction of bilirubin with diazotized sulfanilic acid, known as the diazo reaction, discovered by Ehrlich in 1883 and applied to the measurement of bilirubin in serum and bile by van den Bergh and Muller in 1916, is the basis of the most widely used methods for measuring bilirubin. The observation that the reaction was slow in sera from jaundiced infants and required an accelerator (ethanol) to proceed and that it was rapid in bile and in adult sera without addition of ethanol led to the terms **indirect bilirubin** and **direct bilirubin**, respectively.

The reaction of the coupling of bilirubin with a diazo compound is shown in Figure 28-11. In this example, diazotized sulfanilic acid (the diazo reagent) reacts with bilirubin to produce two azodipyrroles (azopigments), which are reddish purple at neutral pH and blue at low or high pH values. Numerous

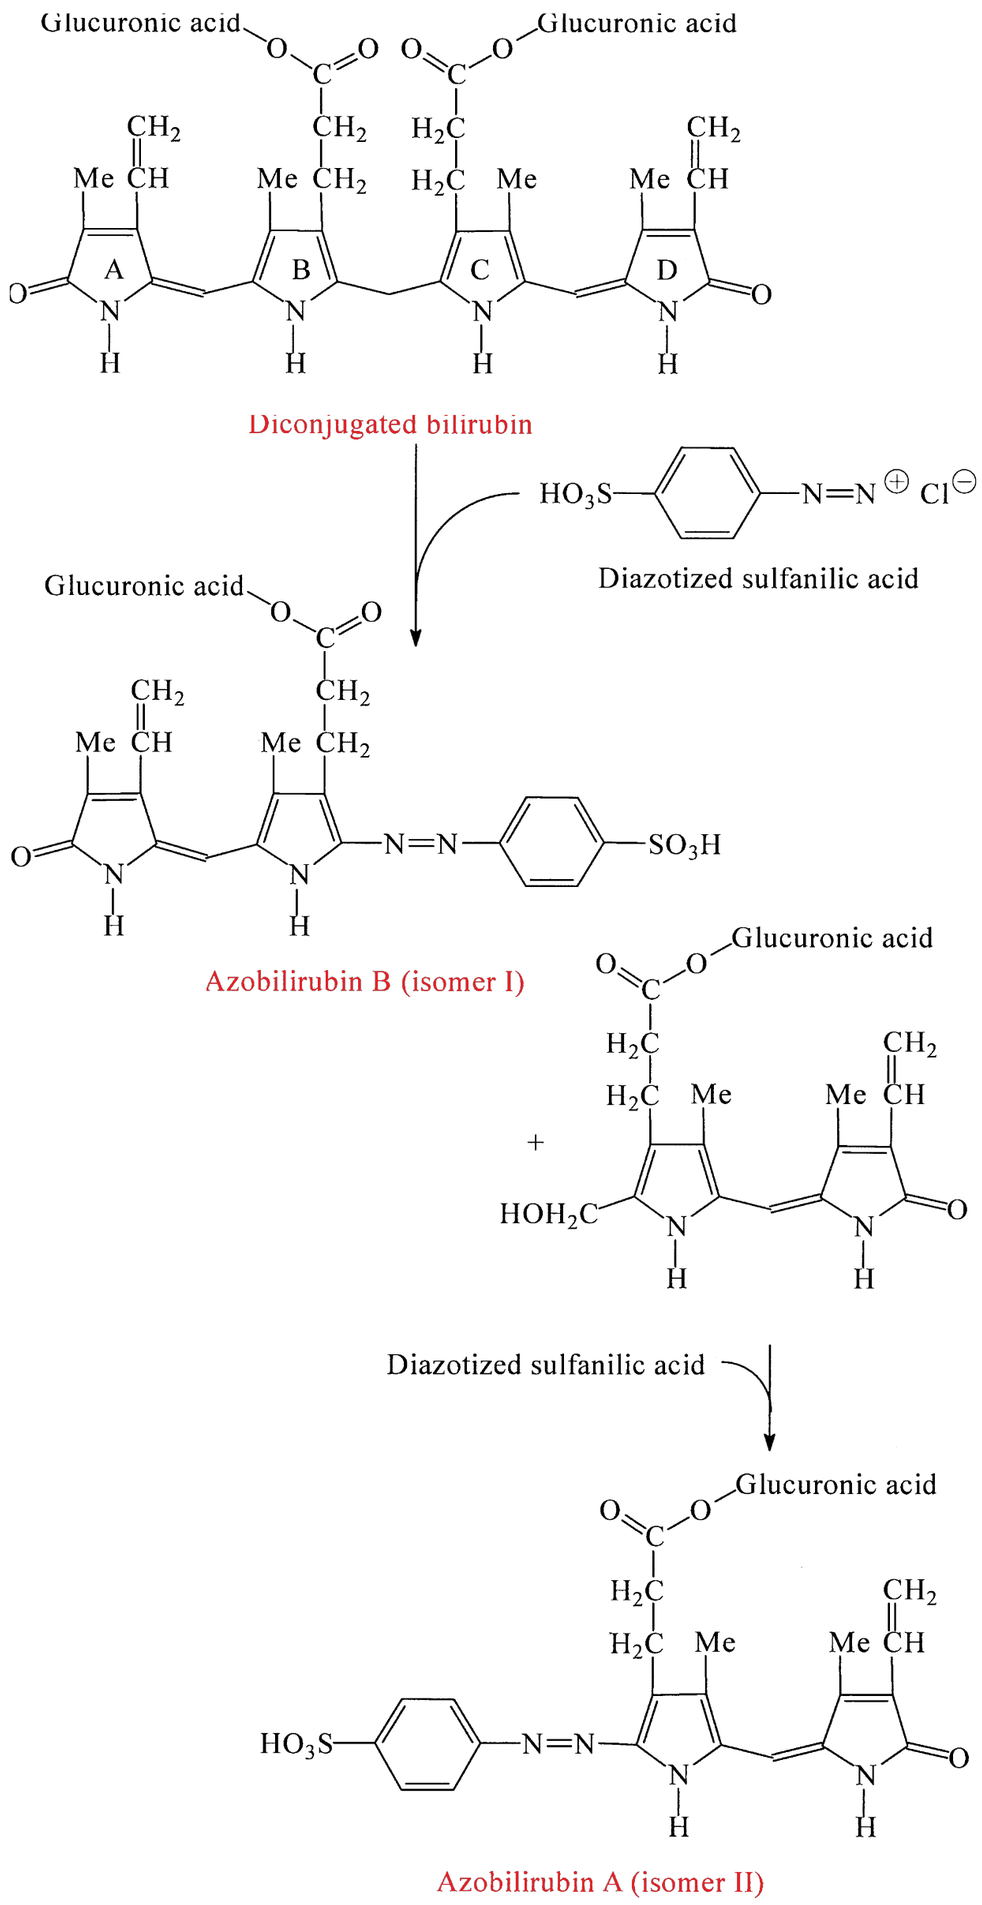

Figure 28-11 The reaction of bilirubin glucuronide with diazotized sulfanilic acid to produce isomers I and II of azobilirubin B. Unconjugated bilirubin reacts in the same way to produce isomers I and II of azobilirubin A.

variations of the van den Bergh method have been developed. All use one of a variety of "accelerators," which facilitate the reaction of unconjugated (indirect) bilirubin with the diazo reagent. The most commonly used accelerators are (1) caffeine,[10] dyphylline, and (3) several surface active agents (surfactans). The diazo method of Malloy and Evelyn, which used methanol as an accelerator and is virtually abandoned today, is mentioned here for historical reasons only.

Total Bilirubin. The diazo method described by Jendrassik and Grof in 1938 and later modified by Doumas and colleagues[11] measures quantitatively the sum of (1) unconjugated, (2) monoconjugated, (3) di-conjugated, and (4) δ-bilirubin fractions in serum, yielding results that are reproducible and reliable.

In this procedure, serum is added to an aqueous solution of caffeine and sodium benzoate (accelerator), which displaces unconjugated bilirubin from its association sites on albumin. Formation of hydrogen bonds with caffeine renders the bilirubin water soluble and facilitates its reaction with diazotized sulfanilic acid. After 10-minute incubation at room temperature, alkaline tartrate is added, and absorbance of the alkaline azobilirubin is measured at 598 nm.

With automated clinical analyzers, addition of alkaline tartrate is omitted and absorbance is measured at 530 nm. The method is calibrated with solutions of known bilirubin concentrations prepared by adding unconjugated bilirubin of known purity to human serum. Such bilirubin, Standard Reference Material (SRM) No. 916, is available from the National Institute of Standards and Technology (NIST), in Gaithersburg, Maryland. This method has acceptable transferability among laboratories and is currently the reference method of choice for measuring total bilirubin in serum.

Direct Bilirubin. Bilirubin monoconjugates and diconjugates (mainly glucuronides) and δ-bilirubin, because they are water soluble, react with the diazo reagents in the absence of accelerators. A reliable method for direct bilirubin should not measure any unconjugated bilirubin. To prevent the unconjugated bilirubin from reacting, it is necessary to keep the pH of the reaction mixture near 1.0.[10] A preferred manual method for direct bilirubin is available.[11] Ditaurobilirubin (bilirubin conjugated with taurine and available as the disodium salt), a water-soluble synthetic material, is used by instrument manufacturers for calibrating direct bilirubin methods; it is also present in materials used for quality control and for proficiency testing.

Direct Spectrophotometry

This method is based on the absorption of light by bilirubin near 460 nm and is restricted primarily to blood specimens from healthy newborns, among whom unconjugated bilirubin is the predominant species. Correction for oxyhemoglobin, invariably present in sera form neonates, is achieved by measuring absorbance at two wavelengths and solving a system of two simultaneous equations with two unknowns. If absorbance (A) is measured at 454 nm and 540 nm—the isosbestic wavelengths for hemoglobin—the concentration of bilirubin is then calculated from a single equation.

Note, this method requires determination of the absorptivity of pure unconjugated bilirubiin in human serum at the chosen wavelengths, and of hemoglobin if the chosen wavelengths are not isosbestic.

Calibrators for Bilirubin Measurements

The primary calibrator for all bilirubin methods should consist of unconjugated bilirubin dissolved in human serum. Several instrument manufacturers are using bovine serum, instead of human serum, as the protein base in preparing fluids for calibrating methods for total and direct bilirubin; the protein base is enriched with unconjugated bilirubin or ditaurobilirubin or both. Unconjugated bilirubin in human serum reacts completely with the reference method and with diazo methods

BOX 28-3 Bilirubin Fractions

Unconjugated bilirubin (α-bilirubin)
Monoconjugated bilirubin (β-bilirubin)
Di-conjugated bilirubin (γ-bilirubin)
A fraction irreversibly bound to protein (δ-bilirubin)

available in commonly used clinical analyzers. However, its reaction in bovine serum from commercial sources is incomplete and unpredictable; this makes virtually impossible the assignment of accurate bilirubin values to calibrators, the protein base of which is commercial bovine serum.[21] In human serum, ditaurobilirubin was underestimated by two of seven clinical analyzers tested; the calibrators of these two analyzers were made in bovine serum. Ditaurobilirubin in commercial bovine serum was underestimated by all analyzers and by the reference method. Consequently, it is recommended that the practice of using bilirubin calibrators made in bovine sera be abandoned because it compromises the accuracy of bilirubin measurements in jaundiced neonates.[21]

High-Performance Liquid Chromatography (HPLC)

HPLC methods have been developed for relatively rapid separation and quantification of the four main bilirubin fractions: (1) α-unconjugated bilirubin; (2) β-bilirubin monoglucuronide; (3) γ-bilirubin diglucuronide; and (4) δ-bilirubin (Box 28-3). More complex methods can be used to detect and separate the various bilirubin photoisomers produced in newborns during phototherapy.

δ-Bilirubin is formed in blood and in vitro by a spontaneous reaction between serum albumin and the bilirubin glucuronides; unconjugated bilirubin does not react with albumin to form δ-bilirubin. Because δ-bilirubin is water soluble, it reacts directly (without a promoter) with diazotized sulfanilic acid.

The discovery of δ-bilirubin solved the mystery of persistently high bilirubin concentrations, mostly direct reacting, in patients with intrahepatic or obstructive jaundice long after hepatitis has subsided or obstruction has been relieved. Because δ-bilirubin is the slowest fraction to clear from serum, it follows the catabolism of albumin, which has a half-life of approximately 17 to 19 days.

It should be noted that the various bilirubin fractions have been separated by capillary electrophoresis.

Enzymatic Methods

Enzymatic methods for total and direct bilirubin and for bilirubin conjugates with glucuronic acid are based on the oxidation of bilirubin to biliverdin by bilirubin oxidase and molecular oxygen. At a pH near 8 and in the presence of sodium cholate and sodium dodecylsulfate, all four bilirubin fractions are oxidized to biliverdin, which is further oxidized to purple and finally colorless products. The decrease in absorbance at 425 or 460 nm is proportional to the concentration of total bilirubin. Results obtained by the bilirubin oxidase method have been shown to correlate with those obtained by the Jendrassik-Grof procedure. Direct bilirubin is measured at pH 3.7 to 4.5; at this pH range, the enzyme oxidizes bilirubin conjugates and δ-bilirubin, but not unconjugated bilirubin. At pH 10, the enzyme oxidizes selectively the two glucuronides. δ-Bilirubin is not oxidized, and only 5% of unconjugated bilirubin is measured as conjugates.[12]

Transcutaneous Measurement of Bilirubin

A noninvasive approach for measuring bilirubin was introduced in 1980 by Yamanouchi and colleagues. The first bilirubinometer (icterometer) was a reflectance photometer that used two filters to correct for the color of Hb and required measurements at eight body sites. The accuracy of commercially available devices has improved substantially, and two of them (the BiliChek, http://bilichek.respironics.eu\; accessed October 14, 2013; and the Minolta JM 103 Jaundice Meter, http://www5.konicaminolta.eu/; accessed October 14, 2013) have been cleared by the U.S. Food and Drug Administration for clinical use in the United States[13]; furthermore, the U.S. National Academy of Clinical Biochemistry has approved transcutaneous bilirubin measurement for point-of-care testing.[19] A review of this subject has been published.[13]

Although transcutaneous bilirubin measurements may not substitute for laboratory quantitative determinations, they (1) provide instantaneous information, (2) reduce the necessity for serum bilirubin determinations, (3) spare infants the trauma of heel sticks, and (4) save money. Furthermore, they are useful in determining whether in a jaundiced infant it is necessary to draw blood before initiating treatment, such as phototherapy or exchange transfusion (currently this is extremely rare). Another application involves predicting those babies who require follow-up according to the "hour-specific" serum bilirubin nomogram.[13]

Urine Bilirubin

Because only conjugated bilirubin is excreted in urine, its presence indicates conjugated hyperbilirubinemia. The most commonly used method for detecting bilirubin in urine involves the use of a dipstick impregnated with a diazo reagent. Dipstick methods are capable of detecting bilirubin concentrations as low as 0.5 mg/dL. A number of these methods are available commercially.

Review Questions

1. Heme is a:
   a. chelate of iron with the four pyrrole groups of a porphyrin.
   b. conjugated protein and an oxygen-carrying pigment of the erythrocytes.
   c. protein found in red skeletal muscle that releases oxygen.
   d. colorless compound formed in the intestines by the reduction of bilirubin.
2. The role of hemoglobin is to:
   a. transport iron between organs.
   b. store iron and readily release it when body iron stores are low.

c. reversibly bind oxygen.
d. conjugate bilirubin in the liver.

3. What is bilirubin conjugated to in a hepatocyte to form conjugated bilirubin?
   a. Cholic acid
   b. Glycogen
   c. Bile acid
   d. Glucuronic acid
4. In an individual with suspected β-thalassemia, which of the following laboratory results would correctly indicate the presence of this disease?
   a. Increased hemoglobin concentration, MCV and MCHC with the peripheral blood smear showing increased macrocytes and Howell-Jolly bodies
   b. Decreased hemoglobin concentration, MCV and MCHC with the peripheral blood smear indicating microcytosis, target cells and polychromasia
   c. Decreased hemoglobin concentration, increased MCV and MCHC and persistence of hemoglobin F with the peripheral blood smear indicating spherocytosis and nucleated red blood cells
   d. Increased hemoglobin concentration and normal MCV and MCHC with a normal peripheral blood smear
5. Which of the following is associated with low serum iron and high total iron binding capacity (TIBC)?
   a. Hemochromatosis
   b. Iron deficiency anemia
   c. Iron intoxication
   d. Hemosiderosis
6. The readily soluble iron/protein complex is the form in which iron is stored in tissues:
   a. Ferritin
   b. Transferrin
   c. Hemosiderin
   d. Hemoglobin
7. The correct formula for determining the percent of transferrin saturation % is:
   a. MCV < 70 mL = increased transferrin
   b. total iron binding capacity ÷ serum iron
   c. total iron binding capacity × 100
   d. [total iron binding capacity ÷ serum iron] × 100
8. The major difference between thalassemia and hemoglobinopathy is that:
   a. in thalassemia the globin chains of hemoglobin are structurally altered.
   b. in thalassemia the serum level of conjugated bilirubin is dramatically increased.
   c. in a hemoglobinopathy the globin chains of hemoglobin are structurally altered.
   d. in a hemoglobinopathy the globin chains of hemoglobin are insufficiently produced.
9. An inherited disorder caused by an inherited abnormality of proteins that regulate iron hemostasis with excess circulating iron is called:
   a. hemosiderosis.
   b. primary hemochromatosis.
   c. secondary hemochromatosis.
   d. sideroblastic anemia.
10. Hemolytic disease in a newborn results from maternal-fetal Rh incompatibility. The is produces physiological jaundice that is characterized by:
    a. unconjugated hyperbilirubinemia.
    b. conjugated bilirubinemia.
    c. hemosiderosis.
    d. hemoglobinopathy.
11. Extrahepatic biliary atresia:
    a. is characterized by lack of bile ducts within the liver.
    b. is less common than intrahepatic biliary atresia.
    c. is characterized by a mixed hyperbilirubinemia.
    d. produces jaundice that can be observed within the first few days of life.
12. Bilirubin:
    a. in the conjugated form is highly toxic to the nervous system when elevated.
    b. in the plasma is bound to albumin before conjugation in hepatocytes.
    c. becomes conjugated to cholic acid in the hepatocyte.
    d. All of the above answers are correct.

CHAPTER

29 Porphyrins and Porphyrias

Michael N. Badminton, M.B.Ch.B., Ph.D., F.R.C.Path., Sharon D. Whatley, Ph.D., Allan C. Deacon, Ph.D., F.R.C.Path., and George H. Elder, M.D., F.R.C.P., F.R.C.Path.

Objectives

1. Define the following terms:
   - 5-Aminolevulinic
   - Amino acid
   - Ferrochelatase
   - Heme
   - Porphyrin
   - Porphobilinogen (PBG)
   - Porphyria
   - Zinc protoporphyrin
2. Summarize the biosynthetic pathway of heme, including intracellular sites of each synthetic step, rate-limiting step, and enzyme, and incorporation into hemoglobin.
3. List six functions of heme.
4. Compare and contrast the acute and nonacute porphyrias, including causes, symptoms, and laboratory analyses; describe the screening tests that differentiate between the two categories of porphyria.
5. List and categorize seven porphyrias; state the major elevated intermediates involved in each.
6. List the abnormalities of porphyrin metabolism that are unrelated to porphyria.
7. Explain the effects of lead toxicity on the heme biosynthetic pathway and on iron status.
8. List the specimen collection and storage requirements for samples undergoing porphyrin analysis.
9. Describe the laboratory methods of analysis for the following:
   - Porphobilinogen
   - 5-Aminolevulinic acid
   - Porphyrins in urine, stool, blood, and plasma
   - DNA assessments
10. Analyze and solve case studies related to abnormal porphyrin metabolism and lead toxicity.

Key Words and Definitions

Acute porphyrias Inherited disorders of heme biosynthesis, characterized by acute attacks of neurovisceral symptoms; potentially life threatening; diagnosed by elevated urine PBG.

Acute intermittent porphyria (AIP) An autosomal dominant hepatic porphyria caused by mutation in the HMBS gene (locus: 11q23.3), which encodes hydroxymethylbilane synthase.

5-Aminolevulinic acid (ALA) Immediate precursor of porphobilinogen; two molecules of ALA combine to form one molecule of porphobilinogen.

Congenital erythropoietic porphyria (CEP) An autosomal recessive porphyria due to mutation in the UROS gene (locus: 10q25.2-q26.3), which encodes uroporphyrinogen-III synthase.

Coproporphyrin A porphyrin with four methyl and four propionic acid sidechains attached to the tetrapyrrole backbone.

Cutaneous porphyrias Disorders of heme biosynthesis in which accumulations of porphyrins in the skin cause skin damage on exposure to sunlight.

Erythropoietic protoporphyria (EPP) An autosomal dominant disorder due to mutation in the FECH gene (locus: 18q21.3), which encodes ferrochelatase, causing a partial deficiency of the enzyme.

Ferrochelatase (FECH) A mitochondrial enzyme of the lyase class that catalyzes the insertion of ferrous iron into protoporphyrin IX to form protoheme IX, the heme of hemoglobin.

Hereditary coproporphyria (HCP) An autosomal dominant hepatic porphyria caused by mutations of the CPOX gene (locus: 3q12) that result in partial deficiency of coproporphyrinogen oxidase activity

Porphobilinogen (PBG) Immediate precursor of the porphyrins; a pyrrole ring with acetyl, propionyl, vinyl, and aminomethyl sidechains; four molecules of PBG condense to form one molecule of 1-hydroxymethylbilane, which is then converted successively to uroporphyrinogen-III, coproporphyrinogen-III, protoporphyrinogen-IX, protoporphyrin-IX, and heme.

Porphyrins Any of a group of compounds containing the porphyrin structure; four pyrrole rings connected by methylene bridges in a cyclical configuration, to which a variety of sidechains are attached.

Porphyrias A group of mainly inherited metabolic disorders that result from partial deficiencies of the enzymes of heme biosynthesis, which cause increased formation and excretion of porphyrins, their precursors, or both.

Key Words and Definitions—cont'd

Porphyria cutanea tarda (PCT) The most common form of porphyria, characterized by cutaneous photosensitivity.

Porphyrin precursors ALA and PBG, the biosynthetic intermediates, are metabolized to porphyrinogens and porphyrins.

Protoporphyrin A porphyrin with four methyl, two vinyl, and two propionic acid sidechains attached to the tetrapyrrole backbone; the protoporphyrin-IX/iron complex; heme is the prosthetic group of hemoglobin, cytochromes, and other hemoproteins.

Upregulation A process that results in an increase in the number of receptors on the surface of target cells, making the cells more sensitive to a hormone or another agent. Downregulation is a decrease in the number of receptors on the surface of target cells.

Uroporphyrin A porphyrin with four acetic acid and four propionic acid sidechains attached to the tetrapyrrole backbone.

Variegate porphyria (VP) An autosomal dominant hepatic porphyria due to mutation in the PPOX gene (locus: 1q22), which encodes protoporphyrinogen oxidase.

X-linked protoporphyria (XLDPP) A rare genetic disorder characterized by an abnormal sensitivity to the sun (photosensitivity).

Zinc protoporphyrin (ZPP) A normal but minor by-product of heme biosynthesis found in the red blood cell; when insufficient Fe^{2+} is available for heme biosynthesis, increased ZPP is formed.

The **porphyrias** are a group of diseases characterized by either deficiency in one of the enzymes of heme biosynthesis, leading to the overproduction of intermediates of the pathway or, in one rare disorder, an increase in activity of the rate-controlling enzyme of erythroid heme synthesis.[1,17] These intermediates are excreted in excessive amounts in (1) urine, (2) feces, or (3) both. The clinical consequences depend on the nature of the heme precursors that accumulate. In the **acute porphyrias**, excess **porphyrin precursors (5-aminolevulinic acid [ALA]** and **porphobilinogen [PBG])** are associated with potentially fatal acute neurovisceral attacks, which are often provoked by (1) a number of commonly prescribed or illicit drugs, (2) hormonal factors, (3) alcohol, (4) starvation, (5) stress, or (6) infection. In the nonacute porphyrias, and in those acute porphyrias in which the skin may be affected, accumulation of porphyrins results in photosensitization and skin lesions. Diagnosis depends on laboratory investigation to demonstrate the pattern of heme precursor accumulation specific for each type of porphyria. This requires examination of appropriate specimens for key metabolites using adequately sensitive and specific methods.

Technical advances in the field of molecular genetics have made it possible to investigate all porphyrias at the molecular level. Although not essential for diagnosis of symptomatic cases, these techniques are important for the investigation of families with porphyria.

Porphyrin and Heme Chemistry

In this section, porphyrin (1) structure, (2) nomenclature, and (3) chemical characteristics are reviewed.

Porphyrin Structure and Nomenclature

The basic **porphyrin** structure consists of four monopyrrole rings connected by methene bridges to form a tetrapyrrole ring (Figure 29-1). Many porphyrin compounds are known, but only a limited number are of clinical interest. The porphyrin compounds of relevance to the porphyrias (Table 29-1) differ in the substituents occupying peripheral positions 1 through 8. Variation in the distribution of the same substituents around the peripheral positions of the tetrapyrrole ring gives rise to porphyrin isomers, which are usually depicted by Roman numerals (I, II, III, etc.). The reduced form of a porphyrin, known as a porphyrinogen (see Figure 29-1), differs by the presence of six additional hydrogens (four on the methylene bridges and two on the ring nitrogens). Porphyrinogens are unstable in vitro and are spontaneously oxidized to the corresponding porphyrins. Under the lower oxygen tension of the cell, porphyrinogens are stable and form intermediates of the heme biosynthetic pathway; aromatization to **protoporphyrin** at the penultimate step requires an enzyme.

Chelation of Metals

The arrangement of four nitrogen atoms at the center of the porphyrin ring enables porphyrins to chelate various metal ions. Protoporphyrin that contains iron is known as heme; ferroheme refers specifically to the Fe^{2+} complex and ferriheme to Fe^{3+}. Ferriheme associated with a chloride counter ion is known as hemin, or hematin when the counter ion is hydroxide.

Spectral Properties

Porphyrins were named from the Greek root for "purple" (porphyra) and owe their color to the conjugated double-bond structure of the tetrapyrrole ring. The porphyrinogens

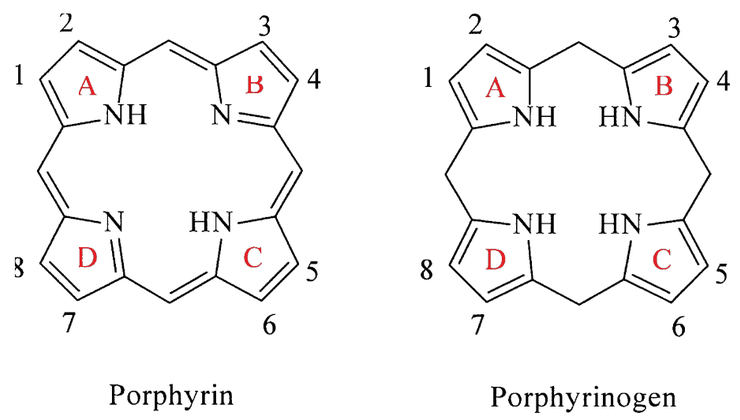

Figure 29-1 Representations of porphyrin and porphyrinogen. Numbering system and ring designations are based on the Fischer system.

TABLE 29-1 Substituents Around the Macrocycle in Porphyrins of Clinical Importance

	Position							
Porphyrin	1	2	3	4	5	6	7	8
Uroporphyrin-I	C_m	C_{et}	C_m	C_{et}	C_m	C_{et}	C_m	C_{et}
Uroporphyrin-III	C_m	C_{et}	C_m	C_{et}	C_m	C_{et}	C_{et}	C_m
Heptacarboxylate porphyrin-III	C_m	C_{et}	C_m	C_{et}	C_m	C_{et}	C_{et}	Me
Hexacarboxylate porphyrin-III	Me	C_{et}	C_m	C_{et}	C_m	C_{et}	C_{et}	Me
Pentacarboxylate porphyrin-III	Me	C_{et}	Me	C_{et}	C_m	C_{et}	C_{et}	Me
Coproporphyrin-III	Me	C_{et}	Me	C_{et}	Me	C_{et}	C_{et}	Me
Coproporphyrin-I	Me	C_{et}	Me	C_{et}	Me	C_{et}	Me	C_{et}
Isocoproporphyrin	Me	Et	Me	C_{et}	C_m	C_{et}	C_{et}	Me
Dehydroisocoproporphyrin	Me	Vn	Me	C_{et}	C_m	C_{et}	C_{et}	Me
Deethylisocoproporphyrin	Me	H	Me	C_{et}	C_m	C_{et}	C_{et}	Me
Protoporphyrin	Me	Vn	Me	Vn	Me	C_{et}	C_{et}	Me
Pemptoporphyrin	Me	H	Me	Vn	Me	C_{et}	C_{et}	Me
Deuteroporphyrin	Me	H	Me	H	Me	C_{et}	C_{et}	Me
Mesoporphyrin	Me	Et	Me	Et	Me	C_{et}	C_{et}	Me

C_m, carboxymethyl (—CH_2COOH); $C_{et}C_{et}$, carboxyethyl (—CH_2CH_2COOH); Me, methyl (—CH_3); Et, ethyl (—CH_2CH_3); Vn, vinyl (—$CH_2 = CH_3$).

have no conjugated double bonds and are colorless. Porphyrins show a particularly strong absorbance near 400 nm, often called the Soret band. When exposed to light in the 400-nm region, porphyrins display a characteristic orange-red fluorescence in the range of 550 to 650 nm. Absorbance and fluorescence are altered by substituents around the porphyrin ring and by metal binding. Zinc chelation shifts the fluorescence peak of protoporphyrin to shorter wavelengths and reduces the fluorescence intensity. The strong binding of iron alters the character of protoporphyrin to the extent that heme lacks significant fluorescence.

Solubility

Porphyrins are only marginally soluble in water. The differing solubilities of individual porphyrins are of importance not only in the design of analytical methods for their extraction and fractionation but in determination of the route of excretion from the body. At pH 7, the carboxyl groups are ionized, and the molecule has a net negative charge. Below pH 2, the pyrrole nitrogens and the carboxyl groups become protonated so that the molecule has a net positive charge.

At physiological pH, the solubility of a given porphyrin is determined by the number of substituent carboxyl groups. For example, **uroporphyrin** has eight carboxylate groups and is the most soluble porphyrin in aqueous media. As protoporphyrin has only two carboxylate groups, it is essentially insoluble in water but dissolves readily in lipid environments and binds readily to the hydrophobic regions of proteins, such as albumin. **Coproporphyrin,** with four carboxylate groups, has intermediate solubility.

Porphyrin Precursors

ALA and PBG are known as porphyrin precursors (Figure 29-2). ALA is sometimes referred to as aminolevulinate (to emphasize its ionic nature at physiological pH). PBG contains a single pyrrole ring (unlike porphyrins, which contain four) and is often referred to as a monopyrrole. PBG polymerizes readily, particularly at high concentrations in acid solution to form primarily the I-isomer of uroporphyrin. Both ALA and PBG are highly water soluble.

Heme Biosynthesis

The complex tetrapyrrole ring structure of heme is built up in a stepwise fashion from the very simple precursors succinyl-coenzyme A (CoA) and glycine (see Figure 29-2).[1] The pathway is present in all nucleated cells, and it has been estimated that daily synthesis of heme in humans consists of 5 to 8 mmol/kg body weight. The pathway is compartmentalized, with some steps occurring in the mitochondrion and others in the cytoplasm. No transport defect has yet been reported in the porphyrias.

5-Aminolevulinate Synthase (EC 2.3.1.37), ALAS

ALAS is the initial enzyme of the pathway with a housekeeping (ALAS1) and an erythroid (ALAS2) isozyme; it catalyzes the formation of ALA from succinyl-CoA and glycine. The enzyme is mitochondrial and requires pyridoxal phosphate as a cofactor, which forms a Schiff base with the amino group of glycine at the enzyme surface. The carbanion of the Schiff base displaces CoA from succinyl-CoA with the formation of α-amino-β-ketoadipic acid, which is then decarboxylated to ALA. The activity of ALAS is rate limiting as long as the catalytic capacities of other enzymes in the pathway are normal.

5-Aminolevulinic Acid Dehydratase (EC 4.2.1.24), ALAD

ALAD (also known as porphobilinogen synthase) is a cytoplasmic enzyme that catalyzes the formation of the monopyrrole PBG from two molecules of ALA with elimination of two molecules of water. The enzyme requires zinc ions as a cofactor and reduced sulfhydryl groups at the active site and is therefore susceptible to inhibition by lead.

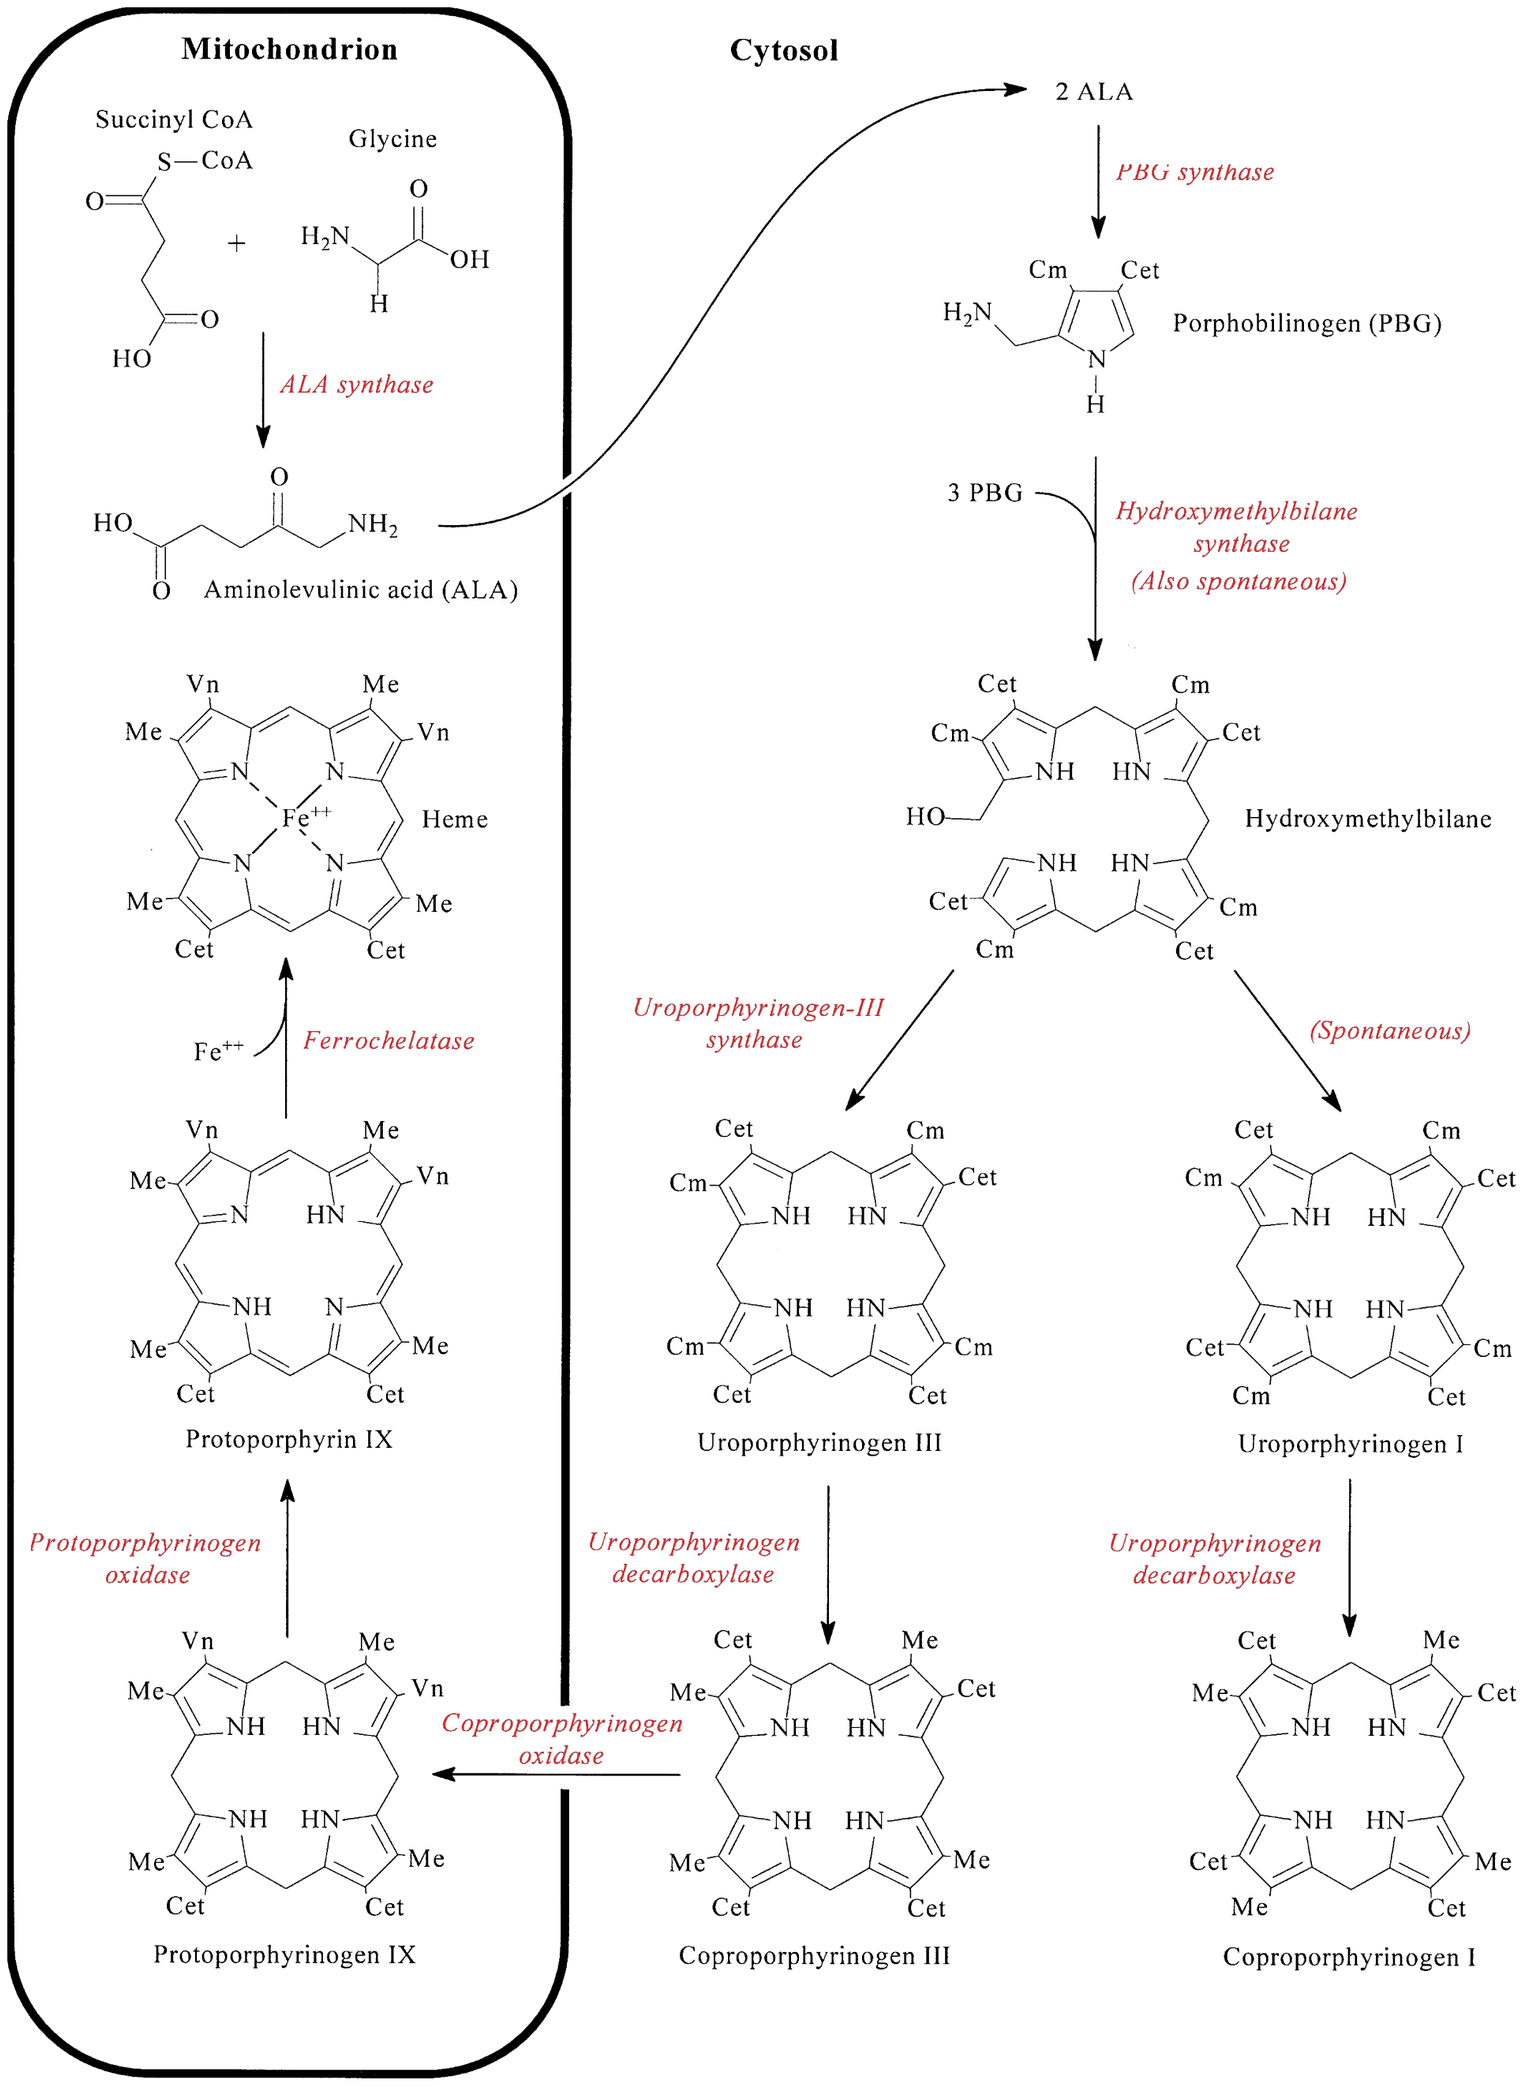

Figure 29-2 Biosynthetic pathway of porphyrins and heme. C_{et}, $—CH_2CH_2COOH$; C_m, $—CH_2COOH$; Me, $—CH_3$; Vn, $—CH = CH_2$.

Hydroxymethylbilane Synthase (EC 2.5.1.61), HMBS

HMBS (also known as PBG deaminase) is a cytoplasmic enzyme that catalyzes the formation of one molecule of the linear tetrapyrrole 1-hydroxymethylbilane (HMB; also known as pre-uroporphyrinogen) from four molecules of PBG with the release of four molecules of ammonia. T e enzyme is susceptible to allosteric inhibition by intermediates farther down the heme biosynthetic pathway, notably coproporphyrinogen-III and protoporphyrinogen-IX.[16]

Uroporphyrinogen-III Synthase (EC 4.2.1.75), UROS

UROS is a cytoplasmic enzyme that rearranges and cyclizes HMB to form uroporphyrinogen-III. Each pyrrole ring of HMB contains methylcarboxylate and ethylcarboxylate substituents, which are in the same orientation. By the rotation of (1) no, (2) one, or (3) two alternate pyrrole rings or (4) two adjacent pyrrole rings, it is possible to arrive at four different isomers (I to IV). Apart from closing the ring structure, the enzyme rotates the D-ring via a spirane intermediate, producing the type III isomer—this rotation is vital because only the type III isomer contributes to heme biosynthesis. HMB is unstable, and in those porphyrias in which excess HMB accumulates, cyclization occurs non-enzymatically with formation of the type I isomer. Normally, only minimal amounts of uroporphyrinogen-I are formed.

Uroporphyrinogen Decarboxylase (EC 4.1.1.37), UROD

T is last cytoplasmic enzyme in the pathway catalyzes the decarboxylation of all four carboxymethyl groups to form the tetracarboxylic coproporphyrinogen. T e enzyme uses both I and III isomers of uroporphyrinogen as substrate. Decarboxylation commences on ring D and proceeds stepwise through rings A, B, and C with formation of heptacarboxylate, hexacarboxylate, and pentacarboxylate intermediates at a single active site. A UROD deficiency causes accumulation of these intermediates in addition to its substrate, uroporphyrinogen. At high substrate concentrations, decarboxylation occurs by a random mechanism.

Coproporphyrinogen Oxidase (EC 1.3.3.3), CPOX

CPOX is situated in the intermembrane space of mitochondria and catalyzes the sequential oxidative decarboxylation of the 2- and 4-carboxyethyl groups to vinyl groups to produce the more lipophilic protoporphyrinogen-IX, with formation of a tricarboxylic intermediate, harderoporphyrinogen. Oxygen is required as the oxidant. T e enzyme requires sulfhydryl groups for activity, making it a target for inhibition by metals. T e enzyme is specific for the type III isomer, so that metabolism of the I-series of porphyrins does not occur beyond coproporphyrinogen-I. T e product of the enzyme differs from the substrate in that replacement of two of the carboxyethyl groups by vinyl groups has introduced a third substituent into the molecule. T erefore the number of possible isomeric forms increases, and conventionally the numbering system changes, so that the III isomer becomes the IX isomer. In UROD-deficient states, one of the ethylcarboxylate groups of accumulated pentacarboxylate porphyrinogen is decarboxylated by an unknown mechanism to form the isocoproporphyrin series of porphyrins.

Protoporphyrinogen Oxidase (EC 1.3.3.4), PPOX

PPOX is a flavoprotein located in the inner mitochondrial membrane that catalyzes the removal of six hydrogens (four from methylene bridges and two from ring nitrogens) to form protoporphyrin IX. Nonenzymatic oxidation also occurs in vitro. However, under the oxygen tension in the cell, PPOX is essential for the oxidation to occur. T e protoporphyrin produced is the only porphyrin that functions in the heme pathway. Other porphyrins are produced by nonenzymatic oxidation and represent porphyrinogens that have irreversibly escaped from the pathway.

Ferrochelatase (EC 4.99.1.1)

Ferrochelatase (FECH/also known as heme synthase) is an iron-sulfur protein located in the inner mitochondrial membrane. T is enzyme inserts ferrous iron into protoporphyrin to form heme. During this process, two hydrogens are displaced from the ring nitrogens. Other metals in the divalent state will also act as substrate, yielding the corresponding chelate (e.g., incorporation of Zn^{2+} into protoporphyrin to yield **zinc protoporphyrin [ZPP]**). In iron-deficient states Zn^{2+} successfully competes with Fe^{2+} in developing red cells, so that the concentration of zinc protoporphyrin in erythrocytes is increased. Furthermore, other dicarboxylic porphyrins will also serve as substrates (e.g., mesoporphyrin).

Function of Heme

Heme functions as a prosthetic group in various proteins in which, depending on the function of the protein, the iron shifts freely between different valence states. Seventy percent to 80% of heme synthesis occurs in the bone marrow, and approximately an additional 15% in the liver. Heme-containing proteins participate in a variety of redox reactions, including:

1. Oxygen transport (by hemoglobin in the blood) and storage (by myoglobin in muscle)
2. Mitochondrial respiration (by cytochromes b_1, c_1, and a_3)
3. Enzymatic destruction of peroxides (by catalase and peroxidase)
4. Drug metabolism (by microsomal cytochrome P-450 mixed function oxidases)
5. Desaturation of fatty acids (by microsomal cytochrome b_5)
6. Tryptophan metabolism (by tryptophan oxygenase)

Reactions of nitric oxide (NO) are often mediated by the reaction of heme with NO in control enzymes such as guanylate cyclase.

Other naturally occurring tetrapyrrole derivatives include vitamin B_{12} and chlorophyll, each of which contains an atom of chelated cobalt and magnesium, respectively.

Excretion of Heme Precursors

Normally, only minute amounts of heme precursors accumulate in the body. T e route of excretion largely depends on solubility. T e porphyrin precursors ALA and PBG are water soluble and are excreted almost exclusively in urine. Uroporphyrinogen, with eight carboxylate groups, is readily water soluble and is also excreted via the kidney. T e last intermediate of the pathway, protoporphyrin and protoporphyrinogen, is excreted in the feces via the biliary tract. T e other porphyrins are of intermediate solubility and appear in both urine and feces. Coproporphyrinogen-I is taken up and excreted by the liver in preference to the III isomer so that coproporphyrinogen-I predominates in feces and coproporphyrinogen-III in urine. All porphyrinogens in the urine or feces are slowly oxidized to the corresponding porphyrins.

Once in the gut, porphyrins are susceptible to modification by gut flora. T e two vinyl groups of protoporphyrins are (1) reduced to ethyl groups, (2) hydrated to hydroxyethyl groups, or (3) removed, giving rise to a variety of secondary porphyrins. Gut flora also metabolizes heme to produce a variety of dicarboxylic porphyrins. Furthermore, some bacteria are capable of de novo synthesis of porphyrins.

Regulation of Heme Biosynthesis

Heme supply in all tissues is controlled by the activity of mitochondrial ALAS, the first enzyme of the pathway. Two isoforms of ALAS are known. T e ubiquitous isoform, ALAS1, is encoded by a gene on chromosome 3p21 and is expressed in all tissue. Because it has a half-life of approximately an hour, changes in its rate of synthesis produce short-term alterations in enzyme concentration and cellular ALAS activity.

Synthesis of ALAS1 is under negative feedback control by heme. In the liver, ALAS1 is induced by a wide range of drugs and chemicals that induce microsomal cytochrome P-450–dependent oxidases (CYPs). This effect is thought to be mediated primarily by direct transcriptional activation by drug-responsive nuclear receptors rather than being secondary to depletion of an intracellular regulatory heme pool. Induction of ALAS1 is prevented by heme, which acts by destabilizing messenger ribonucleic acid (mRNA) for ALAS1, by blocking mitochondrial import of pre-ALAS1, and possibly by inhibiting transcription.

The erythroid isoform, ALAS2, is encoded by a gene on chromosome Xq21-22 and is expressed only in erythroid cells. Its activity is regulated by two main mechanisms. One: Transcription is enhanced during erythroid differentiation by the action of erythroid-specific transcription factors. Two: mRNA concentrations are regulated by iron. Iron deficiency in erythroid cells promotes specific binding of iron regulatory proteins to an iron-responsive element in the 5′ untranslated region (UTR) of ALAS2 mRNA with consequent inhibition of translation.

Primary Porphyrin Disorders

The porphyrias are a group of metabolic disorders that result from partial deficiencies of the enzymes of heme biosynthesis, or in one disorder, a gain of function mutation[18] (Table 29-2). All are inherited in monogenic patterns, except some forms of **porphyria cutanea tarda (PCT)** and rare types of erythropoietic porphyria. Large numbers of disease-specific mutations have now been identified in each of the genes encoding the defective enzymes (www.hgmd.cf.ac.uk/; accessed October 29, 2013). Each type of porphyria is defined by the association of characteristic clinical features with a specific pattern of accumulation of heme precursors. These patterns reflect increased formation of substrates for the enzyme that is deficient in that type of porphyria (Table 29-3).

The porphyrias are characterized clinically by two main features: skin lesions on sun-exposed areas and acute neurovisceral attacks, typically comprising (1) abdominal pain, (2) peripheral neuropathy, and (3) mental disturbance. The skin lesions are caused by porphyrin-catalyzed photo damage, of which singlet oxygen is the main mediator. Acute attacks are associated with increased formation of ALA from induced activity of hepatic ALAS1 and partial hepatic heme deficiency, often in response to induction of hepatic CYPs by drugs and other factors. The relationship of these biochemical changes to the neuronal dysfunction that underlies all clinical features of the acute attack is uncertain.

As listed in Table 29-2, the porphyrias are categorized as (1) acute porphyrias, in which acute neurovisceral attacks occur, and (2) nonacute porphyrias.

Acute Porphyrias

Acute porphyrias include (1) acute intermittent porphyria (AIP), (2) **variegate porphyria (VP)**, and (3) **hereditary coproporphyria (HCP)**. The inherited defect in autosomal dominant acute porphyrias is a mutation leading to complete or near complete inactivation of one of the pairs of allelic genes that encode the enzyme whose partial deficiency causes the disorder. Enzyme activities are therefore half normal in all tissue in which they are expressed, reflecting the activity of the normal gene trans to the mutant allele. Heme supply is maintained at healthy or near healthy amounts by **upregulation** of ALAS with a consequent increase in the substrate concentration of the defective enzyme. These compensatory changes vary between tissues and are most prominent in the liver and undetectable in most other organs. These changes also vary between individuals with (1) some showing no evidence of overproduction of heme precursors and (2) some biochemically manifesting disease. Low clinical penetrance is a prominent feature of all the autosomal dominant acute porphyrias. Family studies indicate that about 80% of affected individuals are asymptomatic throughout life. Long-term complications of acute porphyria include chronic renal failure, hypertension, and hepatocellular carcinoma.[1,17]

In AIP the primary defect is a deficiency of HMBS, which results in accumulation of its substrate PBG (and to a lesser

TABLE 29-2 The Main Types of Human Porphyria

Disorder	Defective Enzyme	Prevalence*	Neurovisceral Crises	Skin Lesions	Inheritance
Acute Porphyrias					
ALA dehydratase deficiency porphyria (ALADP)	ALAD	Very rare	+	—	AR
Acute intermittent porphyria (AIP)	HMBS	1-2:100,000	+	—	AD
Hereditary coproporphyria (HCP)	CPO	1-2:1,000,000	+	+†,‡	AD
Variegate porphyria (VP)	PPOX	1:250,000	+	+†,‡	AD
Nonacute Porphyrias					
Congenital erythropoietic porphyria (CEP)	UROS	1:3,000,000	—	+‡	AR
Porphyria cutanea tarda (PCT)	UROD	1:25,000	—	+‡	Complex (20% AD)
Erythropoietic protoporphyria (EPP)	FECH	1:140,000	—	+§	AR
X-linked dominant protoporphyria	ALAS2	1:3,000,000	—	+§	X-linked

AD, Autosomal dominant; AR, autosomal recessive.
*Estimated prevalence of clinically overt disease in the United Kingdom.
†Skin lesions and neurovisceral crises may occur alone or together.
‡Fragile skin, bullae.
§Acute photosensitivity without fragile skin, bullae.

TABLE 29-3 The Porphyrias: Patterns of Overproduction of Heme Precursors During Clinically Overt Phase of Disease

Porphyria	Urine PBG/ALA	Urine Porphyrins	Fecal Porphyrins	Erythrocyte Porphyrins	Plasma Fluorescence Emission Peak
ALADP	ALA	Copro-III	Not increased	Zn-proto	—
AIP	PBG> ALA	Mainly uroporphyrin from PBG	Normal, or slight increase in Copro, ProtoProto*	Not increased	615-620 nm†
CEP	Not increased	Uro-I, Copro-I	Copro-I	Zn-proto, Proto, Copro-I, Uro-I	615-620 nm
PCT	Not increased	Uro, Hepta‡	Isocopro, Hepta‡	Not increased	615-620 nm
HCP	PBG> ALA§	Copro-III, uroporphyrin from PBG	Copro-III	Not increased	615-620 nm†
VP	PBG> ALA§	Copro-III, uroporphyrin from PBG	Proto-IX> Copro-III, X-porphyrin	Not increased	624-628 nm
EPP	Not increased	Not increased	±Proto±Proto‖	Proto	626-634 nm¶
XLDPP	Not increased	Not increased	±Proto	Zn-proto, Proto,	626-634 nm¶

*Total porphyrin may be increased because of the presence of excess uroporphyrin.
†Not always increased during acute attack.
‡Other methylcarboxylate substituted porphyrins are increased to a smaller extent; uroporphyrin is a mixture of type I and III isomers; heptacarboxylate porphyrin is mainly type III.
§PBG and ALA may be normal when only skin lesions are present.
‖Not increased in about 40% of patients.
¶Protoporphyrin¶ bound to globin (if hemolysis is in the sample) has a peak at 626 to 628 nm.

extent ALA). In VP and HCP inherited deficiencies of enzymes further down the pathway lead to the accumulation of porphyrinogens, which are potent allosteric inhibitors of HMBS,[16] and lead to secondary accumulation of PBG (and ALA). In the very rare recessive disorder ALADP (ALA dehydratase deficiency porphyria), an inherited deficiency of ALAD leads to accumulation of ALA and coproporphyrin-III but not PBG.

The life-threatening, acute neurovisceral attacks that occur in AIP, VP, and HCP are clinically identical.[17] Acute attacks are more common in women, usually occurring first between the ages of 15 and 40 years. They are very rare before puberty.

Acute attacks of porphyrias almost always start with abdominal pain that rapidly becomes very severe. However, they are not accompanied by peritonism or other signs of an acute surgical condition. Pain may also be present in the back and thighs and may occasionally be most severe in these regions. Signs of autonomic neuropathy, such as (1) vomiting, (2) constipation, (3) tachycardia, and (4) hypertension, are frequent. When convulsions occur, they are often caused by hyponatremia. Pain may resolve within a few days, but in severe cases a predominant motor neuropathy develops that may progress to flaccid quadriparesis (weakness of both arms and both legs). Persistent pain and vomiting may lead to weight loss and malnutrition. The acute phase may be accompanied by mental confusion with abrupt changes in (1) mood, (2) hallucinations, and (3) other psychotic features. However, these mental disturbances disappear with remission. Persistent psychiatric illness is not a feature of the acute porphyrias, although mild anxiety or depression may be present in some patients. Abdominal pain usually resolves within 2 weeks, but recovery from neuropathy may take many months and is not always complete. In fact, most patients have one or a few attacks followed by complete recovery and prolonged remission. About 5% have repeated acute attacks that in women may be premenstrual.

Precipitating factors have been identified in about two-thirds of patients who have acute attacks. The most important are (1) drugs, (2) alcohol, especially binge drinking, (3) the menstrual cycle, (4) calorie restriction, (5) infection, and (6) stress. Although pregnancy is typically uncomplicated in acute porphyria patients, acute attacks can occasionally occur. Drugs known to provoke acute attacks include (1) barbiturates, (2) sulfonamides, (3) progestogens, and (4) many anticonvulsants, but many others have been implicated in the precipitation of acute attacks[1] (www.porphyria-europe.org/; accessed October 29, 2013). Many of these precipitating factors induce hepatic CYPs.

Skin lesions similar to those of PCT and other bullous porphyrias are present in about 80% of patients with clinically manifest VP (see Table 29-2). About 60% of patients with this condition have skin lesions alone. The skin is less commonly affected in HCP; skin lesions without an acute attack are uncommon and are usually provoked by intercurrent cholestasis.

Nonacute Porphyrias

These fall into two categories, depending upon whether patients have (1) bullous skin lesions or (2) acute photosensitivity.

Nonacute Porphyrias with Bullous Skin Lesions

These include PCT and **congenital erythropoietic porphyria (CEP)**. In addition the acute porphyrias, VP and HCP, may have identical skin lesions. Lesions on sun-exposed skin, particularly the (1) backs of the hands, (2) forearm, and (3) face, are present in all patients. Increased mechanical fragility of the skin, with trivial trauma leading to erosions, and subepidermal bullae are present in virtually all patients. Hypertrichosis (excess growth of hair) of the face and patchy pigmentation are also common. Erosions and bullae heal slowly to leave

(1) atrophic scars, (2) milia (small, white or yellowish cyst-like masses just below the surface of the skin), and (3) depigmentated areas.

CEP is a rare condition that usually occurs in early childhood and is transmitted in an autosomal recessive manner. The skin lesions resemble those of PCT, VP, and HCP but are more severe and persistent throughout life. With advancing age, progressive scarring, particularly if erosions become infected, and atrophic changes lead to photomutilation with erosions of the terminal phalanges; destruction of ears, nose, and eyelids; and alopecia. Accumulation of porphyrin in bone is visible as erythrodontia—brownish-red teeth that fluoresce red in ultraviolet A (UVA) light. Hemolytic anemia with splenomegaly is common in CEP. Hemolysis may be fully compensated or mild, but in some patients, anemia is severe enough to require repeated transfusion.

PCT is the most common of all the porphyrias, usually occurring during the fifth and sixth decades, with most patients having evidence of liver cell damage, usually minor, and some degree of hepatic siderosis (deposition of iron in tissue). PCT results from a decrease in activity of UROD in the liver, which leads to overproduction of uroporphyrinogen and other carboxymethyl-substituted porphyrinogens. Two main types of PCT are identified by measurement of UROD activity in liver and extrahepatic tissue, or by analysis of the UROD gene. About 80% of patients have the sporadic (type I) form of PCT in which the enzyme defect is restricted to the liver and the UROD gene appears to be normal. The rest have familial (type II) PCT. In this form, mutation of one UROD gene leads to half-normal UROD activity in all tissue, which is inherited in an autosomal dominant manner. In both types, clinically overt PCT is strongly associated with (1) alcohol abuse, (2) estrogens, (3) infection with hepatotropic viruses, particularly hepatitis C (HCV) and human immunodeficiency virus (HIV), (4) increased hepatic iron stores, and (5) mutations in the hemochromatosis (HFE) gene.[4] PCT may also be caused by exposure to certain polyhalogenated aromatic hydrocarbons, such as hexachlorobenzene and 2,3,7,8-tetrachlorodibenzo-p-dioxin.

Nonacute Porphyria with Acute Photosensitivity

Erythropoietic protoporphyria (EPP) and **X-linked dominant protoporphyria (XLDPP)** are characterized by lifelong acute photosensitivity caused by accumulation of protoporphyrin-IX in the skin.[12,18] The absence of (1) fragile skin, (2) subepidermal bullae, and (3) hypertrichosis distinguishes protoporphyria clinically from all other **cutaneous porphyrias.** Onset of acute photosensitivity typically occurs between the ages of 1 and 6 years, and both sexes are equally affected. Once a child within an EPP or XLDPP family reaches the age of 14, the risk of developing acute photosensitivity becomes very low. Onset during adult life is very rare; most cases have been associated with myelodysplasia and are caused by acquired somatic mutations of the FECH or ALAS2 gene in hematopoietic cells.

Exposure to sun is followed, usually within 5 to 30 minutes, by an intensely painful, burning, prickling, itching sensation in the skin, most frequently on the face and backs of the hands. Symptoms persist for several hours or occasionally for days and are not relieved by shielding the skin from light. Patients characteristically seek relief by plunging their hands into water or covering their skin with wet towels. Young children may become very distressed by the pain. The skin may appear normal throughout, although there is often erythema (redness of the skin), which may be followed by edematous swelling with crusting. These changes usually subside within a few hours, so that by the time the child reaches the doctor, there is nothing to be seen, and the episode may be dismissed as severe sunburn. Recurrent episodes lead to chronic skin changes that are often minor and hard to detect. Typical lesions are shallow linear scars over the bridge of the nose and elsewhere on the face; the skin may become thickened and waxy, especially over the knuckles. Symptoms tend to be more severe during spring and summer and may improve during pregnancy.

The most severe complication of EPP and XLDPP is progressive hepatic failure, which is caused by accumulation of protoporphyrin in the liver.[17,18] About 15% of patients have abnormal biochemical tests of liver function, particularly increased aspartate aminotransferase, but only about 2% develop liver failure. EPP may also increase the risk of cholelithiasis—the formation of gallstones being promoted by high concentrations of protoporphyrin in the bile.

In EPP, overproduction of protoporphyrin-IX results from decreased activity of FECH, whereas in XLDPP, gain-of-function mutations in ALAS2, usually deletions within the C-terminal region, lead to formation and accumulation of protoporphyrin in excess of the amount required for hemoglobinization. Although FECH activity is decreased in all tissue in EPP, as in XLDPP, the excess protoporphyrin is formed mainly in erythroid cells. XLDPP is inherited in an X-linked pattern with expression of disease in males and in most females. EPP is an autosomal recessive disease; most individuals are compound heterozygotes for an FECH mutation that abolishes or severely decreases FECH activity and a hypomorphic FECH IVS3-48C allele.[9] In about 4% of EPP families, clinically affected individuals are heteroallelic or homoallelic for rare FECH mutations. Patients in these families, as in XLDPP, are at greater risk of severe liver disease than those with a hypomorphic FECH allele. Most FECH mutations are restricted to one or a few families; more than 130 have been identified (www.hgmd.cf.ac.uk/; accessed October 29, 2013).

Abnormalities of Porphyrin Metabolism not Caused by Porphyria

Abnormalities of porphyrin metabolism or excretion or both may occur in the absence of porphyria. A number of other diseases need to be considered when data from patients in whom porphyria is suspected are interpreted. These include: (1) exposure to various toxins, (2) hereditary tyrosinemia type I (3) renal disorders, (4) hepatobiliary disorders, (5) hematological disorders, (6) dietary, bacterial, and gastrointestinal bleeding factors, and (7) pseudoporphyria.

Exposure to Lead and Other Toxins

Lead exposure increases urinary ALA and coproporphyrin-III excretion and causes accumulation of ZPP in erythrocytes. The definitive test for lead toxicity is measurement of blood lead, but occasionally lead exposure is responsible for porphyria-like symptoms and sometimes is an unexpected finding when patients are investigated for suspected porphyria.

Increased ALA excretion is secondary to inhibition of ALAD caused by lead displacing zinc at its catalytic center. Lead also leads to increased excretion of coproporphyrin-III in urine. CPO requires sulfhydryl groups for activity and so is potentially a target for inhibition by lead. However, if lead-induced coproporphyrinuria is caused by inhibition of this enzyme, then it is not clear why fecal excretion of coproporphyrin is not increased. Increased concentrations of red cell ZPP associated with lead exposure probably are not caused by inhibition of FECH because inhibition of this enzyme requires higher lead concentrations than are usually encountered after lead exposure. The current view is that lead exposure creates an intracellular iron deficiency (perhaps by affecting iron transport into the cell or inhibition of iron reductase) so that zinc replaces iron as a substrate for FECH. Once formed, erythrocyte ZPP remains elevated for the life of the red cell. Because the half-life of an erythrocyte is longer than that of blood lead, monitoring of lead workers requires both whole-blood lead and ZPP testing. ZPP measurement also offers the advantage that there is no interference from lead contamination via the skin when the blood sample is collected, especially if a finger-prick sample is used.

Secondary coproporphyrinuria also is caused by the toxic effects of (1) alcohol, (2) arsenic, (3) other heavy metals, and (4) various drugs.

Hereditary Tyrosinemia Type I

Succinylacetone, which accumulates in this disease, has a structural resemblance to ALA and is therefore a competitive inhibitor of ALAD. Consequently ALA accumulates, and excess amounts are excreted in urine. Patients with hereditary tyrosinemia suffer neurological crises very similar to attacks of acute porphyria.

Renal Disorders

Impaired glomerular function reduces the clearance of water-soluble porphyrins normally excreted in the urine. Furthermore, these porphyrins are poorly cleared by dialysis, and, as a consequence, concentrations of plasma porphyrins are raised in end-stage renal failure. Even in the absence of biochemical evidence of porphyria, dermatological problems commonly affect dialysis patients and often share common features with PCT such as (1) melanosis, (2) actinic elastosis, (3) fragility, and (4) bullae. The concentrations of plasma porphyrin found in dialysis patients are often much higher than normal but rarely approach those found in patients with the active skin lesions caused by PCT. The term "dialysis porphyria" has been coined for these patients, even though it is unlikely that raised porphyrins are responsible for the skin lesions. Genuine PCT may occur in dialysis patients, and some cases of dialysis porphyria in the literature have not been adequately investigated to exclude PCT. Patients are often anuric, and without the benefit of urinary analysis, careful evaluation of plasma and fecal porphyrins is necessary to distinguish pseudoporphyria from PCT and acute porphyrias in which skin lesions may occur.

Hepatobiliary Disorders

In diseases such as (1) obstructive jaundice, (2) cholestatic jaundice, (3) hepatitis, and (4) cirrhosis, urinary excretion of predominantly coproporphyrin-I is increased because liver disease causes a diversion of the secretion of coproporphyrin-I from the biliary to the renal route.

In the Dubin-Johnson syndrome, urinary excretion of coproporphyrin-I is increased and excretion of coproporphyrin-III is reduced. In the Rotor syndrome, urinary excretion of coproporphyrin-I is increased with normal coproporphyrin-III excretion, and in Gilbert disease urinary excretion of both isomers is increased.

Hematological Disorders

In iron deficiency anemia, zinc acts as an alternative substrate for FECH, leading to increased ZPP. Increased red cell protoporphyrin (mostly ZPP) may also occur in (1) sideroblastic, (2) megaloblastic, and (3) hemolytic anemias.

Dietary, Bacterial, and Gastrointestinal Bleeding Factors

The dicarboxylic porphyrin fraction of feces contains protoporphyrin and other dicarboxylic porphyrins derived from it by bacterial reduction or removal of vinyl side groups. Additional protoporphyrin and other dicarboxylic porphyrins may be formed by the action of gut flora on heme-containing proteins derived from the diet or by gastrointestinal hemorrhage. Even minor gastrointestinal hemorrhage, particularly if it occurs high in the gut, which may not give rise to a positive occult blood test, greatly increases the concentration of dicarboxylic porphyrins in feces. Confusion with EPP may occur when associated iron deficiency increases erythrocyte total porphyrin, and skin lesions from some other causes are present, or with VP when coexisting liver disease causes coproporphyrinuria. Porphyria is excluded when no porphyrin fluorescence is detectable on fluorescence emission spectroscopy of plasma. Porphyrins may also come directly from the diet.

Pseudoporphyria

The term "pseudoporphyria" was originally applied to patients with PCT-like skin lesions in whom no abnormality of accumulation or excretion of porphyrins could be demonstrated.[10] Many drugs are potent photosensitizers and may produce porphyria-like lesions.

Laboratory Diagnosis of Porphyria

A number of clinical situations are known to benefit from laboratory testing for porphyrins and precursors. These include patients with symptoms of (1) acute porphyria or (2) typical cutaneous lesions, and (3) relatives of patients known to have porphyria.

Patients with Symptoms of Porphyria

The clinical features of the porphyrias are not specific enough to enable their diagnosis without laboratory investigation. In patients with current symptoms caused by porphyria, it is always possible to demonstrate excessive production of porphyrins and/or porphyrin precursors. Diagnosis depends on demonstrating specific patterns of overproduction of heme precursors (see Table 29-3) and is usually straightforward, provided appropriate specimens are examined for the relevant intermediates using adequately sensitive techniques.[3,6] DNA and enzyme studies (1) give no information about disease activity, (2) are rarely necessary to confirm the diagnosis in clinically overt porphyria, and (3) are mainly useful for family studies.

Patients with Acute Neurovisceral Symptoms

The single essential investigation in patients with suspected acute porphyria is an adequately sensitive test for excess urinary PBG.[3,6] Failure to correctly diagnose an attack of acute porphyria not only delays appropriate life-saving treatment, but may lead to unnecessary surgery or the administration of porphyrinogenic drugs. Either of these risky medical interventions may further aggravate the attack with potentially fatal consequences. A false diagnosis of porphyria may be just as serious by delaying vital surgery or other treatment and may lead to analgesic (e.g., opiates) misuse and dependency.

During an attack, PBG excretion is grossly elevated, and the increase is usually in excess of 10 times the upper reference limit. Normal PBG, at a time when symptoms are present, excludes all acute porphyrias, except the very rare ALADP, as its cause. In AIP, PBG usually remains elevated for years after an attack.[14] However, in VP or HCP, PBG may rapidly return to normal (sometimes within days) once the attack starts to resolve, although urine porphyrin excretion will still be increased. Therefore, if a suspected attack is entering remission, or clinical suspicion of acute porphyria persists, analysis of fecal and plasma porphyrins, with measurement of ALA if these are normal, is advisable even if PBG excretion is normal. Increased urinary PBG requires careful evaluation; although the patient clearly has an acute porphyria, the disease may not be the cause of current symptoms. Some patients with AIP have very high rates of PBG excretion in the absence of symptoms, and there is poor correlation between urinary PBG and symptoms, with no "threshold" above which symptoms appear. PBG excretion increases during an acute attack, but detection of this change requires information about the patient's baseline excretion. The higher the urinary PBG excretion, the greater the likelihood that porphyria is responsible for symptoms; however, the final diagnosis must always be made on clinical grounds.

If elevated urinary PBG was found by a qualitative/semiquantitative screening test, then this finding must be confirmed by a specific, quantitative method[12] to eliminate the possibility of a false-positive test. This is best done on the original urine specimen (ideally stored frozen) because by the time a new specimen is obtained, PBG may have returned to normal.

Management of the attack is the same regardless of the type of porphyria, so further investigation is not a matter of urgency. Differentiation between the acute porphyrias is essential for the selection of appropriate tests for family studies; the absence of skin lesions does not exclude VP or HCP (see Table 29-2). If total fecal porphyrin is normal, then VP and HCP are excluded, and the patient must have AIP. Assay of red cell HMBS activity is not essential and may mislead. If total fecal porphyrin is elevated, porphyrins should be fractionated by a high-performance liquid chromatography (HPLC) technique capable of resolving coproporphyrin isomers.[13] In HCP, coproporphyrin-III is grossly elevated and protoporphyrin-IX minimally raised or normal. In VP, protoporphyrin-IX and other dicarboxylate porphyrins are elevated, and a smaller increase in coproporphyrin is seen (with the type III isomer predominating) (see Table 29-3). It is important to remember that protoporphyrin-IX and other dicarboxylate porphyrins may arise by the action of gut flora on heme (whether the heme is of dietary origin or is the result of gastrointestinal bleeding). Therefore, if the fecal porphyrin pattern resembles VP, plasma should be examined by fluorescence emission spectroscopy for the characteristic fluorescence maximum at 624 to 628 nm (see Table 29-3).[11]

Sometimes the laboratory is asked to make a retrospective diagnosis of porphyria after the patient has fully recovered from an attack or as the cause of a chronic neuropsychiatric disorder sometime after the onset of illness. The first step is to quantify urinary PBG, but it should be noted that screening tests are too insensitive for this purpose. Fecal porphyrin is measured (to exclude HCP) and plasma fluorescence emission spectroscopy performed (to exclude VP). If all of these tests are negative, it is very unlikely that symptoms are or were caused by porphyria. However, it is difficult to exclude porphyria after periods as long as several years of clinical remission. Depending on the degree of clinical suspicion, enzyme and DNA studies may be pursued but are often unrewarding.

Patients with Cutaneous Symptoms

Skin lesions of the **cutaneous porphyrias** are always accompanied by overproduction of porphyrins. The route of investigation should be dictated by the clinical presentation (see Table 29-2).

Patients with Bullae, Fragility, and Scarring

Four main porphyrias have been identified in which clinically indistinguishable skin lesions of fragile skin and bullae occur (see Table 29-2). Total urinary and fecal porphyrin should be measured by a spectrophotometric[3,6] or fluorometric[3] method with adequate sensitivity. Plasma porphyrins are then determined by fluorescence emission spectroscopy.[11] In practice, fecal analysis is often unnecessary because the two most common bullous porphyrias—PCT and VP—are identified by analysis of urine and plasma (see Table 29-3). If these tests are normal, then porphyria is excluded as the cause of any active skin lesions. Any increase in total urinary or fecal porphyrin should be further investigated by determination of individual porphyrins using a technique capable of resolving all porphyrins of clinical interest, including isomers.[13] The pattern observed in each of these porphyrias is unique.

Patients with Acute Photosensitivity

For suspected EPP or XLDPP, the essential investigation consists of measurement of whole blood (or erythrocyte) porphyrin using a sensitive fluorometric method. Screening tests using solvent extraction of blood or fluorescence microscopy of erythrocytes are unreliable and should not be used. If the erythrocyte/whole-blood porphyrin concentration is within reference limits, EPP is excluded. If the erythrocyte/whole-blood porphyrin concentration is high, it is important to determine whether the increase could be caused by (1) free protoporphyrin (as in EPP); (2) free protoporphyrin and/or ZPP (as in XLDPP); or (3) ZPP in iron deficiency, or lead toxicity.). Distinguishing between the protoporphyrins requires first extraction with a neutral solvent such as ethanol[8] to avoid the removal of metal caused by strong acids. Extraction is followed by fluorescence spectroscopy or HPLC to distinguish free protoporphyrin from ZPP (fluorescence emission maxima 630 nm and 587 nm, respectively) (Figure 29-3). Of note, the measurement of fecal protoporphyrin is not of use in the diagnosis of EPP or XLDPP because increases may be caused by the action of gut flora on heme from the diet or from gastrointestinal bleeding.

Relatives of Patients with Porphyria

Screening family members to identify asymptomatic individuals who have inherited AIP, VP, or HCP and therefore are at risk for acute attacks is an essential part of management of

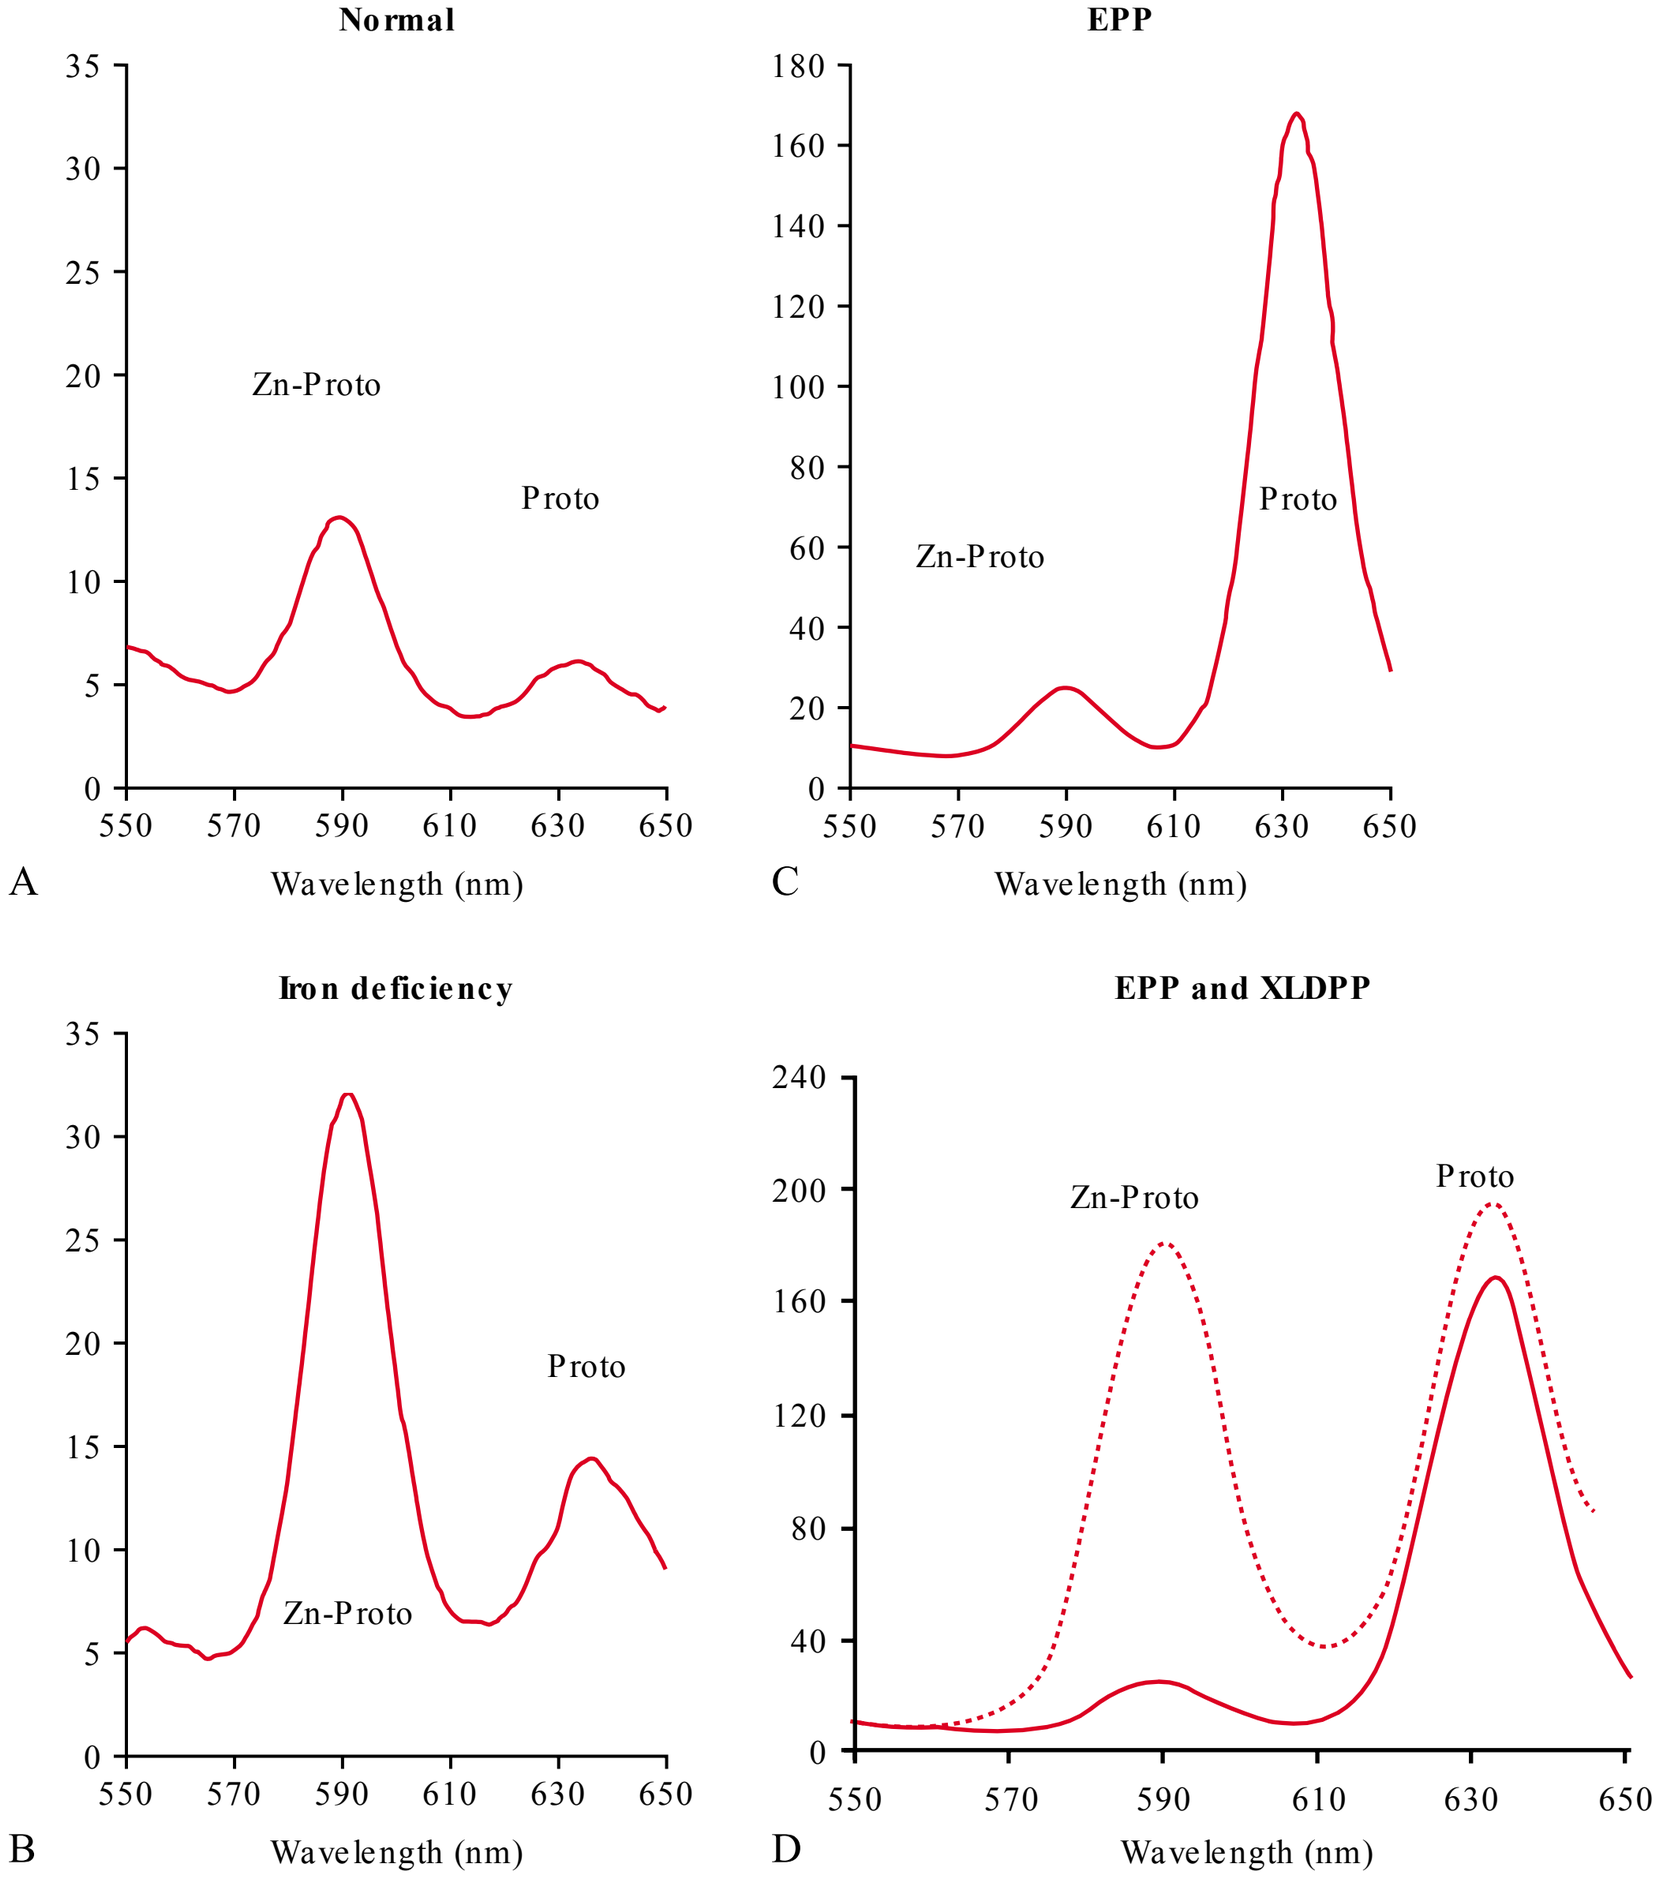

Figure 29-3 Fluorescence emission spectra (excitation at 405 nm) of ethanolic extracts of erythrocytes from individuals who are healthy (Panel A), who have iron defciency (Panel B), who have been diagnosed with erythropoietic protoporphyria—EPP (Panel C), and who have been diagnosed with X-linked dominant protoporphyria—XLDPP (Panel D). Note that different scales are used.

families with these disorders. Screening may be carried out by (1) metabolite measurement, (2) enzyme assay, (3) DNA analysis, or (4) a combination of these approaches. Metabolite measurement is simple but has low sensitivity; furthermore these tests are almost always normal before puberty and therefore are not suitable for the investigation of children. Measurement of defective enzyme activity is clinically more sensitive, but both clinical sensitivity and specificity are limited by the overlap between activities in disease and in a healthy population. Mutation detection by DNA analysis is more specific and sensitive than biochemical methods. In practice, it is quickly replacing other methods, particularly because it offers the additional advantage of enabling asymptomatic disease to be excluded with certainty. However, its use depends on prior identification of a disease-specific mutation in the family under investigation.

Family investigation has a more limited role in the clinical management of other porphyrias. In PCT, the autosomal dominant familial form is identified by erythrocyte UROD assay or mutational analysis, but as yet no evidence suggests that family studies are necessary unless requested by anxious relatives. However, patients of Northern European ancestry should be tested for the C282Y mutation in the hemochromatosis (HFE) gene. Hemochromatosis should be considered in families shown to have a C282Y homozygous member.

In EPP testing, the unaffected parent for the presence of the IVS3-48C low-expression FECH allele is helpful for assessing the risk that a future child will have clinically overt disease. Mutational analysis of the FECH gene may be required for genetic counseling of some families.[9] Mutational analysis of the ALAS2 gene is essential for confirming the diagnosis of XLDPP.

Analytical Methods

T e analytical methods used to diagnosis and monitor porphyria are described here briefly. T ese are described in greater detail in an expanded version of this chapter.[2]

Specimen Collection and Stability

It is important that all samples for porphyrin assay be protected from light. For example, urinary porphyrin concentrations have been observed to decrease by up to 50% if kept in the light for 24 hours. Urinary porphyrins and PBG are best analyzed in fresh, early morning (10 to 20 mL) specimens collected without preservative. Dilute urine (creatinine <2 mmol/L [23 mg/dL]) is unsuitable for analysis.

Twenty-four-hour collections (1) offer little advantage, (2) delay diagnosis, and (3) increase the risks of incomplete collection and light exposure during the collection period. PBG and porphyrins are stable in urine in the dark at 4 °C for up to 48 hours and for at least a month at –20 °C. Specimens for ALA estimation should be promptly refrigerated. Urine specimens can be stored at 4 °C in the dark for at least 2 weeks without significant loss of ALA, and frozen specimens are stable for weeks. Whereas PBG is more stable around pH 8 to 9, ALA is more stable around pH 3 to 4, although more acidic environments greatly reduce ALA stability.

About 5 to 10 g wet weight of feces is adequate for porphyrin measurements. Diagnostically important changes in concentration are unlikely to occur within 36 hours at room temperature, and samples are stable for many months at –20 °C.

Whole blood, anticoagulated with ethylenediamine tetraacetic acid (EDTA), shows no loss of protoporphyrin for up to 8 days at room temperature and for at least 8 weeks at 4 °C in the dark.

It is good practice to treat all samples received from patients with suspected bullous porphyria as "high risk" because the frequency of infection with hepatotropic viruses, particularly HCV, is increased in PCT.

Methods for Metabolites

Porphobilinogen

Most methods for PBG are based on the reaction of Ehrlich's reagent (4-dimethylaminobenzaldehyde in acidic solution) with the α-methene carbon of the pyrrole ring to form a colored product variously described as "rose-red" or "magenta." It has a characteristic absorption spectrum with a peak at 553 nm and a shoulder at 540 nm. Porphyrins do not contain any α-methene hydrogens and so do not react. Some other substances in urine may react with the reagent to give red products, notably urobilinogen, may inhibit the reaction, or are pigmented themselves and so mask the red chromogen. All interferences need to be removed. T is is best achieved by ion exchange chromatography, as in methods for the accurate quantification of PBG based on the procedure first described by Mauzerall and Granick[15]. Methods based on HPLC and tandem-mass spectrometry (MS) that are suf ciently sensitive to measure PBG in plasma have recently been described.[7]

Qualitative screening tests in which urine is reacted directly with Ehrlich's reagent and is assessed visually for the formation of the red chromogen (e.g., the Watson-Schwartz- and Hoesch tests) are convenient but have been criticized for low analytical sensitivity and specificity, even when solvent extraction has been used to separate the PBG-Ehrlich compound from the urobilinogen/Ehrlich complex. T e Mauzerall and Granick method has been modified in attempts to produce an alternative that is acceptable for screening purposes. Buttery and Stuart[5] avoided the use of columns by employing batchwise treatment with resin, and visually compared the final color with that of a surrogate reference solution. Blake et al[3] eliminated the centrifugation steps by using resin-filled syringes with detachable filters and compared the final color with a range of artificial reference solutions. T ese modifications reduced the time taken to perform the test to 10 minutes and produced a semi-quantitative result. A commercial kit based on Blake's method is available (PBG Kit, T ermo Scientific, Pittsburgh, PAPA; http://www.thermoscientific.com/; accessed October 29, 2013) and is advertised to be more sensitive and specific for initial screening than qualitative, solvent extraction procedures. If a qualitative screening test is used, it is essential to include appropriate reference

solutions and controls and to confirm all positive tests using a specific quantitative method.

5-Aminolevulinic Acid

ALA is measured directly but is more usually converted into an Ehrlich-reacting pyrrole by condensation with a reagent, such as acetylacetone, after separation from PBG by two-stage anion exchange chromatography. A method for the measurement of PBG and ALA, based on that of Mauzerall and Granick,[15] is available commercially (Bio-Rad Laboratories, Hercules, CA; http://www.bio-rad.com/; accessed October 29, 2013).

Analysis of Porphyrin in Urine and Feces

Methods of porphyrin fractionation are complex and time-consuming and are not available in every laboratory. For this reason, simple qualitative screening tests are often used to exclude most specimens that do not require further investigation from the few that justify fractionation of the individual porphyrins. Screening tests in which extracts of urine or feces are examined visually for typical red-pink fluorescence of porphyrins lack sensitivity and should not be used. Methods based on spectrophotometric scanning of acidified urine or fecal extracts for the presence of the Soret band are recommended and yield semi-quantitative information.[6] Quantitative fluorometric methods are also available.[3]

All methods used for the fractionation of porphyrins are based on the different solubilities of individual porphyrins because of their different β-substituents, and to a lesser extent on their order around the macrocycle. These methods include (1) differential extraction with solvents, (2) paper and thin-layer chromatography, and (3) HPLC. Solvent extraction methods yield only limited and sometimes misleading information and should not be used. Reversed-phase HPLC,[13] the current method of choice, separates all porphyrins of clinical interest, including isomers and metal chelates, without the need for prior methylation.

Analysis of Blood Porphyrins

All of the methods described next require a spectrofluorometer fitted with a red sensitive photomultiplier. If such equipment is not available locally, samples should be referred to a reference laboratory.

The simplest method for whole-blood or erythrocyte protoporphyrin is that described by Piomelli and modified by Blake et al.[3] Porphyrins are extracted, and hemoglobin and other proteins are precipitated by mixing diluted blood with a diethyl ether–acetic acid mixture. Porphyrins are then back-extracted into hydrochloric acid and are measured fluorometrically (see Figure 29-3). This method has the disadvantage that the acidic conditions result in the release of zinc from ZPP, and it therefore provides a measure of total protoporphyrin. To preserve the zinc chelate, neutral or basic extraction conditions are required. Diluted cells are mixed with ethanol, which precipitates hemoglobin and other proteins and extracts porphyrins without dissociating heme from hemoglobin.[8] The extract is scanned in a spectrofluorometer to distinguish the emission maxima of protoporphyrin from its zinc chelate.

Analysis of Plasma Porphyrins

Plasma porphyrins have been determined by fluorescence emission spectroscopy of saline-diluted plasma[9] or deproteinized extracts, or by HPLC. The first of these methods provides the advantages of simplicity and inclusion of porphyrins that are bound covalently to plasma proteins. Porphyrins at neutral pH fluoresce in the 610 to 640 nm region; the wavelength of maximum emission depends primarily on the porphyrin structure but is also influenced by the nature of the porphyrin/protein complex. This method is useful in front-line investigation for suspected cutaneous porphyria.

Enzyme Measurements

Assay of individual enzymes of the heme biosynthetic pathway is rarely required for the investigation of patients with symptoms of porphyria. However, measurement of enzyme activities is useful for family studies (1) when the individual mutation cannot be identified, (2) when DNA analysis is not available, and (3) for the identification of subtypes, such as nonerythroid AIP and "homozygous" forms of autosomal dominant porphyrias. Erythrocytes are a convenient source of cytoplasmic enzymes (ALAD, HMBS, UROS, and UROD), but assay of the mitochondrial enzymes (CPO, PPOX, and FECH) requires nucleated cells, such as lymphocytes or cultured fibroblasts. Assays for enzymes that use porphyrinogens as substrates are technically difficult because the substrate (1) is unstable, (2) has to be prepared in situ, and, particularly with protoporphyrinogen, (3) undergoes nonenzymatic oxidation during the assay.

DNA Analysis

Screening families for porphyria by DNA analysis is a two-stage process. First, the mutation that causes porphyria in the family under investigation needs to be identified by analysis of DNA from a family member in whom the diagnosis of a specific type of porphyria has been established unequivocally. Second, that patient's relatives are screened for the mutation. The first part of this process is the more complex task. Because most mutations are restricted to one family or a few families, identification of a mutation in a new family almost always requires at least analysis of all exons with their flanking intronic sequences and the promoter region. Only in those countries where founder mutations predominate, as with VP in South Africa and AIP in Sweden, is initial testing for a single mutation worthwhile. Standard techniques of mutation analysis are employed.

Review Questions

1. The precursors of the tetrapyrrole ring structure of porphyrin are:
   a. 5-aminolevulinic acid and iron.
   b. acetyl CoA and porphyrin.
   c. succinyl CoA and glycine.
   d. zinc and porphyrinogen.

2. The important initial screening test that allows for differentiation between the two categories of porphyria is:
   a. serum coproporphyrin.
   b. urine aminolevulinic acid (ALA) and porphobilinogen (PBG).
   c. serum zinc protophyrin.
   d. red blood cell zinc protoporphyrin.
3. Another name for protoporphyrin that contains iron is:
   a. heme.
   b. PBG.
   c. coproporphyrin.
   d. ferrochelatase.
4. The skin lesions and photosensitivity observed in patients with nonacute cutaneous porphyrias are the result of:
   a. autonomic neuropathy.
   b. excessive production of ALA.
   c. accumulation of porphyrins in the liver.
   d. excess presence of porphyrins in skin that generate oxygen radicals.
5. In lead toxicity, what replaces iron as a substrate for ferrochelatase to be incorporated into protoporphyrin?
   a. Carbon dioxide
   b. Zinc
   c. Copper
   d. Lead
6. The most common of all the porphyria disorders is:
   a. variegate porphyria.
   b. acute intermittent porphyria.
   c. porphyria cutanea tarda.
   d. congenital erythropoietic porphyria.
7. The initial steps of heme synthesis occur in the:
   a. mitochondrion.
   b. cytosol.
   c. endoplasmic reticulum.
   d. cell nucleus.
8. The best specimen type for analyzing porphobilinogen is:
   a. heparinized plasma separated and frozen immediately after collection.
   b. a 24-hour urine collection collected in a dark brown container and preserved with 0.1% HCl.
   c. a fresh early morning urine specimen collected without preservative and protected from light.
   d. blood anticoagulated with EDTA and protected from light.
9. Erythropoietic protoporphyria is characterized by which of the following symptoms?
   a. Flaccid quadriparesis caused by accumulation of porphobilinogen in muscle
   b. Lifelong acute photosensitivity caused by protoporphyrin-IX accumulation in skin
   c. Liver damage and hepatic siderosis caused by iron accumulation in cells
   d. Severe abdominal pain and peripheral neuropathy caused by induction of hepatic cytochromes
10. The reduced form of a porphyrin is known as a:
    a. protoporphyrin.
    b. heme molecule.
    c. pyrrole ring.
    d. porphyrinogen.

CHAPTER

30

Therapeutic Drugs and Their Management*

Christine L.H. Snozek, Ph.D., D.A.B.C.C., and Gwendolyn A. McMillin, Ph.D., D.A.B.C.C.

Objectives

1. Define the following terms:
   - Bioavailability
   - First-order metabolism
   - Half-life
   - Mechanism of action
   - Peak and trough (pre-dose) drug concentration
   - Pharmacodynamics
   - Pharmacokinetics
   - Prodrug
   - Steady state
   - Therapeutic range
2. List and describe the four processes of drug disposition and the physiological or pathological factors that affect these.
3. State the need for therapeutic drug management; state the criteria that make a drug a candidate for therapeutic drug monitoring.
4. Explain the difference between protein-bound and free drug concentration; state the physiological effect of free drug concentration and the physiological systems that affect equilibrium between bound and free components.
5. List three prodrugs and their active metabolites.
6. Describe the phases of drug metabolism in relation to pharmacokinetics, including the metabolic phases and processes, the enzymes involved, and what can affect each of these.
7. State six categories of therapeutic drugs and give examples of drugs in each category; describe each drug's mechanism of action and major active metabolite; state which specimen type is best suited for specific drugs.
8. Discuss the importance of timing of specimen collection when managing drug dosing, including time of draw and rationale, result interpretation, and possible problems if the protocol is not followed.
9. Describe sources of drug interactions and how these affect laboratory analysis.
10. List common laboratory methods available for measuring drug concentration; discuss the advantages and disadvantages of using immunoassays for therapeutic drug monitoring.
11. Analyze and solve case studies related to the use and management of therapeutic drugs.

Key Words and Definitions

Bioavailability The degree to which a drug or other substance becomes available to the target tissue after administration.

Cytochrome P_{450} A generic term for mixed-function, oxidative enzymes important in animal, plant, and bacterial physiology. Note: Often abbreviated as CYP usually followed by an arabic numeral, a letter, and another arabic numeral (e.g., CYP 2D6).

Drug half-life Time required for one-half of an administered drug to be lost through metabolism and elimination.

Drug interactions The effects of a drug on absorption, metabolism, or action of another drug.

Drug monitoring The process of studying the effects of a chemical substance administered to an individual.

Enzyme induction Increased synthesis of an enzyme in response to an inducer or other stimulus.

Enzyme inhibition Decreased enzymatic activity due to substrate competition or the presence of a compound that reduces enzyme function.

First-pass metabolism Extensive hepatic metabolism of a drug before it reaches the systemic circulation.

Generic form A drug not protected by a trademark. Also, the scientific name as opposed to the proprietary, brand name.

*The authors gratefully acknowledge the original contributions of Thomas P. Moyer, Charles E. Pippenger, and Leslie M. Shaw, on which portions of this chapter are based.

Key Words and Definitions—cont'd

Immunosuppression The prevention or diminution of the immune response by irradiation or by administration of antimetabolites, antilymphocyte serum, or specific antibody.

Mechanism of action The mechanism by which a pharmacologically active substance produces an effect on a living organism or in a biochemical system.

Peak concentration The highest concentration achieved within the dosing cycle.

Pharmacodynamics (PD) The study of the physiological response to drugs (what the drug does to the body); encompasses the interaction of drugs with target sites, and the biochemical and physiological consequences that lead to therapeutic or adverse effects.

Pharmacogenomics The study of the inherited variations in genes that dictate drug response and the way these can be used to predict individual responses to a drug, using a genome-wide approach.

Pharmacokinetics (PK) The activity or fate of drugs in the body over a period of time, including the processes of absorption, distribution, metabolism, and elimination (what the body does to the drug).

Prodrug A drug that is administered in a form that is pharmacologically inactive or only weakly active. Once absorbed, the prodrug is biotransformed (enzymatic or nonenzymatic) into a pharmacologically active compound(s).

Therapeutic drug monitoring/management (TDM) A process used to measure blood drug levels so that the most effective dosage is maintained and toxicity prevented.

Therapeutic range The interval between the minimum and maximum doses of a drug.

Trough concentration The lowest concentration achieved just before the next dose.

Xenobiotic A chemical foreign to a given biologic system.

It has long been recognized that individuals respond very differently to the same dose of the same drug. Physicians have traditionally used clinical judgment and factors such as weight and comorbidities to individualize each patient's drug dosage. Over time, individualization of drug dosage has evolved into a multidisciplinary science, known as **therapeutic drug monitoring** and **therapeutic drug management (TDM)**. Ideally, this activity synthesizes clinical information and laboratory testing results to facilitate selection of the optimal drug and dose for each patient; it also allows assessment of therapeutic compliance and efficacy, and detection of **drug interactions** and drug-induced toxicity. TDM traditionally involves quantitation of drugs and active metabolites in biological fluids, but it is evolving to include assessment of biomarkers indicative of response, and of genetic variants that may affect drug response (i.e., **pharmacogenomics,** see Chapter 46).

TDM essentially provides a photograph of the disposition of a drug at the moment the specimen is drawn, indicating how much has been (1) absorbed, (2) distributed, (3) metabolized, and (4) eliminated. These processes constitute the **pharmacokinetics (PK)** of a drug. PK is often described as "what the body does to a drug," in contrast to **pharmacodynamics (PD)**, "what the drug does to the body"), which consists of the physiological responses to a compound. Individual deviations in PK will indicate (1) genetic variants, (2) drug-drug or drug-food interactions, (3) organ failure, or (4) patient noncompliance. Note that pharmacology refers to broad knowledge of the systemic effects of a drug, encompassing both PD and PK; PD relates to the interaction of a drug at its site of action and at off-target sites, whereas PK is a mathematical description of drug disposition. These terms are quite different and should not be used interchangeably.

Toxicology is the subdiscipline of pharmacology concerned with adverse effects of chemicals on living systems (see Chapter 31). The toxic effects and metabolism may be different from the therapeutic effects and metabolism for the same drug. Similarly, at the high dose of drugs at which toxic effects may be produced, the rates of processes such as metabolism are frequently altered compared with those at therapeutic doses. For these reasons, the terms toxicodynamics and toxicokinetics are applied to these special situations.

More detailed discussion of the concepts and specific drugs outlined in this chapter, as well as a more extensive reference list, is found in Chapter 34 of Tietz Textbook of Clinical Chemistry and Molecular Diagnostics.[12]

Basic Concepts

The pharmacological effects of a drug arise by interaction of the drug with receptors or other target molecules involved in physiological processes. This interaction and its downstream consequences are referred to as the drug's **mechanism of action**. The location (organ or specific cell type) of the target molecules upon which a drug acts is called the site of action of the drug. Most drugs exert their effects by binding to a protein target such as an enzyme or a transporter. For example, most antidepressants act upon the transporters that regulate synaptic concentrations of monoamine neurotransmitters such as serotonin. Drugs also may target nonprotein molecules such as lipids or nucleic acids; one example is topoisomerase, a chemotherapeutic agent that binds DNA to prevent tumor cell replication.

The utility of monitoring drug concentration is based on the premise that physiological response correlates with the concentration of drug. This is true for many drugs, which demonstrate increasing clinical effects with increasing dose (Figure 30-1). Often, a maximum effect or plateau is reached, for example, as the result of saturation at the receptor or overload of a drug transporter. Ideally, one would monitor drug concentrations at the site of action (receptor), but this generally

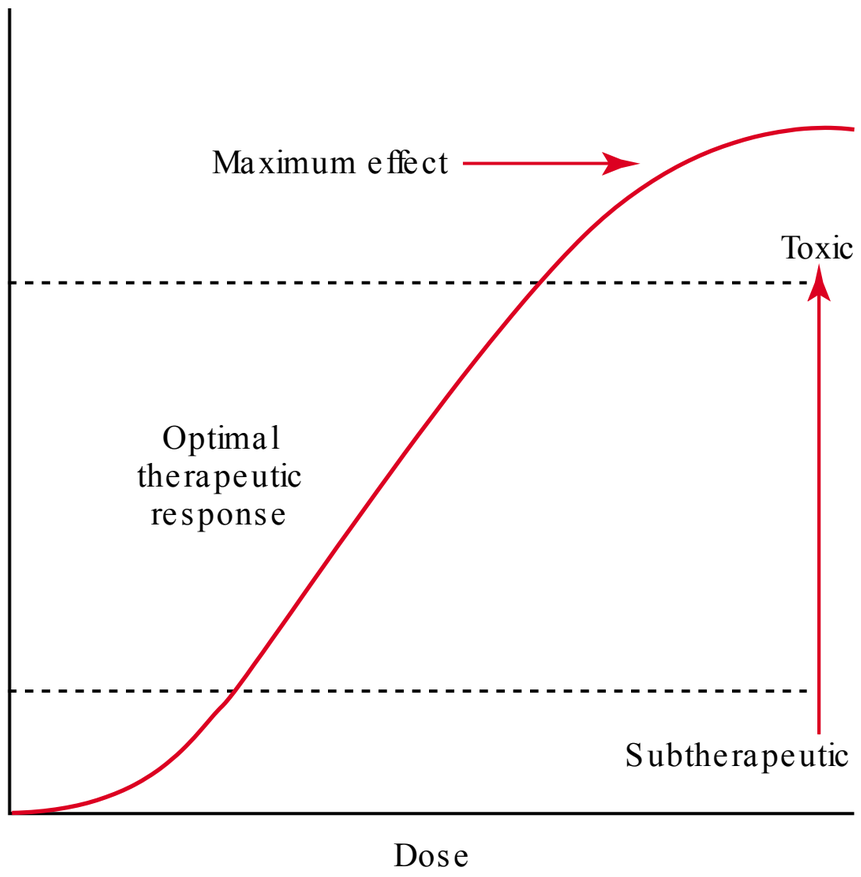

Figure 30-1 The dose-effect relationship. The probability of increasing pharmacological response and risk of toxicity parallels concentration for most drugs. The plateau (maximum effect) is likely due to saturation at the receptor.

is not feasible, so a surrogate such as serum concentration must be used. Differences in physiological responses between individuals have been known to occur despite similar serum drug concentrations; thus measurement of biomarkers—if available—will complement TDM and improve prediction of individual responses to drug therapy.

The use of a surrogate for drug concentration at the receptor is important in TDM because it is the basis upon which all therapeutic and toxic concentration reference values are established. Drug concentrations in a surrogate matrix such as serum are measured to define a **therapeutic range** (Figure 30-2) that represents the relationship between minimum effective concentration (MEC) and minimum toxic concentration (MTC). In an optimal dosing cycle, the **trough concentration** (the lowest concentration achieved just before the next dose) should not fall below the MEC, and the **peak concentration** (the highest concentration achieved within the dosing cycle) should not rise higher than the MTC. Dosing regimens should achieve steady-state serum drug concentrations consistently within the therapeutic range defined by the MEC and the MTC. Steady state requires equilibrium between the rate of drug administration (dosing) and elimination; this occurs roughly 5 half-lives after initiation of therapy if the dose interval (τ) is the same as the **drug half-life**.

MTC and MEC are useful guidelines in therapy because concentrations greater than the MTC put patients at risk for toxicity, whereas concentrations less than the MEC put them at risk for the disorder that the drug is supposed to treat. The therapeutic range, therefore, represents the range of drug concentrations within which the probability of the desired clinical response is relatively high, and the probability of unacceptable toxicity or failure to achieve further clinical benefit is relatively low. The smaller the difference between MEC and MTC, the narrower the therapeutic index and the more likely TDM will be necessary.

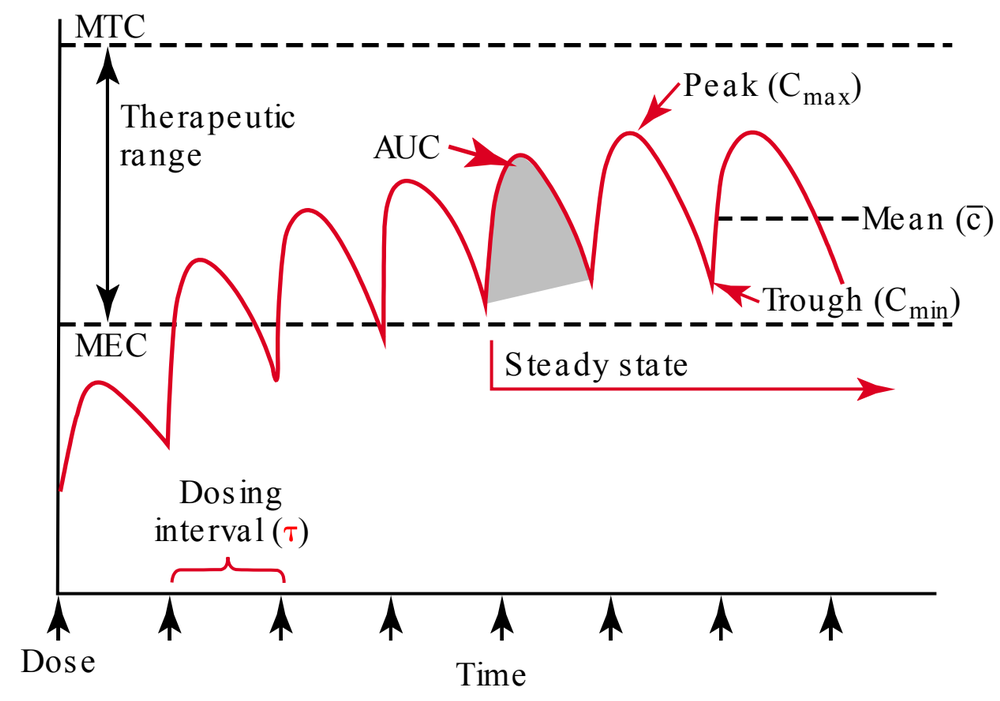

Figure 30-2 Peak, mean, and trough drug concentrations increase with multiple identical doses administered once each half-life until they reach steady state. For most drugs, it takes five to seven half-lives to reach steady state. At steady state, optimal peak and trough concentrations are less than the MTC and greater than the MEC. The range of values between MEC and MTC is referred to as the therapeutic range. AUC, Area under the concentration-time curve; MEC, minimum effective concentration; MTC, minimum toxic concentration. (Modifed from Gilman AG, Goodman L, Gilman A, eds. The pharmacological basis of therapeutics, 6th edition. New York: Macmillan, 1980. Reproduced with permission of The McGraw-Hill Companies.)

Pharmacokinetics

Pharmacokinetics is the mathematical description of the physiological disposition of **xenobiotics** (a chemical compound that is foreign to a living organism) or endogenous chemicals. The key processes of drug disposition include (1) **a**bsorption, (2) **d**istribution, (3) **m**etabolism, and (4) **e**xcretion, commonly referred to by the acronym ADME. These processes are affected by factors specific to the individual receiving the drug, including (1) disease state, (2) co-medication, (3) age, and (4) sex (Box 30-1). Such factors contribute to interindividual and intraindividual variability in both drug concentration and pharmacological response, as summarized in Figure 30-3.

Absorption

Generally, the most direct route of administering a drug is intravenous delivery, which places the entire dose into immediate circulation. However, drugs are frequently delivered by alternate means, most commonly via oral administration. Oral dosing requires the drug to pass from the gastrointestinal tract into the vascular system through a process known as absorption. To be absorbed, a compound must dissociate from its dosing formulation into digestive fluids (called liberation), then must cross through cell membranes by passive diffusion or, less commonly, by active transport. The ability to negotiate these steps determines the rate and extent of drug absorption and is affected greatly by the nature of the drug itself (e.g., solubility, pK_a), the formulation matrix (e.g., immediate-release, sustained-release), and the physiological environment (e.g., pH, gastrointestinal motility).

Most drugs are weak acids or bases that assume ionized or nonionized forms depending on the surrounding pH.

BOX 30-1 Factors That Influence Drug Disposition in Humans

Demographic Factors
Age category (premature infant, neonate, infant, child, adolescent adult, elderly adult)
Weight (obesity, malnourishment)
Sex
Race
Genetic constitution (metabolic enzyme polymorphisms)

Disease-Related Factors
Liver disease (cirrhosis, hepatitis, cholestasis)
Kidney disease
Thyroid disorders (hypothyroidism or hyperthyroidism)
Cardiovascular disease (arrhythmias, congestive heart failure)
Gastrointestinal disease or disorder (sprue or other malabsorption syndromes, peptic ulcer, colitis)
Cancer
Surgery
Burns
Volume status (e.g., dehydration)
Nutritional status (cachectic or anorexic state)

Extracorporeal Factors
Hemodialysis
Peritoneal dialysis
Cardiopulmonary bypass
Hypothermia or hyperthermia

Chemical and Environmental Factors Influencing Absorption of Drug
Food or coadministered drug affecting extent and rate of absorption
Immediate- or extended-release formulation
Gastric pH and motility
Activity of transporters (e.g., P-glycoprotein) and GI metabolic enzymes (e.g., CYP3A4)

Distribution of Drug
Coadministered drug affecting binding to plasma proteins or tissue receptors
Changes in physiological composition (e.g., rapid weight loss)
Pregnancy, aging, or other condition affecting plasma proteins and body composition

Metabolism of Drug
Food, herbs, or drugs competing for metabolism
Coadministration of drug that induces metabolic enzymes (e.g., phenobarbital)
Coadministration of drug that inhibits metabolic enzymes (e.g., cimetidine)

Excretion of Drug
Coadministration of drug that competes for renal tubular secretory paths (e.g., probenecid, penicillin)
Changes in urinary flow rate
Coadministration of compounds that enhance tubular reabsorption (e.g., sodium bicarbonate, phenobarbital)

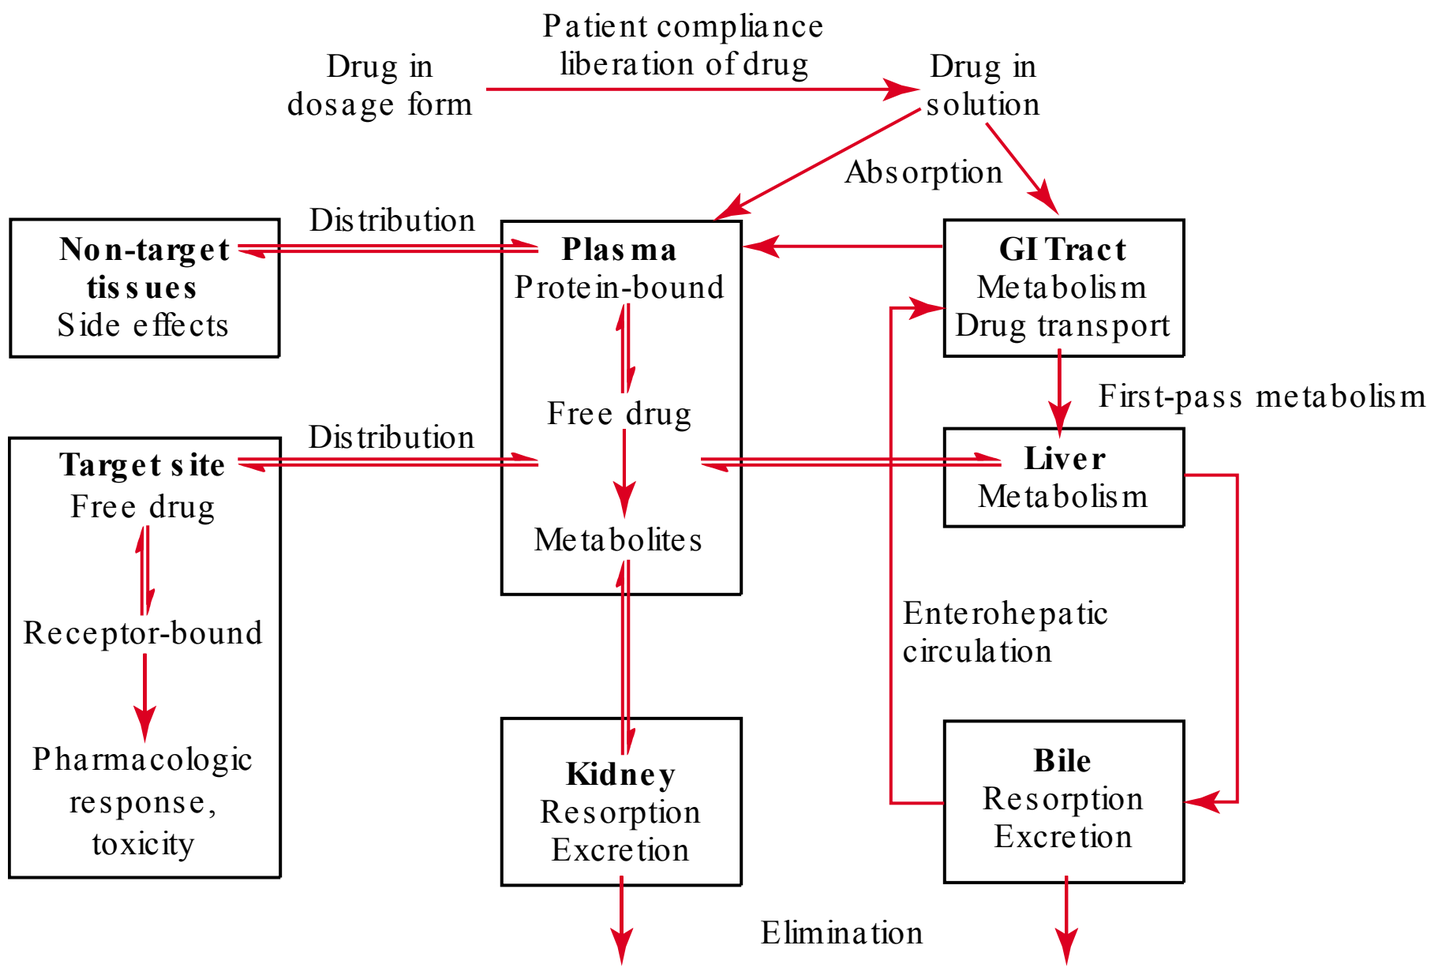

Figure 30-3 Factors affecting plasma drug concentration. Absorption: Patients must comply with administration, and the formulation must ensure bioavailability from the GI tract or other site of absorption. First-pass metabolism occurs for many drugs absorbed via the GI. Distribution: The drug may be found in both target and nontarget tissues. Interaction with a receptor or other target molecule can induce intended (therapeutic), unintended (side), or toxic effects. Metabolism: Conversion of the drug to pharmacologically active or inactive compounds may occur in tissue other than the liver. Elimination: Excretion in urine or feces is most common, but it can also occur via saliva, expired air, breast milk, or other means.

Passive diffusion across lipid membranes requires the drug to be nonionized; thus absorption will occur most readily at a pH at which the nonionized form is favored. For this reason, alterations in gastrointestinal pH (e.g., antacid use) affect the ability of a compound to enter the circulation. Likewise, ingestion of absorptive resins or medications and diseases that influence gastrointestinal motility change the extent or rate of drug absorption. Absorption generally occurs more rapidly than elimination; however, sustained-release formulations prolong the rate of drug absorption, allowing less frequent dosing and lessening the variability in drug concentrations between doses.

The amount of drug absorbed relative to the quantity given is referred to as its **bioavailability** (f). This is calculated as the ratio of drug exposure after equivalent doses of oral and intravenous forms, where exposure is measured as the area under the curve (AUC) of plasma drug concentration over time:

$$f = \frac{AUC_{oral}}{AUC_{iv}} \quad (1)$$

Thus, the more efficiently a drug is absorbed, the more its exposure (AUC) after oral dosing resembles exposure after intravenous administration, up to a maximum of 100% bioavailability or identical exposure for the two formulations. To be useful as an oral agent, a compound must be absorbed rapidly and extensively enough to provide therapeutically effective concentrations.

Bioavailability is affected by **first-pass metabolism**, which reflects the activity of metabolic enzymes in the intestine and liver. After absorption from the gastrointestinal lumen, drugs are metabolized in intestinal cells before reaching the bloodstream. In addition, drugs absorbed from the small intestine are transported via the portal vein directly to the liver, where they are exposed to hepatic metabolic enzymes. Thus, first-pass metabolism after absorption will reduce the quantity of drug to reach the systemic circulation. Drug transporters in the gastrointestinal tract or liver also are able to expel an absorbed drug, further reducing the apparent bioavailability.

Distribution

Once in the bloodstream, drugs undergo distribution and spreads throughout the systemic circulation and into various tissues. Some drugs remain primarily in the blood plasma (e.g., ibuprofen, warfarin); others localize extensively to tissue (e.g., amiodarone, chloroquine). The distribution of a drug to a particular site in the body depends on numerous factors, including (1) molecular size, (2) degree of ionization, (3) lipid solubility, (4) extent of protein binding, and (5) body composition. In general, drugs that distribute extensively into tissues tend to be lipophilic, as this facilitates passage through cell membranes. Widely distributed compounds often show relatively slow clearance because of the need to remove drug stored in tissue.

Many drugs bind to one or more plasma proteins, most notably, (1) albumin, (2) globulins such as α_1-acid glycoprotein (AAG), and (3) lipoproteins. In general, acidic drugs associate primarily with albumin, whereas basic drugs preferentially bind globulins and lipoproteins. An equilibrium exists between the amount of drug that is protein-bound and the amount of *f*ree or unbound drug. As free drug is more accessible to drug receptors, the free fraction is considered the active component. Serum-free drug concentrations have been estimated with the use of ultrafiltration or ultracentrifugation techniques. In addition, measurement in oral fluid (saliva) has been proposed as an estimate of free concentrations but is unacceptable for many compounds.

Changes in equilibrium between free and bound drug will greatly affect the physiological response to that compound. Drugs that bind the same plasma macromolecules are capable of displacing one another, increasing the free fraction. Physiological (e.g., pregnancy, aging) or pathological conditions affect the concentrations of drug-binding molecules, or the rate of elimination of free drug. Patients may experience adverse effects, even severe toxicity, as a direct consequence of increased free drug concentrations. For highly protein-bound drugs, clinically significant changes in the free fraction often go unnoticed if only the total (bound plus free drug) concentration is monitored; the total serum drug concentration may not change or may even decrease in situations that significantly elevate the free fraction. Management of these situations requires careful attention to clinical presentation and, if available, free drug measurements.

Metabolism

Metabolism is the biotransformation of a compound, whether endogenous or exogenous. In the context of drug therapy, metabolism is typically thought to enhance excretion by increasing water solubility. Note that this does not necessarily inactivate or detoxify the drug; for example, acetaminophen hepatotoxicity is the result of a minor metabolite (N-acetyl-p-benzoquinone imine) rather than the parent compound. Many drug metabolites are active, and this must be considered when the clinical effect of a medication is assessed. Some therapeutics (e.g., acetylsalicylate [aspirin], codeine) are delivered as inactive or low-activity compounds, called **prodrugs**, which require metabolism by the body to exert the desired physiological effect.

Drug metabolism in humans is typically the result of enzymatic activity. Metabolic enzymes are expressed throughout the body, with largest concentrations in (1) liver, (2) gastrointestinal tract, and (3) kidneys. Mathematically, it is possible to describe metabolism by using similar models as those applied to other enzymatic processes (see Chapter 14). Most drugs exhibit *f*irst-order metabolism, in which excess metabolic capacity is available and the rate of metabolism depends primarily on the drug concentration. First-order metabolism leads to a log-linear association of drug concentration versus time, meaning that a given *f*raction of drug is metabolized per unit time. This is frequently expressed as the hal*f*-li*f*e ($t_{1/2}$), the time required to metabolize 50% of the drug present.

Some agents (e.g., ethanol, salicylate) instead follow zero-order or nonlinear kinetics; many other drugs will convert to zero-order in overdoses. Nonlinear kinetics occurs when drug concentrations exceed the available metabolic capacity. In this situation, the amount of enzyme is the rate-limiting factor and the rate of metabolism is independent of drug concentration. A familiar example is the "one drink per hour" clearance estimate used for alcoholic beverages: The same quantity of ethanol is eliminated per hour, regardless of the number of drinks consumed. Compounds with zero-order kinetics do not have a true half-life because a constant amount of drug, rather than a constant percentage, is eliminated per unit time. However, for a given quantity of a drug, an apparent hal*f*-li*f*e is defined, reflecting the time required to eliminate 50% of the initial concentration. Apparent half-life changes as the amount of drug changes increasing with higher concentrations and decreasing with lower concentrations. For this reason, in nonlinear kinetics, small dose increases create disproportionately large elevations in drug concentrations (Figure 30-4).

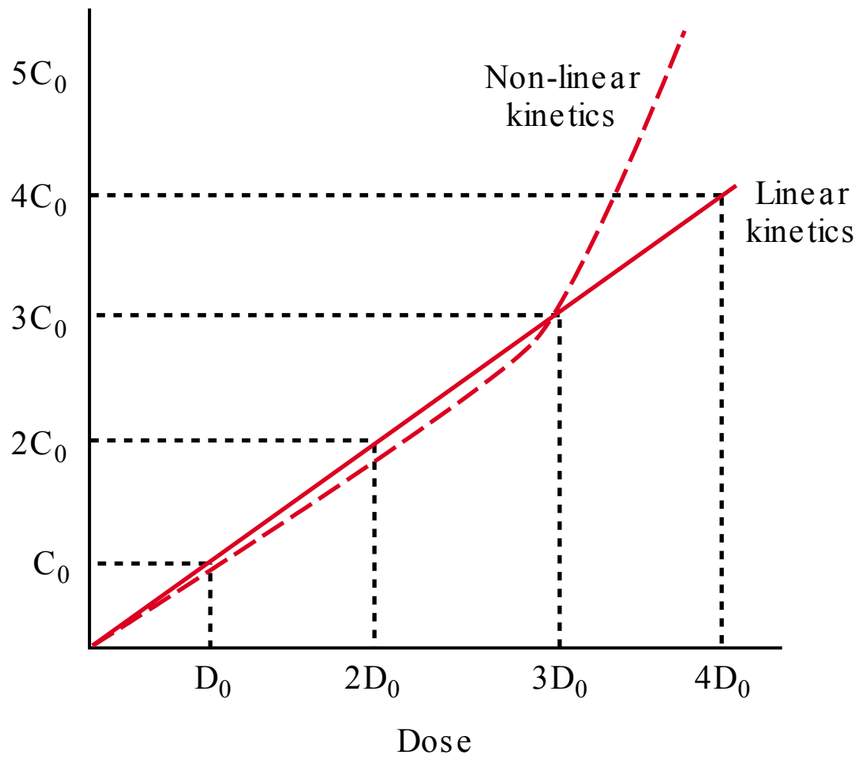

Figure 30-4 Nonlinear and linear responses to dose changes. Drugs with linear kinetics (solid line) display serum steady-state concentrations (C) that vary proportionately with dose (D). In contrast, for drugs with nonlinear kinetics (dotted line), an increase in dose may result in a disproportionate elevation in serum steady-state concentrations.

Metabolic processes are typically classified as phase I or phase II. Phase I metabolism is chemical modification (e.g., reduction/oxidation, hydrolysis). Phase II involves conjugation to another moiety such as glucuronic acid. The names do not indicate the order in which metabolic processes occur. The most important phase I enzymes are the **cytochromes P_{450}** (CYPs), with just a few CYP isoenzymes accounting for biotransformation of the vast majority of current pharmaceuticals. Several families of phase II enzymes are known (e.g., glucuronyltransferases, methyltransferases).

Genes that encode for the P_{450} enzymes, and the enzymes themselves, are designated with the abbreviation CYP, followed by an Arabic numeral for the subfamily and another numeral for the individual gene. The convention is to italicize when referring to the gene. For example, CYP2E1 is the gene that encodes for the enzyme CYP2E1—one of the enzymes involved in paracetamol (acetaminophen) metabolism. Cytochromes CYP 1 to 3 are the ones involved with drug metabolism, and most human drug oxidation is due to CYP isoenzymes (1) CPY1A2, (2) CPY2B6, (3) CPY2C9, (4) CPY2C19, (5) CPY2D6, (6) CPY2E1, and (7) CPY3A4. Drug metabolism displays a great deal of interindividual variability, both genetic and environmental. Genetic variability is covered extensively in later chapters and will not be discussed here. Environmental variability often occurs by **enzyme induction** or **enzyme inhibition**. Induction refers to enhanced metabolic activity, typically due to increased expression of genes encoding drug-metabolizing enzymes. An example of this is upregulation of CYP3A4 by the herbal product St. John's Wort, which accelerates metabolism of other CYP3A4 substrates, including oral contraceptives and immunosuppressive drugs, leading to unintended pregnancies and transplant rejection. Enzyme inhibition is more common than induction and frequently occurs via substrate competition, wherein more than one compound must compete for a limited number of enzyme binding sites. This slows the metabolism of all substrates of that enzyme, although the difference may be more apparent for one of the involved drugs.

Many therapeutic drugs, herbal products, and foods have been reported to inhibit metabolic enzymes. In practice, the site of inhibition is important, for example, grapefruit juice inhibits CYP3A4 in intestinal cells, reducing first-pass metabolism and increasing bioavailability of CYP3A4 substrates. Several algorithms are available to predict potential drug-drug interactions by using current information on metabolic enzyme (mainly CYP) inhibitors, inducers, and substrates.

Elimination

Elimination is the final removal of drugs from the body. The most common routes of elimination are excretion into (1) urine or (2) stool, although drugs are also eliminated into (3) breast milk, (4) sweat, and (5) hair. Clearance can be measured directly, and renal elimination can be estimated by using the glomerular filtration rate. Direct measurement of drug clearance requires multiple samples from the patient. However, it is infrequently done, except to monitor certain therapeutic agents or to more accurately define the glomerular filtration rate.

Although urine is used extensively in toxicology testing, the correlation between urine drug concentrations and serum concentrations is poor at best. This is the result of wide variability in several factors that affect renal drug elimination, including (1) patient hydration status, (2) urine pH, and (3) circadian fluctuations in renal function. It is theoretically possible to normalize urine drug concentrations with the use of 24-hour urine samples and correction to a marker of renal function such as creatinine. In practice, however, urine is rarely used for TDM purposes.

Pharmacokinetic Models

The ADME processes are not completely independent steps, but rather occur in an overlapping fashion, often simultaneously, within the body. This is especially true if a subsequent dose is given before the first dose has been completely eliminated. Thus, pharmacokinetic models have been developed to estimate factors such as (1) the amount of drug present at a given time, (2) the rate of clearance of a drug from the system, and (3) overall exposure to a drug for a given dose.

The concept of physiological compartments is used to envision the systemic distribution of a drug. A compartment is not a true corollary to a particular organ or fluid; rather, a compartment is a representation of the regions of the body to which a compound displays similar affinity. For example, some drugs remain preferentially in blood, while others distribute extensively into tissues. For the former, only a single pool of drug (in the blood) needs to be considered, whereas the latter drug has a pool in blood and a second pool in tissues. The first compound could be described by a one-compartment model, but the second may be more accurately represented by a two-compartment model (Figure 30-5). A drug that

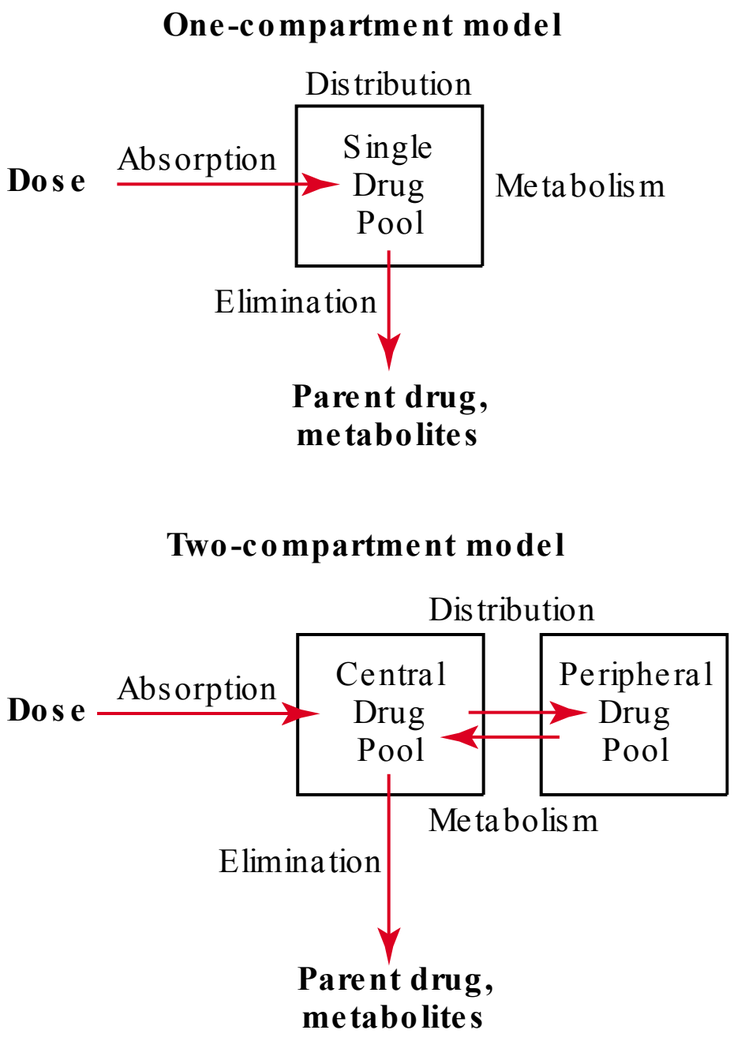

Figure 30-5 One- and two-compartment pharmacokinetic models. For a one-compartment model (top), an administered dose is considered as being contained within a single pool of drug in the body. All pharmacokinetic processes affect that single pool. For a two-compartment model (bottom), pharmacokinetic estimates must consider the equilibration of drug between the central and peripheral compartments. Final elimination from the body generally occurs from the pool of drug contained in the central compartment, thus peripherally distributed drug must re-enter the central compartment to be removed.

distributes to tissue is modeled reasonably accurately with one compartment, so long as the drug exhibits similar kinetics in the tissues and fluids involved; the compartments are not regions of the body, merely representations of distinct aspects of drug kinetics.

In a one-compartment model, the rate of elimination is governed by metabolism or clearance from a single pool of distributed drug. First-order elimination from a single compartment is shown graphically in Figure 30-6. T e slope of the line describing the decline is the elimination constant, k, which is a measure of overall elimination that includes loss of drug into urine or feces, metabolism, and so on. T e elimination constant is related to half-life according to the following formula:

$$t_{1/2} = \frac{0.693}{k} \qquad (2)$$

In this model, the concentration of drug at any time (C_t) after a single dose is calculated from the original concentration (C_0), the elimination constant, and the time (t):

$$ct = C_0 e^{-Kt} \qquad (3)$$

In a two-compartment model, the kinetics of distribution and elimination are distinct from one another (Figure 30-7). T e initial plasma concentration of drug declines rapidly as

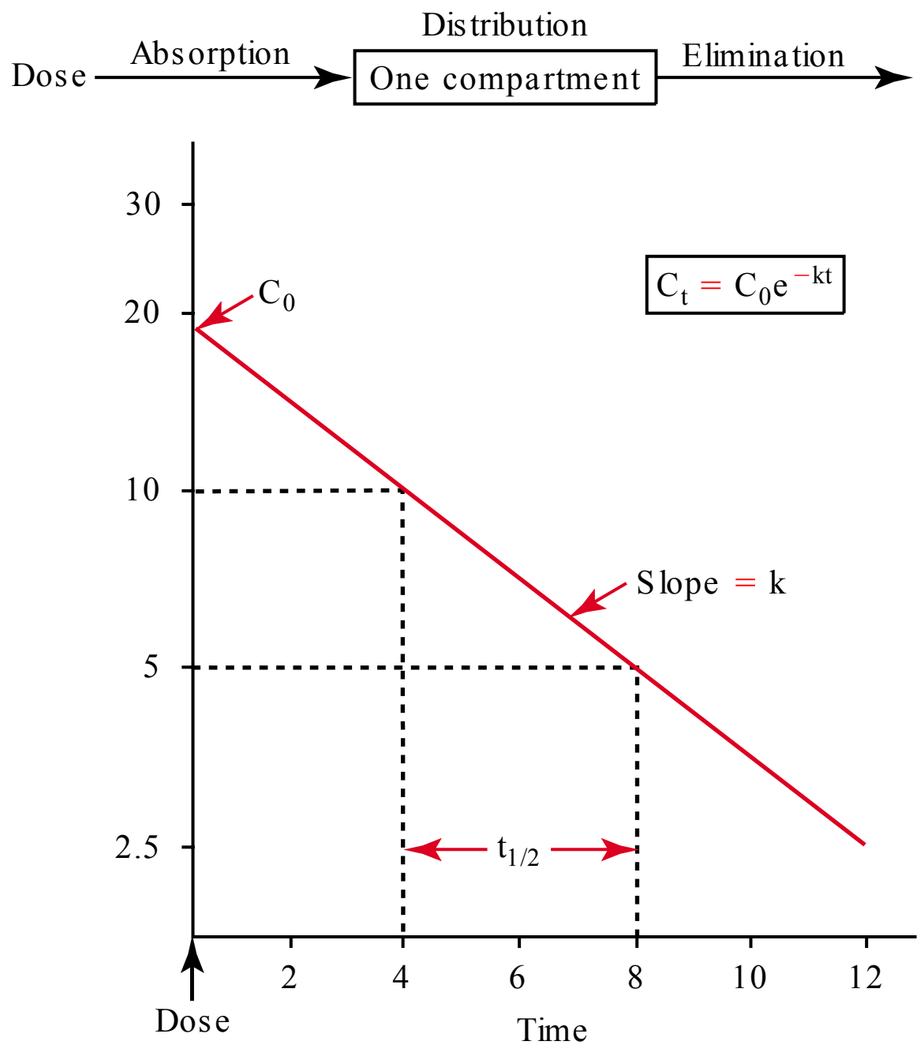

Figure 30-6 Drug concentration in plasma after administration of a dose for a one-compartment model. Monoexponential decline from the original concentration (C_0) is described by the elimination constant (k), which is related to the drug half-life ($t_{½}$). Drug concentration at any time (C_t) can be estimated with knowledge of C_0, k, and the time (t).

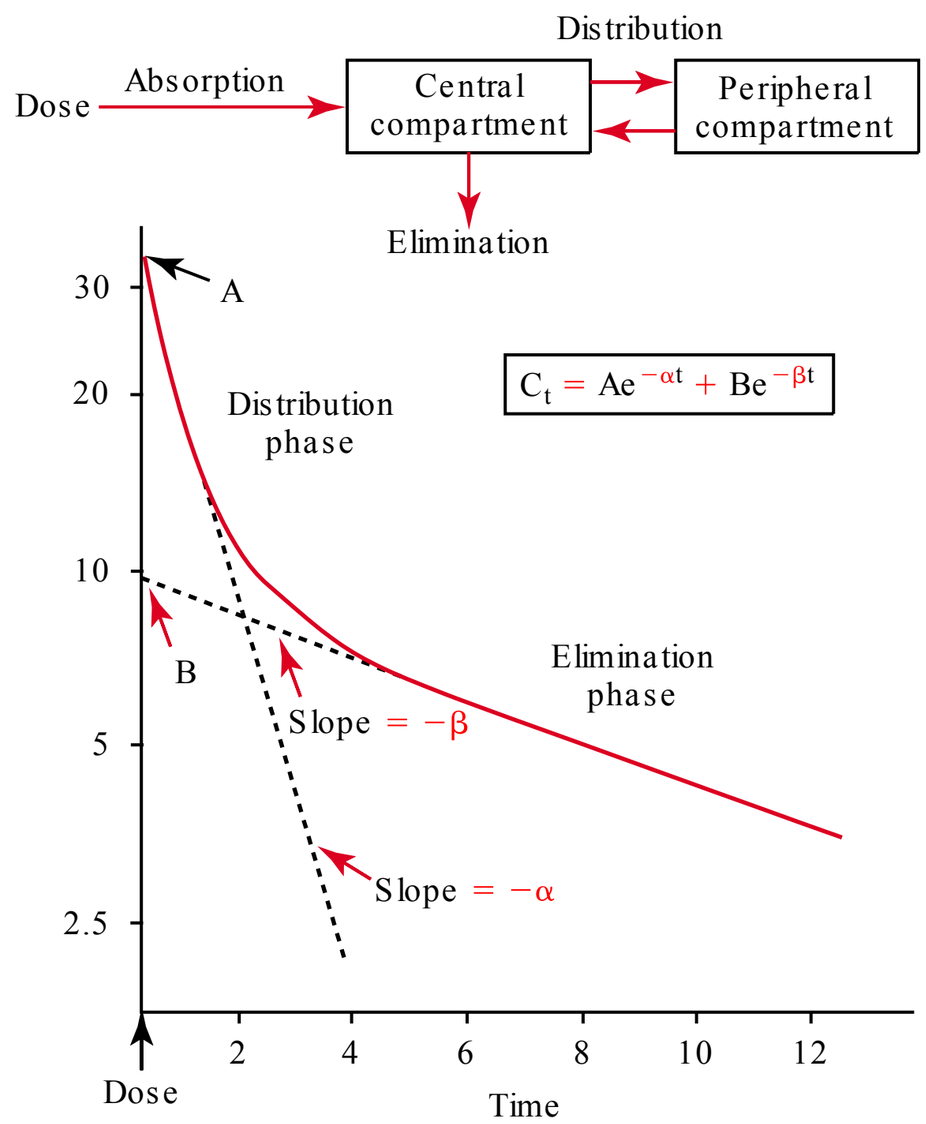

Figure 30-7 Drug concentration in plasma after administration of a dose for a two-compartment model. Decline from the original concentration (C_0) is affected by both the distribution phase (characterized by the constant α) and the elimination phase (characterized by the constant β).

the compound equilibrates between the two compartments (distribution phase). After distribution, the dominant kinetic mechanism becomes the elimination of drug from the central pool (elimination phase). The slopes of each phase are the distribution (α) and elimination (β) constants, respectively, which are related to the distribution or alpha half-life, and the elimination or beta half-life. Calculation of concentration incorporates both phases, as is evident in the following equation:

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} \quad (4)$$

As was discussed earlier, the extent of distribution into tissue varies between drugs. This difference is reflected in the volume of distribution (V_d) of each drug. The V_d is defined by the relationship between a single dose (D_0) corrected for bioavailability (f) and the plasma concentration (C_0) observed after dosing:

$$V_d = \frac{D_0 Xf}{C_0} \quad (5)$$

The V_d is not an actual physiological volume; rather, it is a calculated parameter that can be much larger than the volume of a human body. A helpful description is that the V_d is the volume of blood theoretically required to dilute a given dose to the measured drug concentration in blood. If most of a compound enters tissue, its measured concentration will be low, resulting in a higher calculated V_d. Thus a large V_d reflects extensive distribution, and a small V_d suggests that the drug is preferentially retained in the vasculature. V_d is expressed as a volume (e.g., in liters) or as a volume per unit body weight (e.g., L/kg).

The V_d is useful for estimating drug concentrations after dosing and for predicting the clearance rate of a drug. Total body clearance (Cl_T), the amount of blood or plasma completely cleared of drug per unit time, depends on both the V_d and the elimination constant k:

$$Cl_T = V_d k \quad (6)$$

Steady State

Although the example of a single dose is helpful for understanding basic pharmacokinetic principles, in practice TDM is performed for drugs administered multiple times. Almost invariably, doses are administered before the preceding dose has been completely eliminated; thus TDM models must account for both residual and newly introduced drug. As seen in Figure 30-2, at steady state the amount of drug administered is in balance with the amount being eliminated. Each dose produces a peak (C_{max}) and a trough (C_{min}), but at steady state each dose provides a similar profile of drug concentration versus time. For this discussion, the dosing interval (τ) will be assumed to equal the half-life, although this is not universally true in practice.

If doses are given at each half-life, a drug requires approximately five doses to approach steady-state concentrations (>95% of C_{ss}). Similarly, at the end of therapy, five to seven half-lives after the last dose must pass for >95% of the steady-state concentration to be eliminated. Reaching steady state typically takes many days to weeks for drugs with long half-lives; such agents are often given in a larger, initial bolus known as a loading dose to rapidly elevate plasma concentrations closer to steady-state concentrations.

Once steady state is achieved, TDM measurements are generally made at trough, that is, immediately before a scheduled dose. Trough sampling minimizes interpatient variability in ADME and improves the reliability of comparison of a single plasma concentration versus population therapeutic ranges.

Calculation of trough C_{ss} is possible if several parameters (D_0, f, V_d, k, τ, and t [time since last dose]) are known:

$$C_{SS} = \frac{(D_0 \times f)\, e^{-kt}}{V_d \left(1 - e^{-kt}\right)} \quad (7)$$

It is also possible to estimate a median steady-state concentration (C) using D_0, f, Cl_T, and τ:

$$C = \frac{D_{0 \times f}}{Cl_T \times \tau} \quad (8)$$

Clinical and Analytical Considerations

A robust TDM program offers clinicians the means to better manage patients and has the potential to improve patient quality of life by (1) optimizing dose, (2) supporting compliance, and (3) minimizing toxicity. The practice of TDM has been expanded and enhanced by advancements in rapid, sensitive, and specific analytical techniques for a wide variety of therapeutic agents.

Clinical Utility

The best candidate drugs for TDM are those that meet one or more of the following criteria: (1) a narrow therapeutic index; (2) used for long-term therapy; (3) correlation between serum concentration and clinical response; (4) wide interindividual or intraindividual variability in pharmacokinetics; (5) absence of a biomarker associated with therapeutic outcome; and (6) administered with other, potentially interacting compounds. Ideally, TDM allows determination of a baseline drug concentration at a time when the patient is responding well clinically and is known to be compliant; this baseline therapeutic concentration is then used over time to (1) assess compliance, (2) address physiological or pathological changes, and (3) maintain optimal dosing for each individual patient. Single measurements of serum drug concentrations should always be interpreted in the context of (1) clinical presentation, (2) length of therapy, (3) comedications, and (4) other factors capable of affecting serum concentrations.

Long-term pharmacological therapy is a necessary component in the management of many conditions. Some therapeutic agents have convenient biomarkers or clinical indicators of their efficacy, for example, statin treatment is assessed by quantifying cholesterol, and antihypertensive therapy is evaluated by following blood pressure. However, for many drugs,

biomarkers and clinical indicators are absent or are not visible until after the onset of therapeutic failure (e.g., transplant rejection resulting from inadequate immunosuppression). Such drugs are frequently managed using TDM, particularly when the condition for which they are prescribed involves the potential for serious risk to the patient, as with antiseizure therapy or post-transplant immunosuppression. Even for agents with available biomarkers, use of TDM often assists clinical decision making. For example, if a patient receiving antiarrhythmic therapy fails to improve cardiac rhythm, TDM may be used to clarify whether (1) the patient requires a different dose, (2) is refractory to that particular drug, or (3) is simply noncompliant.

The potential to detect noncompliance is a major asset of consistent use of TDM. The World Health Organization estimates that only half of patients receiving long-term drug therapy comply with the prescribed regimen. It should be noted that noncompliance may be a result of taking the medication (1) erratically, (2) too often, (3) too infrequently, or (4) not at all. Noncompliance is often very costly to the patient and to society. Patients at particular risk include (1) the elderly, who frequently must manage several drug regimens for comorbidities; (2) those with conditions prone to reducing ability or will to comply (e.g., severe depression); and (3) individuals whose conditions include asymptomatic periods, wherein patients feel better and forget or do not feel the need to continue treatment. Without routine TDM, noncompliance with therapy may remain unnoticed until symptoms resume (e.g., renewed seizure activity in an epileptic individual) or the treatment fails (e.g., rejection of a transplanted organ).

Serum drug concentrations are useful at many stages of treatment. Initial selection and dosing of a drug may be guided by TDM, particularly if wide interpatient variability in (1) absorption, (2) metabolism, or (3) other parameters of drug disposition is noted. Without measuring drug concentrations, it is difficult to discern which patients respond poorly to therapeutic concentrations of a particular drug and which patients simply are not within the therapeutic range. Similarly, the presence of comorbidities (e.g., hepatic failure, renal dysfunction) or the use of comedications will complicate the process of establishing an effective dose; population pharmacokinetics often does not adequately address comorbidities or drug interactions, necessitating TDM for such patients.

Routine TDM is also helpful for detecting and managing alterations in drug disposition within an individual. Such changes occur with physiological processes such as (1) puberty, (2) pregnancy, and (3) aging. However, they may also reflect development or progression of a pathological state. Conditions that seem as simple as weight loss or as complex as severe illness radically affect the disposition of a drug within a single patient; these changes occur rapidly and may be very difficult to manage clinically. Both acute and chronic shifts in pharmacokinetic behavior are addressed more effectively with TDM because dose adjustments are guided by each individual patient's serum drug concentrations.

Analytical Concerns

A wide variety of analytical techniques, including numerous permutations of immunoassay methods, are available to facilitate TDM. Chromatographic techniques, such as (1) gas chromatography–mass spectrometry (GC-MS), (2) liquid chromatography–mass spectrometry/mass spectrometry (LC-MS/MS), and (3) high performance liquid chromatography–ultraviolet (HPLC-UV), are often used. These techniques are discussed in Chapters 12 through 15. Immunoassays provide rapid results and ready automation; chromatographic techniques improve specificity and limits of detection, although at a lower throughput. Unfortunately, commercial immunoassays are not available for many of the newer-generation drugs. LC-MS/MS is progressively replacing other HPLC-based methods; it displays greater selectivity and permits less analytical interference, allowing development of multianalyte assays with higher throughput and less influence from metabolites or other potentially coeluting compounds. The choice of analytical method typically depends on the availability of resources (e.g., technologist expertise, laboratory funding) and the clinical demand for turnaround.

TDM analysis embodies many of the same concerns as other areas of clinical chemistry, including (1) the need for accurate, reproducible methods; (2) the requirement for quality assurance and proficiency testing programs; and (3) the necessity of establishing target ranges (therapeutic indices) and critical values (e.g., toxic concentrations). Certain preanalytical and analytical issues are of particular importance for drug assays, for example, some pharmaceuticals adsorb to the gel matrix in serum or plasma separator tubes, causing falsely low apparent drug concentrations and making these collection devices unacceptable for many tests. Similarly, the time of blood draw relative to administration of the drug is often a key factor in the interpretation of TDM results. Most TDM protocols require sampling at trough immediately before the next scheduled dose, particularly for compounds with short half-lives or variable pharmacokinetics.

Other considerations for TDM include the determination of which metabolites and which drug fractions (e.g., free, protein-bound) are clinically relevant. Active metabolites should be quantified, and if the parent compound is also active (i.e., not a prodrug), the concentrations of parent and metabolite should be considered together when the results are interpreted. Inactive metabolites are often of interest as well. They may be associated with toxicity that is independent of the drug's intended activity (e.g., the acetaminophen metabolite N-acetyl-p-benzoquinone imine) or may serve as a reservoir for conversion to active drug (e.g., the glucuronide conjugate of the immunosuppressant mycophenolic acid). Metabolites often accumulate at a different rate than the parent drug; thus inactive metabolites may provide longer detection windows or in vivo assessment of an individual's metabolic capacity.

TDM of drugs with extensive protein binding may benefit from monitoring of free drug concentrations. In reasonably healthy individuals free of conditions affecting protein concentrations (e.g., pregnancy, malnutrition) or of comedications capable of altering the free versus bound equilibrium,

analysis of free drug concentrations typically is not necessary. However, illness, physiological alterations, or changes in comedications may shift the balance of free drug concentrations; similarly, free drug measurements are helpful in the management of digoxin overdose treated with a drug-binding agent that nullifies but does not remove the excess digoxin. Equilibrium dialysis is the reference method for most free drug assays but is extremely time-consuming. In practice, ultrafiltration is used to remove larger molecules, including protein-bound drug; removal is followed by analysis of the remaining unbound fraction.

Finally, one further issue of clinical and analytical relevance to TDM is the format in which concentration units are expressed. Measured therapeutic drug concentrations are often expressed in units of micrograms per milliliter (μg/mL) or milligrams per liter (mg/L). However, it is recognized that use of the abbreviation μ could adversely affect patient safety. For example, in prescribing medication, a handwritten "μg" can be mistaken for mg (milligram), resulting in a thousand-fold overdose of drug, which clearly has the potential to harm a patient. Institutions accredited by The Joint Commission now use "mcg" rather than μg when prescribing medication. Drug concentrations in this chapter are provided as mg/L (equivalent to μg/mL) or as μg/L (equivalent to ng/mL) unless conventionally reported in molar units.

Specific Drug Groups

Drugs that are routinely monitored are conveniently classified by the type of therapy they support, such as (1) control of epilepsy or infection, (2) management of respiratory or cardiac function, and (3) suppression of immune response. The following discussion is organized in accordance with classifications commonly recognized. Proprietary (brand) names are provided in parentheses after the compound name where pertinent. Note that some drugs such as salicylate are discussed in Chapter 31.

Antiepileptics

Many drugs are available for treating seizures (Table 30-1). In general, antiepileptic drugs prevent or minimize seizures by augmenting inhibitory processes, for example, by enhancing γ-aminobutyric acid (GABA)-mediated neurotransmission or inhibiting excitatory processes (e.g., voltage- or ligand-gated ion channels, glutamate-mediated neurotransmission) in the brain. Therefore, some of these drugs are also used as sedatives and are used to treat (1) neuropathic pain, (2) migraine headache, and (3) psychiatric conditions, as well as (4) to manage addictions. The discussion presented here is limited to application of antiepileptic TDM to support management of seizures.

Antiepileptic drugs were among the first class of drugs monitored to establish appropriate dosing, in part because both underdosing and overdosing are manifested by seizure activity, making it difficult to titrate and optimize dose clinically. In addition, therapeutic and toxic effects of early drugs such as phenobarbital and phenytoin were shown to be related to serum concentrations. Antiepileptic drugs are frequently described as first-generation or classical (introduced clinically before 1990) versus newer or second-generation drugs (introduced clinically after 1990).

TABLE 30-1 Pharmacokinetic Parameters of Antiepileptic Drugs

Drug	Recommended[9,14] Therapeutic Range, mg/L	Mean Time to Steady State, d	Observed Range of Half-life in Adults, h[†]	Mean Volume of Distribution, L/kg	Mean Oral Bioavailability, %	Protein Binding, %	Important Metabolizing Enzymes
Carbamazepine	4-12	2-4	8-12	1.4	70	75	CYP3A4
Clonazepam	0.02-0.07	3-10	17-56	3.2	>90	85	CYP3A4
Ethosuximide	40-100	7-10	30-60	0.7	>90	0	CYP3A4
Gabapentin	2-20	1-2	5-9	0.9	Variable	0	NA
Lamotrigine	2.5-15	3-6	20-30	1.2	>90	55	NA
Levetiracetam	12-46	1-2	6-8	0.6	>90	0	NA
Monohydroxy oxcarbazepine (MHD)[*]	3-35	2-3	8-15	0.8	>90	40	NA
Phenobarbital	10-40	12-24	70-140	0.7	>90	50	CYP2C19
Phenytoin	10-20 (free: 1.0-2.0)	5-17	30-100	0.6	80	90	CYP2C9, 2C19
Primidone	5-10	2-4	3-22	0.7	>90	20	CYP2C9, 2C19
Topiramate	5-20	4-5	20-30	0.7	80	15	NA
Valproic acid	50-100	2-4	11-20	0.2	>90	90	CYP2C9, 2C19, 2B6, 2E1, 2A6
Zonisamide	10-40	9-12	50-70	1.4	65	50	CYP2C19, 3A4

*Active metabolite not available as a unique drug.
[†]Based on average half-life and no interfering medications.
NA, Not applicable.

Although therapeutic ranges and toxic thresholds are proposed for all antiepileptic drugs, the overwhelming caution is to "treat the patient, not the level." Consequently, most antiepileptic therapy is administered over the long term, possibly on a lifelong basis, meaning that dosing requirements will change with (1) age, (2) stage of development, and (3) clinical status. In addition to comparing steady-state concentrations of antiepileptic drugs, TDM for antiepileptics is used early in therapy to ensure that steady-state concentrations have been achieved before efficacy is evaluated, particularly for drugs that exhibit nonlinear and/or variable pharmacokinetics. With maintenance therapy, TDM is useful for (1) identifying and managing drug-drug interactions, (2) managing changes in dose or drug formulation, and (3) evaluating compliance, particularly when signs of therapeutic failure or toxicity are evident. In general, older antiepileptic drugs are monitored more frequently than the newer drugs, in part because of the wide availability of automated immunoassays. In general, immunoassay procedures target a single analyte (usually the parent drug) and are (1) fast, (2) inexpensive, and (3) available for a wide variety of analyzers. When immunoassays are not available, or in certain clinical situations for which higher sensitivity and specificity are needed, chromatographic methods are applied to support antiepileptic TDM.

Some antiepileptics (e.g., phenytoin) are extensively bound to circulating plasma proteins. As with most drugs, only the unbound (free) fraction of drug passes through membranes to exert pharmacological activity, and many drug-drug interactions occur as a result of competition for protein-binding sites. For patients with unpredictable protein concentrations, or for whom drug-drug interactions are a significant concern, it may be appropriate to provide TDM for the free fraction of drug. For example, if the proportion of drug bound to proteins changes from 95% to 80%, the amount of active (free) drug in circulation will increase dramatically, while the total drug concentration for that patient may not change. As such, risk of toxicity could be missed and TDM results could be misinterpreted, particularly for pregnant women and elderly persons with poor nutritional status who are managed with multiple medications. Most analytical techniques are designed to measure total drug concentrations and do not distinguish between free and bound drug concentrations. To accommodate TDM of free drug concentrations, protein-bound drug is separated and removed from plasma using physical or chemical techniques. Resulting free drug concentrations are determined by immunoassays or chromatographic techniques, with the method's calibration and lower limit of detection designed to accommodate lower concentrations than those observed when total drug concentrations are measured.

A brief discussion of TDM support for specific antiepileptic drugs is provided here. They have been organized as: (1) Traditional and still widely used, (2) contemporary, and (3) historical and no longer widely used.

Traditional Antiepileptics, Still Widely Used

Antiepileptic drugs introduced before 1990 and currently in use include (1) benzodiazepines (diazepam and clonazepam), (2) carbamazepine, (3) ethosuximide, (4) phenobarbital and primidone, (5) phenytoin and fosphenytoin, and (6) valproic acid.

Benzodiazepines (e.g., Diazepam, Clonazepam)

Benzodiazepines are a diverse class of drugs that reduce neuronal excitation through agonist activity at the $GABA_A$ receptor. Although many benzodiazepines have antiseizure activity, those used most often in management of seizures include diazepam (Valium) and clonazepam (Klonopin). Both drugs are available in a wide variety of formulations and are sold under other names. Diazepam is frequently administered by the rectal or intravenous route in emergency situations, such as to gain control of status epilepticus (a life-threatening condition in which the brain is in a state of persistent seizure). Diazepam is not used for long-term control of seizure disorders and is not monitored routinely for this purpose because tolerance at the $GABA_A$ receptor develops rapidly, and the drug becomes ineffective within 2 to 3 days. Also, because tolerance to clonazepam does not develop rapidly, it is used to manage seizures and may be monitored through TDM.

Clonazepam is rapidly and completely absorbed after oral dosing, and peak plasma concentrations occur after 1 to 4 hours. Clonazepam is extensively metabolized by CYP3A4, as well as by glucuronidation and sulfation reactions. As such, modulators of CYP3A4 will affect plasma concentrations of clonazepam. The 7-amino-clonazepam metabolite has some pharmacological activity and is present in approximately equal concentrations to parent drug at steady state.

Serum concentrations of clonazepam increase in a linear fashion with doses for both children and adults; however, serum concentrations are not well correlated with efficacy or toxicity because of the development of tolerance that occurs to some extent with long-term administration. The proposed therapeutic range is 20 to 70 μg/L. At concentrations higher than 80 μg/L, no additional seizure protection is observed, and toxicity (drowsiness and ataxia) ensues.

Carbamazepine

Carbamazepine (Tegretol) is available under other names and in **generic form**. Similar to phenytoin, carbamazepine modulates the synaptic sodium channel, which acts to reduce central synaptic transmission, aiding in control of abnormal neuronal excitability. Carbamazepine also has an antidiuretic effect, reducing concentrations of antidiuretic hormone, although it is unlikely that this contributes to antiepileptic activity.

After oral administration, carbamazepine is slowly but erratically absorbed with wide individual formulation–based variability. The active metabolite of carbamazepine is carbamazepine-10,11-epoxide, formed by the action of CYP3A4. This metabolite has been found to accumulate in children and exists in concentrations equivalent to carbamazepine. Monitoring of ratios may be useful for evaluating compliance and drug-drug interactions. Cross-reactivity of this metabolite in commercial immunoassays is variable and should be considered when carbamazepine TDM is provided. The therapeutic concentration range for optimal pharmacological effects of carbamazepine

is 4 to 12 mg/L. Toxicity associated with excessive carbamazepine may occur at plasma concentrations in excess of 15 mg/L (or free carbamazepine >3 mg/L) and is characterized by symptoms of (1) blurred vision, (2) paresthesia, (3) nystagmus, (4) ataxia, (5) drowsiness, and (6) diplopia. Side effects unrelated to plasma concentration include development of an urticarial rash, which usually disappears on discontinuation of the drug, and hematological depression (leukopenia, thrombocytopenia, and aplastic anemia).

Ethosuximide

Ethosuximide (Zarontin) is used for the treatment of absence seizures characterized by brief loss of consciousness. Ethosuximide reduces the flow of calcium through T-type calcium channels in the synapse and slows the rate of these seizure-inducing pulses. Ethosuximide is a chiral molecule that is used clinically as a racemic mixture.

Ethosuximide is readily absorbed from the gastrointestinal tract with near complete bioavailability. T e drug is cleared primarily by metabolism mediated by CYP3A4 (hydroxyethyl metabolite) and the glucuronide. Drug-drug interactions occur primarily as a result of enzyme induction or through CYP3A4.

T e established therapeutic range of ethosuximide is 40 to 100 mg/L, although it is not uncommon that higher concentrations are required. Toxicity related to an excessive blood concentration of ethosuximide is rare. Symptoms of gastrointestinal distress, lethargy, dizziness, and euphoria may be encountered early in therapy, but patients usually become tolerant to these symptoms.

Phenobarbital and Primidone

Phenobarbital is a broad-spectrum antiepileptic drug that was introduced clinically in 1912 under the name Luminal. It is now (1) known by a wide variety of proprietary names, (2) given alone or in combination with many other drugs, and (3) used to manage all but absence seizure types. It is also the active component of the prodrug primidone (Mysoline) and is known to reduce synaptic transmission through action on the $GABA_A$ receptor, resulting in decreased neuronal excitability.

Serum concentrations of phenobarbital are well correlated with dose; however, pharmacokinetics is widely variable. Absorption of oral phenobarbital is near complete, but the rate of absorption is age dependent—rapid in adults, slow in children. T us, the time at which peak plasma concentrations are reached ranges from 4 to 10 hours after the dose. Primidone is rapidly and nearly completely absorbed after oral administration. Phenobarbital is metabolized by CYP2C19 to p-hydroxyphenobarbital, which is largely excreted as the glucuronide. Phenobarbital is also recognized to induce hepatic enzymes, which will affect the concentrations of other coadministered medications.

T e widely recognized therapeutic range of phenobarbital for adults is between 15 and 40 mg/L. T e predominant side effect observed in adults at blood concentrations greater than 40 mg/L is sedation, although tolerance to this effect develops with long-term therapy. Actual optimal concentrations vary and may not be realized until tolerance to the sedative effects has occurred. Because of the long elimination half-life of phenobarbital, the blood concentration does not change rapidly. T erefore, it is possible to collect blood for TDM at any time of day, once steady state has been achieved.

T e optimal therapeutic concentration of primidone has been established as 5 to 10 mg/L. Because phenobarbital is an active metabolite of primidone, concurrent analysis of phenobarbital is required for complete interpretation of results. In addition to revealing drug-drug interactions, evaluating the ratio of phenobarbital to primidone may assist with detection of noncompliance.

Phenytoin and Fosphenytoin

Phenytoin (diphenylhydantoin), most commonly available as Dilantin but also available under other names and in generic form, is used in the treatment of all but absence seizures. Phenytoin interferes with sodium channel activity by prolonging inactivation, which reduces synaptic transmission and assists in control of abnormal neuronal excitability.

T e pharmacokinetics of phenytoin is complex and unpredictable as the result of variable absorption, high (>90%) protein binding, saturable metabolism, and drug-drug interactions. Phenytoin is not readily soluble in aqueous solutions. When administered by intramuscular injection, most of the dose precipitates at the site of injection and then is slowly absorbed. A prodrug called fosphenytoin (Cerebyx) allows intramuscular injection and rapid conversion to and liberation of phenytoin. Monitoring of fosphenytoin is accomplished through the use of routine phenytoin assays. However, specimens collected shortly after administration of fosphenytoin may not accurately reflect active drug concentrations; interpretation of TDM for fosphenytoin should be performed after phenytoin concentrations reach steady state.

Phenytoin is metabolized by CYP2C19 and CYP2C9. T e principal metabolite is 5-(p-hydroxyphenyl)-5-phenylhydantoin, which is excreted principally as a glucuronide. Hepatic metabolism of phenytoin may become saturated within the therapeutic range. Once metabolism is saturated, small dose increments result in large changes in blood concentration. T is phenomenon partially explains the wide variation in dose among patients that is required to achieve a therapeutic effect. Because of this saturation phenomenon, the half-life of phenytoin varies tremendously.

T e optimal therapeutic concentration for seizure control without side effects is 10 to 20 mg/L. Free phenytoin concentrations of 1 to 2 mg/L are optimal. Total phenytoin concentrations greater than 20 mg/L usually do not enhance seizure control and often are associated with nystagmus and ataxia. Total phenytoin plasma concentrations greater than 35 mg/L have been shown to precipitate seizure activity. A side effect of phenytoin not related to plasma concentration is development of gingival hyperplasia.

Valproic Acid

Valproic acid (Depakote) is most commonly used for the treatment of absence seizures. T e drug inhibits the enzyme GABA

transaminase, resulting in increased concentrations of GABA and overall inhibition of neuronal activity in the brain.

Valproic acid is rapidly and almost completely absorbed after oral administration. Peak concentrations occur 1 to 4 hours after an oral dose of conventional tablets or solutions is given, but they are extended for enteric-coated and sustained-release formulations, as well as when taken with food. The metabolism of valproic acid is extensive, involving β-oxidation and production of several glucuronide conjugates. The half-life is shortened from approximately 20 hours with the initial dose to approximately 12 hours as steady state is achieved. The half-life is shorter in children than in adults, with the exception of neonates with hepatic disease, in whom the half-life becomes prolonged. Relatively poor correlation has been noted between dose and serum concentrations. Valproic acid modulates the pharmacokinetics of many other antiepileptic drugs.

The minimum effective therapeutic concentration of valproic acid is 50 mg/L. Concentrations greater than 100 mg/L have been associated with hepatic toxicity and acute toxic encephalopathy. Free concentrations are sometimes clinically useful.

Contemporary Antiepileptics

Examples of antiepileptic drugs introduced after 1990 and currently in use include (1) gabapentin, (2) levetiracetam, (3) lamotrigine, (4) oxcarbazepine, (5) topiramate, and (6) zonisamide

Gabapentin

Gabapentin (Neurontin) is a chemical analog of GABA that promotes the release of GABA. It does not interact directly with the GABA receptor, and its mechanism of action is somewhat unclear.

Absorption of oral gabapentin is mediated by the l-amino transport system in the small intestines through a saturable process. Thus, bioavailability is dose dependent. Peak concentrations are observed 2 to 3 hours after a dose. Absorption is reduced by concomitant use of antacids. The minimum effective concentration of gabapentin is 2 mg/L, and the optimally effective therapeutic serum concentration of gabapentin is reported as between 2 and 20 mg/L. Side effects observed in adults at serum concentrations greater than 12 mg/L include somnolence, ataxia, dizziness, and fatigue.

Lamotrigine

Lamotrigine (Lamictal) is a broad-spectrum antiepileptic drug that is thought to act through multiple mechanisms, including blocking sodium and calcium channels and reducing glutamate release.

Lamotrigine is completely absorbed from the gastrointestinal tract after oral administration, with peak concentrations occurring at 1 to 3 hours. A linear relationship between dose and serum concentrations is observed. Lamotrigine is extensively metabolized and is eliminated primarily as the glucuronide ester. Autoinduction reduces serum concentrations by ≈20% with approximately 2 weeks of therapy. Enzyme-inducing drugs such as (1) phenobarbital, (2) phenytoin, or (3) carbamazepine lead to reduced lamotrigine concentrations. Clearance is greater in children and increases up to 300% in pregnancy.

The proposed therapeutic range for lamotrigine is between 2.5 and 15 mg/L. Signs of toxicity that have been reported include (1) dizziness, (2) ataxia, (3) diplopia, (4) blurred vision, (5) nausea, and (6) vomiting. However, these effects are rare when plasma concentrations are less than 15 mg/L. Lamotrigine is a potent inhibitor of dihydrofolate reductase. Folate concentrations are decreased when this drug is administered. If folate replacement is not implemented, rash and anemia may be experienced when lamotrigine is within the therapeutic range. Lamotrigine has been associated with the development of severe rash that is not dose-related (Stevens-Johnson syndrome) in approximately 1% of patients.

Levetiracetam

Levetiracetam (Keppra) is a broad-spectrum antiepileptic that acts through synaptic vesicle protein SV2A, which is involved in the release of neurotransmitters from presynaptic terminals. This drug is chiral, and its antiepileptic activity is highly enantioselective.

Levetiracetam is 100% bioavailable after an oral dose and reaches maximum concentration in approximately 1 hour. Levetiracetam is not extensively metabolized. Renal function and age are the major determinants of elimination kinetics. The possibility of in vitro metabolism by blood esterases (after the specimen is collected) has been proposed, so plasma should be separated from cells promptly. The half-life ranges from 16 to 18 hours for newborns and from 6 to 8 hours in healthy adults.

The minimal effective serum concentration of levetiracetam for seizure control is 3 mg/L, but the effective concentration is not well defined. A proposed therapeutic range is 12 to 46 mg/L. Toxicity known to be associated with levetiracetam, sometimes at therapeutic concentrations, includes (1) decreased RBC count, (2) decreased hematocrit, (3) decreased neutrophil count, (4) somnolence, (5) asthenia, and (6) dizziness.

Oxcarbazepine

Oxcarbazepine (Trileptal), a 10-keto analogue of carbamazepine, is a chiral prodrug that is metabolized to 10-hydroxy-10,11-dihydrocarbamazepine, known commonly as monohydroxycarbamazepine (MHD), the metabolite responsible for the therapeutic effect. MHD, similar to carbamazepine, blocks sodium channels; MHD also exhibits inhibitory activity at calcium channels.

Oxcarbazepine is rapidly and completely absorbed, with peak concentrations observed at 1 to 2 hours; food has no effect on rate or extent of absorption. Concentrations of MHD peak at 3 to 5 hours. Concentrations of the S-enantiomer of MHD are much higher than those of the R-enantiomer because conversion is stereoselective. The metabolism of MHD is extensive; about 96% of the dose is excreted in the urine as metabolites. Most of the dose is eliminated and recovered

as the glucuronide ester of oxcarbazepine or MHD. Metabolism does not involve inducible enzymes; however, drug-drug interactions are minimal.

Optimal response is reported in the range of 3 to 35 mg/L. Toxicities that may be observed at therapeutic concentrations include (1) hyponatremia, (2) dizziness, (3) somnolence, (4) diplopia, (5) fatigue, (6) nausea, (7) vomiting, (8) ataxia, (9) abnormal vision, (10) abdominal pain, (11) tremor, (12) dyspepsia, and (13) abnormal gait. Serum sodium concentration less than 125 mmol/L and decreased thyroxine (T_4) have also been seen in patients treated with MHD.

Topiramate

Topiramate (Topamax) is a broad-spectrum antiepileptic drug that exerts activity through several mechanisms. It has sodium and calcium channel blocking activity, potentiates the activity of GABA, and inhibits glutamate release.

Topiramate is absorbed rapidly and peaks at 2 to 4 hours. Approximately 50% of topiramate is metabolized. Most studies have reported a therapeutic range for topiramate of 5.0 to 20 mg/L, yet considerable overlap is seen in serum concentrations between responders and nonresponders.

Zonisamide

Zonisamide (Zonegran) is a sodium and calcium channel blocker. Therefore it is considered a broad-spectrum antiepileptic.

Peak concentrations of zonisamide are observed 2 to 6 hours after dose administration. Pharmacokinetics becomes nonlinear at high concentrations. Zonisamide is extensively metabolized, with a primary pathway mediated by CYP2C19 and CYP3A4. The proposed therapeutic range of zonisamide is 10 to 40 mg/L, but overlap in plasma concentrations between responders and nonresponders occurs. Adverse effects on cognition are reported at concentrations that exceed 30 mg/L. Toxicity is likely at concentrations that exceed 70 mg/L.

Historical and No Longer Widely Used

Antiepileptics of historical interest include (1) bromides, (2) methsuximide, (3) ethotoin, and (4) mephobarbital. As they are no longer widely used they are not discussed here.

Antimicrobial Agents

Antimicrobial agents include a wide range of compounds with very different (1) target organisms, (2) mechanisms of activity, and (3) pharmacokinetics. Efficacy of therapy is dependent on both the drug and the infectious agent, thus TDM for these compounds requires knowledge not only of the pharmacological and toxicological characteristics of the drug itself, but also of the nature of the infection it is intended to treat. Pharmacokinetic details of select antibacterial and antifungal agents are summarized in Table 30-2.

Antibacterials

Bacterial susceptibility to antibiotics is commonly measured in terms of the minimum inhibitory concentration (MIC), that is, the concentration of drug sufficient to inhibit growth of an organism. The MIC varies widely for different strains of the same species; TDM for antibiotics often involves relating the serum drug concentration to the MIC of the specific infectious agent being treated.

Aminoglycosides

Aminoglycoside antibiotics such as (1) amikacin, (2) gentamicin, and (3) tobramycin (available as generics) inhibit protein synthesis to kill aerobic, gram-negative bacteria. Because oral absorption is poor, aminoglycosides are administered intravenously or by intramuscular injection. Elimination is largely renal with minimal metabolism; kidney dysfunction is therefore a concern with use of these agents and may necessitate adjustment of dose or dosing intervals. Aminoglycosides are associated with risk of serious toxicity, particularly nephrotoxicity (renal tubular necrosis) and potentially irreversible ototoxicity (auditory nerve degeneration) leading to hearing loss.

For optimal efficacy, the peak (C_{max}) aminoglycoside concentration must rise to significantly above the minimum inhibitory concentration (MIC) of the organism being treated. This characteristic is termed concentration-dependent killing. However, to avoid toxicity, trough concentrations must be allowed to decline substantially before the next dose; thus these drugs do not reach steady state. Allowing the drug to clear does not adversely affect therapy because aminoglycosides show a

TABLE 30-2 Pharmacokinetic Parameters of Antibiotics and Antifungals

Drug	Therapeutic Targets*	Mean Half-life, h	Mean Volume of Distribution, L/kg	Mean Oral Bioavailability, %	Protein Binding, %	Enzymes Inhibited or Induced
Aminoglycoside Antibiotics[5]						
Amikacin	C_{max}: 25-35; C_{min}: 1-8	2.3	0.3	NA	5	
Gentamicin	C_{max}: 5-12; C_{min}: <1	2.5	0.3	NA	5	
Tobramycin	C_{max}: 5-12; C_{min}: <1	2	0.3	NA	<10	
Glycopeptide Antibiotics[10]						
Vancomycin	C_{min} > 10-15 mg/L	4-12	0.4-1.0	Low	50-55	
Triazole Antifungals[1,4]						
Posaconazole	C_{min}: >1.25 mg/L	24	>100	High, varies	98	3A4
Voriconazole	C_{min}: 1-6 mg/L Toxic: >6 mg/L	6	4.6	96	60	2C9, 3A4, 2C19

*C_{max}, Peak concentration; C_{min}, trough concentration; NA, data not available.

considerable postantibiotic effect, that is, they enhance bactericidal activity that lasts after the drug has been cleared from the body. For these reasons, aminoglycoside TDM samples are drawn at peak (1 hour postdose) and at trough (immediately predose, or at minimum 10 to 12 hours postinfusion) to monitor efficacy and risk of toxicity, respectively.

Vancomycin

Vancomycin (Vancocin) is a glycopeptide antibiotic with activity against antibiotic-resistant bacteria, including methicillin-resistant Staphylococcus aureus (MRSA). In earlier years, vancomycin was suspected to cause nephrotoxicity and ototoxicity (damage to the ear); however, these concerns were likely due to impurities in early formulations of the drug. More recent studies show lower (although not absent) risk for adverse effects unless administered with other agents capable of damaging hearing or renal function, such as aminoglycosides.

TDM of vancomycin has been associated with improved therapy and reduced risk of toxicity. Current guidelines suggest that the preferred means of monitoring vancomycin is the trough serum concentration, obtained immediately before the fourth dose. For most infections, trough vancomycin concentrations should be maintained above 10 mg/L, depending on the MIC of the pathogen; for more severe infection, trough concentrations should be sustained in the range of 15 to 20 mg/L. Peak vancomycin concentrations do not appear to be helpful in monitoring risk of toxicity.

Other Antibiotics

Analytical methods to detect many other types of antibiotics have been described, but TDM is uncommon, and testing remains limited to methods developed in-house or at reference laboratories. TDM for other antibacterial drugs is potentially useful in the management of patients with (1) renal dysfunction, (2) severe hepatic disease, or (3) suspicion of atypical pharmacokinetics (e.g., poor absorption, altered distribution).

Antifungal Agents

T e incidence of fungal infection is increasing with the growth in prevalence of immunocompromised individuals (e.g., transplant recipients). T e most common pathogens are species of Candida yeasts or Aspergillus molds. Advances have expanded the number of fungicidal drugs available to combat such infections; however, data regarding optimal use of TDM for patient management are insufficient. T e triazole group of antifungal drugs is discussed below.

Triazoles

T is group includes two newer agents: voriconazole (Vfend) and posaconazole (Noxafil). T ese broad-spectrum compounds kill by inhibiting synthesis of the major fungal sterol, ergosterol. Bioavailability varies greatly, thus it is recommended to administer these agents while fasting (voriconazole) or with a high-fat meal (posaconazole). All triazoles inhibit one or more of the CYP enzymes, thus their administration can greatly affect concentrations of commonly coadministered drugs such as immunosuppressants. Triazoles are also CYP substrates and subject to induction or inhibition of metabolism. Drug interactions and bioavailability concerns are common rationales for performing triazole TDM.

Voriconazole and posaconazole have broad-spectrum activity and are effective against fungi that are resistant to older triazoles. Voriconazole displays nonlinear kinetics at therapeutic doses. Posaconazole generally follows linear kinetics but converts to nonlinear behavior (saturation) at high doses. Both agents show progressively greater risk of toxicity as serum concentrations increase, but there does not appear to be a single cutoff that clearly delineates toxic concentrations from nontoxic. Target concentrations vary depending on whether the drug is used for active infection or for prophylaxis. Recommended steady-state trough concentrations for voriconazole are 1 to 6 mg/L; targets for posaconazole are as yet poorly defined, although concentrations greater than 1.5 mg/L appear to be effective against invasive fungal infection.

Antineoplastics (Anticancer Drugs)

Treatment of cancer is based on clinical protocols that often utilize a series of drugs or combinations of drugs. TDM is not common for most of the drugs utilized. Two drugs that are sometimes monitored in cancer therapy are busulfan and methotrexate.

Busulfan

Busulfan is a chemotherapeutic drug that inhibits the growth of malignant cells by alkylating DNA. An orally administered formulation was introduced in 1953 as a possible treatment for chronic myelogenous leukemia and was largely replaced by the introduction of an IV formulation (Busulfex). Studies have shown that high-dose oral busulfan combined with 2 or 4 days of cyclophosphamide or fludarabine, before bone marrow transplant, is an effective alternative to cyclophosphamide and total body irradiation. In addition to being an effective antitumor agent, the regimen has been reported to minimize the risk of secondary tumor development and growth retardation in children when compared with irradiation. As such, busulfan is also used to treat malignant and nonmalignant bone marrow disorders, such as (1) acute and chronic leukemias, (2) myelodysplastic syndromes, (3) β-thalassemia major, (4) polycythemia vera, (5) sickle cell anemia, (6) inborn errors of metabolism, and (7) severe immune deficiencies.

A well-accepted dosing paradigm for IV busulfan to replace the historical 1-mg/kg PO dosing consists of 0.8 mg/kg IV (adult) and 1.0 mg/kg IV (children), administered as a 2-hour infusion every 6 hours for 16 doses (4 days). Busulfan pharmacokinetics is affected by (1) age, (2) weight, (3) disease status, (4) hepatic function, and (5) drug interactions. T e optimal range of therapeutic area under the plasma concentration versus time curve (AUC) for standard dose busulfan is 900 to 1350 μmol•min/L. Patients with busulfan concentrations below the therapeutic range are thought to have increased risk of relapse as well as of rejection, even though the immunosuppressive capability of busulfan is controversial. Conversely, patients with plasma concentrations greater than 1500 μmol•min/L are at increased risk of severe treatment-related toxicity, such

as sinusoidal obstruction syndrome (SOS; previously called veno-occlusive disease of the liver) and oral mucositis.

Methotrexate

Methotrexate has proved useful in the management of (1) acute lymphoblastic leukemia, (2) choriocarcinoma, (3) elated trophoblastic tumors, and (4) various carcinomas, and in (5) maintenance of remission in leukemia and (6) treatment of severe psoriasis.

Methotrexate inhibits DNA synthesis and competitively inhibits the enzyme dihydrofolate reductase. T is decreases the concentrations of tetrahydrofolate essential for the methylation of the pyrimidine nucleotides and consequently the rate of pyrimidine nucleotide synthesis. Leucovorin, a folate analog, is used to rescue host cells from methotrexate inhibition and as a synthetic substrate for dihydrofolate reductase. Methotrexate is a nonspecific cytotoxin, and prolongation of blood concentrations appropriate to killing tumor cells may lead to severe, unwanted cytotoxic effects such as (1) myelosuppression, (2) gastrointestinal mucositis, and (3) hepatic cirrhosis.

Serum concentrations of methotrexate are commonly monitored during high-dose therapy (>50 mg/m^2) to identify the time at which active intervention by leucovorin rescue should be initiated. Criteria for serum concentrations indicative of potential for toxicity after single-bolus, high-dose therapy are as follows:

1. Methotrexate concentration greater than 10 μmol/L 24 hours after dose.
2. Methotrexate concentration greater than 1 μmol/L 48 hours after dose.
3. Methotrexate concentration greater than 0.1 μmol/L 72 hours after dose.

Characteristically, serum concentrations are monitored at 24, 48, and 72 hours after the single dose, and leucovorin is administered when methotrexate concentrations are inappropriately high for a postdose phase. T e route of elimination for methotrexate is primarily renal excretion. During the period of high serum concentrations, particular attention must be paid to maintaining output of a large volume of alkaline urine. T e pK_a of methotrexate is 5.5; thus small decreases in urine pH result in significant reduction in its solubility. Keeping urinary pH alkaline diminishes risks of intratubular precipitation of the drug and obstructive nephropathy during the treatment period. Monitoring serum concentrations therefore serves as the basis for decisions related to timing of initiation and continuance of leucovorin treatment and for management of urinary pH.

Cardioactive Drugs

T e major cardioactive drugs requiring TDM are the antiarrhythmic agents and the glycoside digoxin. For over a decade, use of these compounds has benefited from well-established monitoring guidelines that are still valid. However, prescription trends have shifted over time, resulting in less use of older, relatively difficult-to-manage drugs. Pharmacokinetic parameters of select cardioactive drugs are listed in Table 30-3.

Antiarrhythmic Agents

Arrhythmias are disturbances in normal cardiac sinus rhythm and are sometimes associated with substantial morbidity and mortality. Atrial fibrillation is the most common serious arrhythmia. Many antiarrhythmic drugs regulate cation channels (Na^+, K^+, or Ca^{2+}) and are associated with drug interactions and serious toxicity arising at concentrations only slightly above the upper limit of the therapeutic range.

Class I antiarrhythmics primarily affect sodium channel function. Class IA agents are moderate Na^+ channel blockers and include (1) quinidine (generic), (2) disopyramide (Norpace), and (3) procainamide (Pronestyl; monitored with its active metabolite, N-acetylprocainamide). Class IB agents are weak Na^+ channel blockers such as lidocaine (Xylocaine) and mexiletine (Mexitil); these agents are used in acute management of cardiac arrhythmia but are less frequently used as long-term therapy. Immunoassays are available for several class IA and IB agents, making TDM convenient for most providers. Serum concentrations are typically measured to ensure adequate therapy and to minimize toxicity.

Use of strong Na^+ channel blockers (class IC agents) has increased slowly over time, possibly in part because of their

TABLE 30-3 Pharmacokinetic Parameters of Cardioactive Drugs

Drug	Therapeutic Range,[13] mg/L*	Minimum Toxic Concentration, mg/L	Mean Half-life, h	Mean Volume of Distribution, L/kg	Mean Oral Bioavailability, %	Protein Binding, %	Enzymes Involved in Metabolism
Amiodarone	0.5-2	>2.5	45 days	60	45	99	CYP3A4, 2C8
Digoxin	0.5-2 μg/L	>3 μg/L	40	5	70	25	CYP3A4
Disopyramide	2-5	>7	8	0.6	83	65	CYP2D6, 3A4

Lidocaine	1.5-5	6	1.8	1.1	35	70	CYP2D6, 3A4, Pg
Mexiletine	0.5-2	>2	10	5	90	60	CYP2D6, 1A2
Procainamide	4-8	>10	6	1.9	83	20	NAT
N-acetylprocainamide	10-20	>40	8	NA	NA	NA	NA
Quinidine	2-5	>6	6	3	80	85	CYP3A4

NA, Data not available; NAT, N-acetyl transferase.
*Except where noted.

comparatively lower association with serious toxicity. Class IC agents include flecainide (Tambocor) and propafenone (Rythmol). Monitoring is typically performed with the use of chromatographic assays. TDM is recommended to prevent concentration-dependent toxicity (flecainide) and to ensure adequate concentrations after first-pass metabolism (propafenone).

Class III antiarrhythmics such as amiodarone (Cordarone) act primarily via K^+ channel blockade. Amiodarone is used to manage atrial fibrillation; it is less prone to inducing arrhythmia than many of the class I agents but is nonetheless associated with adverse events such as (1) pulmonary fibrosis, (2) hepatic failure (both uncommon, but serious), and (3) disruption of thyroid function (relatively common, but generally manageable). TDM for amiodarone should include measurement of its active metabolite, desethylamiodarone, although recommended therapeutic ranges tend to address only the parent drug.

Acceptance of TDM for antiarrhythmic agents is not universal, although the benefits of a robust program have been shown. Common situations that call strongly for the use of TDM include drug interactions and comorbidities such as renal failure.

Digoxin

Obtained from Digitalis plants such as foxglove, digoxin (Lanoxin) is a cardiac glycoside used in treatment of arrhythmias and heart failure. Cardiac glycosides are a group of related compounds found in a variety of plants, many of which are poisonous (e.g., oleandrin, the toxic component of oleander). Thus, digoxin use is accompanied by the risk of serious toxicity, necessitating TDM. Digoxin is thought to act through several mechanisms to (1) slow heart rate, (2) increase the strength and velocity of cardiac contraction, and (3) regulate the nervous (sympathetic) and endocrine (renin-angiotensin) systems. Digoxin use has declined but the drug is still prescribed, particularly in cases of congestive heart failure, for which it is successful in relieving symptoms, although without substantial improvement in mortality.

Serum digoxin concentrations are an unreliable predictor of efficacy. Digoxin distributes extensively into tissue over several hours after an administered dose. For this reason, TDM samples should be drawn at least 8 hours after the last dose; serum drawn earlier will provide elevated results that are not representative of the true serum concentration after distribution. Similarly, because of its long half-life, digoxin requires 8 to 10 days after a dose adjustment to reach steady state.

However, TDM is essential in assessing risk of digoxin toxicity, particularly in patients with suspicious symptoms. Certain populations (e.g., women, the elderly) are at increased risk for elevated digoxin concentrations and thus toxicity, which begins with nonspecific effects (nausea, vomiting, anorexia) but can progress to severe, potentially lethal cardiac manifestations. Patients with electrolyte imbalances (high calcium, low magnesium, or low potassium) or with renal dysfunction are predisposed to developing toxicity, even at digoxin concentrations within the therapeutic window. Digoxin-binding antibodies are available to treat toxicity by sequestering the drug and preventing its physiological effects. The antidote-bound drug remains in serum for some time after treatment and is detectable in assays measuring total digoxin concentrations. The active fraction (i.e., that which is not bound to antibody) is determined by measuring free digoxin concentrations.

Immunosuppressants

Immunosuppressants (drugs capable of suppressing immune responses) are used to treat (1) autoimmune disease, (2) allergies, (3) multiple myeloma, (4) other cancers, and (5) chronic nephritis, and (most important) (6) to prevent rejection in organ or bone marrow transplantation. Therapeutic ranges and toxic thresholds are proposed and are widely used to optimize dosing of these drugs. TDM is important for optimizing immunosuppressant therapy because serious consequences of underdosing (e.g., graft rejection) and overdosing (e.g., risk of opportunistic infection) are known. TDM also prevents drug-related toxicity (e.g., kidney damage) and is used to evaluate compliance.

Drug regimens used today vary widely according to the transplanted organ type and the specific clinical scenario. All immunosuppressant drugs have narrow therapeutic indices, and their pharmacokinetics is highly variable in transplant patients, particularly in the early post-transplant period. Frequent (sometimes daily) monitoring during the early post-transplant stage of therapy requires rapid response from the laboratory until a stable therapeutic dosing strategy is established. TDM support during the maintenance stage of therapy, often a few weeks post-transplant and potentially lifelong afterward, remains important but is often provided only periodically to verify compliance, to respond to anticipated changes in pharmacokinetics, or as otherwise indicated clinically. Consensus guidelines and position papers regarding immunosuppression and TDM methods and application are available.

Interest in application of LC-MS/MS methods to immunosuppressive TDM is prominent because of increased analytical sensitivity and specificity compared with common immunoassay methods, and as a result of multianalyte capabilities. Note that, because of metabolite cross-reactivity of the detection antibodies on which commercially available immunoassays are based, therapeutic ranges for immunosuppressant drugs may vary with the analytical technique. Values obtained by immunoassay may be 20% to 60% higher than those obtained by chromatographic techniques such as HPLC or LC-MS/MS. The therapeutic ranges and toxic thresholds provided within this chapter are intended to serve as general guidelines but should not be applied to clinical practice without consideration of the analytical technique used and the circumstances surrounding the patient, such as (1) clinical indication, (2) clinical status of the patient, (3) time post-transplant (for tissue or organ transplant recipients), (4) time of specimen collection relative to drug administration, and (5) comedications. In general, therapeutic ranges are higher in the immediate post-transplant period (0 to 3 months) and are lower during maintenance therapy. They may also be lower for combination

therapies and specialized protocols, such as those designed to minimize calcineurin inhibitors.

Discussion here will focus on the common immunosuppressants currently monitored clinically to support initiation and maintenance of immunosuppression in solid organ and bone marrow transplant patients. These include (1) two calcineurin inhibitors (cyclosporine, tacrolimus), (2) an inosine-5′-monophosphate dehydrogenase (IMPDH) inhibitor (mycophenolate mofetil), and (3) two mammalian target of rapamycin (mTOR) inhibitors (sirolimus and everolimus). Pharmacokinetic parameters for immunosuppressants are summarized in Table 30-4.

Calcineurin Inhibitors

Calcineurin inhibitors discussed next include cyclosporine and tacrolimus.

Cyclosporine

Cyclosporine is a fat-soluble cyclical peptide composed of 11 amino acids, some of novel structure, isolated from the fungus Trichoderma polysporum. It is available in many formulations and brand names (e.g., Sandimmune, Neoral). Cyclosporine is considered a calcineurin inhibitor, but it provides **immunosuppression** by blocking the activation of T lymphocytes via a multifaceted mechanism. Cyclosporine formulations are not bioequivalent and cannot be used interchangeably. All formulations are considered to have erratic and incomplete absorption after oral administration, ranging from 5% to 60%, and averaging 30%. Peak concentrations are 1 to 6 hours after oral administration. Cyclosporine undergoes extensive metabolism mediated by CYP3A4. The combination of variable expression of CYP3A4 and the associated multidrug efflux pump known as P-glycoprotein in the small intestine is thought to form a natural barrier to the absorption of cyclosporine after oral administration, and it is thought to explain much of the extensive interpatient range of bioavailability. Because many other drugs are substrates for these two systems, the gastrointestinal tract is an important site for drug-drug interactions. Elimination of cyclosporine is biphasic and is primarily biliary. Terminal half-life is variable with formulation and patient, ranging from 5 to 27 hours.

TDM for cyclosporine is best performed with whole blood. The degree of concentration in erythrocytes is temperature dependent in vitro. Consequently, measurement of plasma concentration is not recommended. Conventional therapeutic concentrations of cyclosporine for renal transplants are 150 to 300 µg/L immediately post-transplant, and 100 to 200 µg/L thereafter. Efforts to minimize toxicity have led to evaluation of lower cyclosporine target ranges, such as 50 to 100 µg/L. Rates of acute rejection have not been different with low-dose versus conventional dosing. Higher target concentrations are commonly used for (1) cardiac, (2) hepatic, and (3) pancreatic transplants.

Tacrolimus

Tacrolimus (Prograf, formerly known as FK506) is a macrolide lactone isolated from Streptomyces tsukubaensis. It is is considered a calcineurin inhibitor that acts by blocking T-lymphocyte function. Tacrolimus is administered in much lower doses than cyclosporine because of its substantially higher potency.

Absorption from the small intestine is generally low, averaging 25%, but is highly variable from patient to patient and with time post-transplant. Low tacrolimus bioavailability, as with cyclosporine, is thought to be due to the presence of CYP3A4 and P-glycoprotein in the small intestinal enterocytes. Peak concentrations are observed 0.5 to 4 hours after administration. The elimination half-life of tacrolimus is variable, averaging 8 to 12 hours, but has been known to range from 4 to 41 hours. As with cyclosporine, CYP3A4 (coupled to P-glycoprotein) is primarily responsible for tacrolimus metabolism; nine metabolites have been identified, including one active metabolite—31-O-desmethyl tacrolimus. This metabolite is generally present at very low concentrations and therefore is negligible in most patients. Most TDM for tacrolimus occurs with single predose blood samples, and, as with cyclosporine, whole blood is the preferred specimen. The originally proposed therapeutic range for tacrolimus was 5 to 20 µg/L, although efficacy has been demonstrated at lower

TABLE 30-4 Pharmacokinetic Parameters of Immunosuppressant Drugs

Drug[2,3,7,8,11]	Minimum Effective Concentration, MEC, µg/L	Minimum Toxic Concentration, MTC*, µg/L	Average Half-life, h	Average Volume of Distribution, L/kg	Average Oral Bioavailability, %	Average Protein Binding, %	Important Metabolizing Enzymes
Cyclosporin A†	50	350*	8.4	3-5	30	90	CYP 3A4, Pg
Everolimus	3	15*	24	NA	16	74	CYP 3A4, Pg
Mycophenolic acid	1.3 mg/L	12 mg/L	18	4	94	97	UGT
Sirolimus	4	20*	62	12	10	90	CYP 3A4, Pg
Tacrolimus	3	20*	21	0.85	15	85	CYP 3A4, Pg

*Trough (predose) concentrations. The minimum effective and toxic concentrations are intended to provide general guidelines but should not be applied to clinical practice without consideration of the analytical technique used, the clinical indication, the clinical status of the patient, time post-transplant (for tissue or organ transplant recipients), time of specimen collection relative to drug administration, and comedications. In general, therapeutic ranges are higher in the immediate post-transplant period (0-3 months) and lower during maintenance therapy. They may also be lower for combination therapies and specialized protocols.

NA, Data not available; Pg, P-glycoprotein; UGT, uridine diphosphate glucuronosyltransferase.

concentrations, particularly for protocols designed to minimize renal toxicity by lowering concentrations of calcineurin inhibitors. The European Consensus Conference of 2007 recommended that laboratories seek methods with lower limits of quantification of 1 µg/L or less to support sparing protocols that lower and narrow the therapeutic range to 3 to 7 µg/L.

IMPDH Inhibitor: Mycophenolate Mofetil

Mycophenolate mofetil (MMF) (CellCept, Myfortic) is the ester prodrug form of the active immunosuppressant mycophenolic acid (MPA). It is derived from a fermentation product of several Penicillium species. MPA is a reversible and uncompetitive inhibitor of IMPDH. T-cell proliferation is arrested by the suppression of guanine nucleotide production when IMPDH is inhibited by MPA

MMF has near complete bioavailability after oral administration and is rapidly hydrolyzed by widely distributed esterases in blood and tissues to produce MPA. MPA usually reaches maximal concentrations within an hour of oral administration of MMF. Clearance of MPA is affected by glucuronidation and enterohepatic circulation. The appearance of a secondary MPA concentration peak anywhere from 4 to 12 hours after the morning dose of MMF is believed to result from enterohepatic circulation, which is inhibited by coadministration of cyclosporine. MPA forms mycophenolic acid glucuronide (MPAG) and is cleared by the kidney. MPAG accumulates to several hundred–fold higher plasma concentrations than MPA in uremic patients.

The specimen of choice for TDM of MPA is plasma or serum. A well-accepted therapeutic range for predose MPA is 1.0 to 3.5 mg/L when combined with cyclosporine, and 1.9 to 4.0 mg/L when combined with tacrolimus. It has been shown that MMF becomes hydrolyzed in vitro, which may lead to determinations that overestimate the proportion of active MPA if specimen is collected too soon after administration of MMF. Of note, a functional method that uses IMPDH, the natural target receptor of MPA, is available. Inhibition of IMPDH activity by MPA in an aliquot of patient serum or plasma is the basis for this method.

mTOR Inhibitors

Examples of mTOR inhibitors include sirolimus and Everolimus.

Sirolimus

Sirolimus (Rapamune, formerly known as rapamycin) is a lipophilic macrocyclic lactone composed of a 31-member macrolide ring. Sirolimus inhibits T-lymphocyte activation and proliferation by inhibiting the mTOR through a mechanism of action unique from calcineurin or IMPDH inhibitors. Briefly, the complex of sirolimus and the intracellular immunophilin FK-BP12 inhibits the specific cell cycle regulatory protein mTOR, preventing cell cycle progression from the G_1 to the S phase.

Formulations of sirolimus are not bioequivalent. Sirolimus is rapidly absorbed from the gastrointestinal tract but has average bioavailability of 15%. As with calcineurin inhibitors, the low bioavailability is attributable to extensive intestinal and hepatic metabolism by CYP3A4 and to countertransport by the multidrug efflux pump P-glycoprotein in the gastrointestinal tract. Metabolism of sirolimus by the human body is driven by CYP3A4, and at least seven metabolites are characterized, which are pharmacologically inactive.

The specimen of choice for sirolimus TDM is whole blood. In practice, an accepted range is 4 to 12 µg/L when sirolimus is used in conjunction with cyclosporine and corticosteroids. Alternative ranges proposed include 5 to 10 µg/L when sirolimus is combined with MMF and corticosteroids, and 12 to 20 µg/L when used with just corticosteroids.

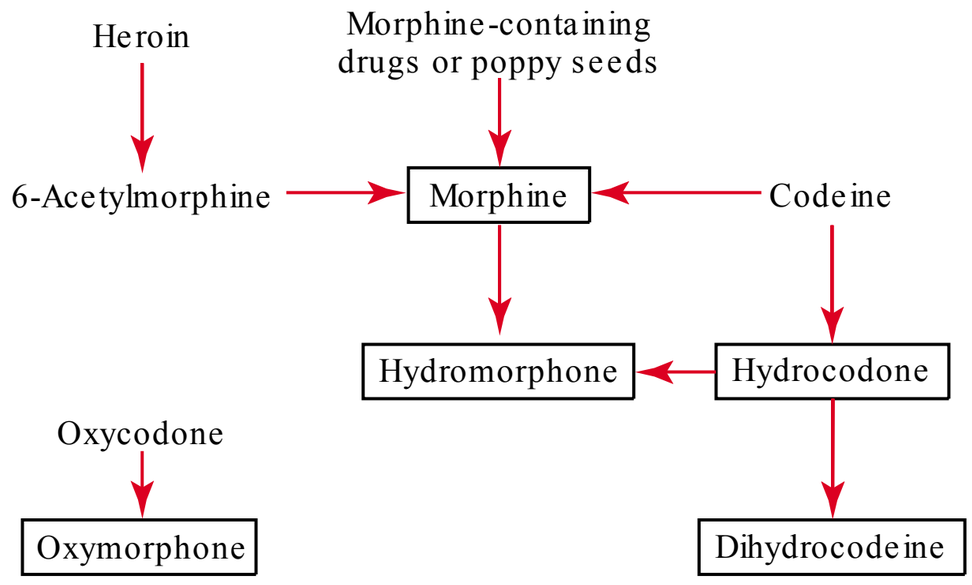
Everolimus

Everolimus (Zortress) is a structural analog of sirolimus with potent immunosuppressive and antitumor activity; it has the same mechanism of action as sirolimus. Everolimus for immunosuppression is typically used in conjunction with cyclosporine. The primary difference between everolimus and sirolimus is the half-life (approximately 32 hours), which is approximately half that of sirolimus (approximately 62 hours), theoretically leading to more rapid attainment of steady-state concentrations.

Everolimus is rapidly absorbed from the gastrointestinal tract, with average time to reach maximal concentration in whole blood of about 3 hours. Low bioavailability (≈30%) is explained by CYP3A4 and P-glycoprotein in the gastrointestinal tract. Cyclosporine inhibits the metabolism of everolimus, requiring everolimus dose reduction when coadministered. Everolimus does not affect cyclosporine metabolism. The primary side effects of concern with everolimus therapy are hyperlipidemia and thrombocytopenia at concentrations >8 µg/L.

The current specimen of choice for supporting TDM of everolimus is predose whole blood, and for kidney transplant patients comedicated with cyclosporine, the target therapeutic range is 3 to 8 µg/L.

Pain Management



Chronic noncancer pain affects approximately one in three Americans during their lifetime and is the leading cause of health-related absenteeism. Escalating medical costs and lost productivity, as well as increased risk of depressive and anxiety disorders associated with chronic pain, have created a tremendous social burden. Pharmacological management of pain involves mechanistically diverse drugs, including (1) antiepileptics, (2) tricyclic antidepressants, (3) muscle relaxants, (4) benzodiazepines, (5) anesthetics, and (6) opioids. Therapeutic ranges for these drugs in the management of pain have not been established, but compliance with prescribed therapy is often evaluated by random urine drug testing. Of particular interest is detection of compliance with opioid therapy because (1) safety concerns, (2) risk of drug diversion, (3) risk of drug abuse, and (4) tolerance to the analgesic properties of these drugs sometimes require dramatic escalation in dosing for continued efficacy. Detection of nonprescribed opioids and classical drugs of abuse (e.g., marijuana, cocaine,

amphetamines) is another objective of **drug monitoring** in this population. However, conventional drugs of abuse tests designed for occupational or forensic purposes may not meet the needs of medical testing because conventional tests have relatively high cutoff concentrations and may not detect drugs of interest such as oxycodone and methadone.

Opioids

Drugs that produce analgesia through interaction with opioid receptors found in the central nervous system are referred to as opioids. Opioids include (1) opiates—those drugs derived naturally from the opium poppy plant (e.g., codeine, morphine), (2) semi-synthetic opiates (e.g., hydromorphone, hydrocodone, oxycodone, oxymorphone, heroin), and (3) fully synthetic opioids (e.g., fentanyl, methadone, tramadol, propoxyphene, buprenorphine, meperidine). T ese drugs are widely used to manage chronic pain and are commonly monitored in urine to detect (1) compliance, (2) diversion, and (3) use of nonprescribed opioids.

Laboratories that provide testing for opioids to verify compliance must recognize that common immunoassays for opiates do not detect all opioids and may have inadequate sensitivity for testing with random urine specimens. Other factors to be evaluated include (1) concentrations of various opioids relative to prescribed doses, (2) individual drug pharmacokinetics, (3) dosing intervals, and (4) consideration of complex metabolism. Figure 30-8 depicts the complexity of opioid metabolism.

Note: Drugs shown in boxes could be parent drug or metabolite of another drug.

Figure 30-8 Opiate metabolism. Metabolic relationships between several of the major natural and semisynthetic opiates are shown. Drugs that appear in boxes could be present in patient specimens as a result of administration of that compound (i.e., parent drug) or as a metabolic product resulting from administration of a related agent.

Psychiatric Therapies

Psychiatry is one area of clinical practice that has welcomed the use of TDM. T erapy in psychiatric illness fits many of the criteria for monitoring. For example, (1) treatment is usually long term; (2) efficacy is difficult to assess from clinical indicators alone; and (3) the toxicity of many psychoactive drugs is concentration dependent and preventable. Compliance rates are often lower in mental disorders than in nonpsychological illnesses, supporting the rationale for measuring psychotropic drug concentrations.

Antidepressants

Antidepressants are commonly used to treat a variety of psychological and mood-related conditions, such as (1) depression, (2) anxiety disorders, (3) obsessive-compulsive behavior, (4) eating disorders, (5) substance abuse, (6) insomnia, and (7) chronic pain. T eir primary mechanism for activity is thought to be modulation of catecholamine neurotransmitters such as (1) serotonin, (2) norepinephrine, and (3) dopamine in the central nervous system. Published guidelines strongly recommend TDM for several tricyclic antidepressants (TCAs) because of the correlation between serum concentration and response, especially toxicity. TDM of other antidepressants is also useful in (1) evaluating individual pharmacokinetics, (2) assessing compliance, (3) managing comedication, and (4) caring for patients with renal or hepatic disease. Pharmacological parameters of antidepressants are shown in Table 30-5.

Tricyclic Antidepressants

TCAs represent one of the first drug classes available to treat depression. Strong evidence supports the utility of monitoring serum TCA concentrations to improve patient management and reduce toxicity. Common TCAs include (1) amitriptyline (many proprietary names, e.g., Elavil), (2) clomipramine (Anafranil), (3) desipramine (Norpramin), (4) imipramine (Tofranil), and (5) nortriptyline (Aventyl, Pamelor).

Of note, several TCAs, including (1) amitriptyline (active metabolite/nortriptyline), (2) clomipramine (active metabolite/norclomipramine), and (3) imipramine (active metabolite/desipramine), are metabolized into compounds with comparable pharmacological activity that must be included in TDM measurements. TCAs generally show an initial positive correlation between increasing serum concentration and clinical improvement; however, they exhibit a threshold concentration past which clinical progress may decline because of return of symptoms (e.g., mood worsening) or development of toxicity. Adverse responses to TCA excess include (1) dry mouth, (2) fever, (3) urinary retention, (4) agitation, (5) confusion, and (6) seizures. Additional cardiovascular complications include hypotension and electrocardiographic changes (QRS widening) that are characteristic of TCA overdose. Serum concentrations correlate with the risk of toxicity but are poor predictors of cardiovascular change or seizures.

Combination of TCAs with other regulators of monoamine neurotransmitters creates the potential for serotonin toxicity, characterized by increased synaptic serotonin, which leads to (1) neuromuscular hyperactivity, (2) fever, (3) tachycardia, (4) tachypnea, and (5) agitation. Severe toxicity is capable of producing (1) dangerously high fever (>38.5 °C), (2) confusion, (3) seizures, and (4) death. Numerous compounds regulate serotonin concentrations, including (1) antidepressants, (2) antipsychotics, (3) anti-Parkinson agents, (4) migraine therapies, and (5) several drugs of abuse such as MDMA (3,4-methylenedioxymethamphetamine; Ecstasy), amphetamine, and cocaine. Overdose of a single agent or use of more than one of these drugs increases the risk of serotonin toxicity.

TABLE 30-5 Pharmacokinetic Parameters of Antidepressants and Antipsychotics

Drug	Recommended[6] Therapeutic Range, µg/L*	Minimum Toxic Concentration, µg/L	Mean Half-life, h	Volume of Distribution, L/kg	Oral Bioavailability, %	Protein Binding, %	CYP Enzymes Involved in Metabolism

NA, Not available.

Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) are second-generation antidepressants whose primary activity is modulation of synaptic serotonin concentrations. In general, they are less toxic than older antidepressants, although serotonin toxicity is a greater potential risk for SSRIs than for most other drugs. SSRIs include (1) citalopram (Celexa), (2) escitalopram (S-citalopram; Lexapro), (3) fluoxetine (Prozac, Sarafem), (4) fluvoxamine (Luvox), (5) paroxetine (Paxil), and (6) sertraline (Zoloft). Many other compounds are nonselective regulators of serotonin but are not strictly considered SSRIs.

Most SSRIs are substrates for multiple CYP enzymes, and several such as fluoxetine and citalopram are CYP inhibitors, resulting in (1) complex metabolism, (2) significant risk for drug-drug interactions, and (3) wide interindividual variability in serum concentrations at a given dose of drug. The usefulness of TDM is less well established for SSRIs than for TCAs because the correlation among serum concentrations, response, and toxicity is weaker. TDM is largely used to assess compliance; this saves costs by preventing hospitalizations and time away from work due to relapse, or by guiding dose adjustment in select populations such as the elderly.

Other Antidepressants

Several other classes of antidepressants are available, including serotonin-norepinephrine reuptake inhibitors (SNRIs)

such as (1) venlafaxine (Effexor) and (2) duloxetine (Cymbalta) and (3) catecholamine receptor antagonists (e.g., trazodone [Desyrel]). Older antidepressants include monoamine oxidase (MAO) inhibitors and tetracyclic antidepressants, which have fallen in popularity with the availability of better tolerated alternatives. TDM for these drugs is less common; when it occurs, primary clinical uses include (1) assessing nonresponders, (2) confirming compliance, and (3) managing comorbidities (e.g., renal or hepatic dysfunction).

Neuroleptic Agents

Neuroleptics are used to treat patients with mental illness involving a psychotic component such as schizophrenia and bipolar disorder, as well as other neurological conditions such as Tourette's syndrome. Most antipsychotics are antagonists or partial agonists of D_2-like dopamine receptors. Several have numerous metabolites, but with one exception (risperidone), current guidelines do not include active metabolites in TDM interpretation.

Classical Antipsychotics

Older antipsychotic agents (called classical or atypical antipsychotics) successfully treat the "positive" aspects of psychotic disorders, including hallucinations and delusions, but are less effective in managing "negative" aspects such as social withdrawal. Many of these agents induce (1) severe cardiac toxicity, (2) prolactin elevation, and (3) involuntary motor activity such as tardive dyskinesia (uncontrollable repetition of purposeless facial motions). They are associated with a rare but potentially fatal condition, neuroleptic malignant syndrome, which is characterized by (1) muscle rigidity, (2) fever, (3) unstable blood pressure, and (4) poor mental status. Risk of this syndrome may be increased with concomitant SSRI use.

Consensus guidelines recommend TDM of haloperidol (Haldol) and several phenothiazines such as (1) fluphenazine (Permitil, Prolixin), (2) perazine (not available in the United States), (3) perphenazine (Trilafon), and (4) thioridazine (Mellaril). Evidence suggests that TDM is best used for optimizing quality of life when concentration-dependent effects such as seizures and tardive dyskinesia are reduced by maintaining patients at the minimum effective concentration for clinical response. Life-threatening adverse responses (e.g., neuroleptic malignant syndrome) are generally unrelated to serum concentration.

Atypical Antipsychotics

Newer antipsychotics are often called atypical antipsychotics, although this nomenclature is somewhat deceiving, given that the mechanism of both classes of drugs is modulation of dopamine receptors. However, atypical antipsychotics have less effect on areas of the brain involved in motor control, leading to reduced incidence of extrapyramidal effects such as tardive dyskinesia. Atypical antipsychotics that are strongly recommended for routine TDM include (1) clozapine (Clozaril), (2) olanzapine (Zyprexa), and (3) amisulpride (not available in the United States), although some studies show promise for monitoring other drugs in the class.

Clozapine is one of the oldest and most toxic atypical antipsychotics. Its adverse effects include several potentially fatal conditions such as severe myocarditis (particularly at the start of therapy), seizures, and agranulocytosis; this last necessitates monitoring of white blood cell counts throughout treatment. Most newer atypical antipsychotics show better safety profiles, although several atypical agents are metabolized by CYP isoforms, and this creates the potential for drug interactions.

Lithium

The monovalent cation lithium (Eskalith, Lithobid) has long been used as a mood-stabilizing agent in the treatment of bipolar disorder and other conditions with a manic component. Lithium exhibits a narrow therapeutic window, with toxic concentrations (>1.5 mmol/L) very near the upper threshold for effective therapy (up to 1.2 mmol/L). The severity of toxicity is concentration related. Early signs include (1) lethargy, (2) muscle weakness, (3) tremors, and (4) speech difficulties. Concentrations greater than 2.5 mmol/L produce signs of severe intoxication, including muscle rigidity and life-threatening seizures.

Bronchodilators

Drugs used as bronchodilators include the β-adrenergic agonists, theophylline and caffeine. These two agents, although not used extensively, may be monitored to benefit management of neonatal apnea.

Theophylline

Theophylline is used primarily to treat persistent asthma and neonatal apnea. The therapeutic effect is likely due to antagonism of adenosine receptors in smooth muscle, whereas the toxic effects are due to inhibition of cyclical nucleotide phosphodiesterase.

Theophylline is readily absorbed, and the blood concentration peaks within 2 hours. If it is administered with food or as the slow-release formula, peak concentrations occur 3 to 5 hours after the dose is given. Once absorbed, it is 50% protein bound. Theophylline is metabolized by CYP1A2. Nonsmoking adults in good health have an elimination half-life averaging 9 hours, and it is 3 to 4 hours in smokers. The half-life in neonates is 20 to 30 hours, depending on the degree of liver immaturity or loss of liver function.

At serum concentrations greater than 20 mg/mL, small dose increases lead to disproportionately large increases in serum concentration and intoxication. Symptoms of theophylline toxicity include (1) nausea, (2) vomiting, (3) headache, (4) diarrhea, (5) irritability, and (6) insomnia. Serious toxicity characterized by cardiac arrhythmias and seizures is usually associated with serum concentrations in excess of 30 mg/mL. TDM for theophylline in neonates should also include caffeine.

Caffeine

A minor metabolite of theophylline in adults, caffeine has been shown to accumulate to significant concentrations in

neonates. Therapy with caffeine alone has been demonstrated to be as effective in the treatment of neonatal apnea as theophylline; caffeine is gaining popularity because of its long half-life in neonates (>30 hours). Caffeine is metabolized by CYP1A2. The optimal therapeutic concentration of caffeine ranges from 8 to 14 mg/mL.

Review Questions

1. The interaction between a drug and its receptors or other target molecules involved in physiological processes, in addition to the consequences of this interaction, is referred to as a drug's:
   a. therapeutic index.
   b. peak and trough concentrations.
   c. mechanism of action.
   d. volume of distribution.
2. A category of therapeutic drug that must be closely monitored because of the serious consequences of underdosing, which might lead to graft rejection, is:
   a. antiarrhythmics.
   b. bronchodilators.
   c. antineoplastics.
   d. immunosuppressants.
3. A glycopeptide antibiotic antimicrobial agent that has activity against methicillin-resistant Staphylococcus aureus is:
   a. vancomycin.
   b. gentamicin.
   c. triazole.
   d. busulfan.
4. The type of therapeutic drug that is inactive when taken and that requires metabolism by the body before it exerts its physiological effect is referred to as a(n):
   a. toxic drug.
   b. immunosuppressant.
   c. prodrug.
   d. free drug.
5. Disorders that affect the synthesis of drug transport proteins alter which component of drug disposition?
   a. Absorption
   b. Distribution
   c. Metabolism
   d. Elimination
6. The amount of body fluid in liters required to dissolve the total amount of drug required to achieve a specific concentration in blood is referred to as:
   a. bioavailability.
   b. pharmacokinetics.
   c. steady-state level.
   d. volume of distribution.
7. The drug group that functions to inhibit DNA synthesis and stop cell division is the:
   a. immunosuppressant group.
   b. antimetabolite group.
   c. antiarrhythmic group.
   d. anticonvulsive group.
8. Pharmacokinetics describes the:
   a. half-life curve.
   b. concentration of drug at its sites of action.
   c. blood concentration of a drug over time.
   d. relationship between blood and tissue drug levels.
9. When would a blood sample be collected to determine the trough level of a drug?
   a. Immediately before the next scheduled dose
   b. Immediately after the dose is given
   c. Two hours after the dose is given
   d. Trough levels cannot be determined.
10. When the amount of a drug in the body is in balance between administration and elimination, it is said to be at:
    a. its bioavailability phase.
    b. normal distribution.
    c. phase 1 metabolism.
    d. steady state.

CHAPTER

31

Clinical Toxicology*†

Loralie Langman, Ph.D., Laura K. Bechtel, Ph.D., and Chris Holstege, M.D.

Objectives

1. Define the following terms:
   - Anion gap
   - Confirmatory test
   - Osmol gap
   - Screening test
   - Spot test
   - Sympathomimetic
   - Toxicology
   - Toxidrome
2. State and explain the formulas for calculating anion gap and osmol gap; given appropriate information, calculate and interpret the results of these formulas and list possible interferences with these calculated measurements.
3. For each of the following cellular hypoxia causative agents, describe the agent, the toxic effects, the treatment, and the method(s) of analysis, including specimen requirements and laboratory results, for each:
   - Carbon monoxide
   - Cyanide
   - Methemoglobin-forming agents
4. For each of the following alcohols, describe the pharmacological action, the metabolites, the antidote, and the method(s) of analysis, including specimen requirements and laboratory results, for each:
   - Ethanol
   - Ethylene glycol
   - Isopropanol
   - Methanol
5. For each of the following analgesics, describe the toxic effects of overdose, the dose and time of symptom onset, the metabolizing enzyme and metabolite, the antidote, and the method(s) of analysis, including specimen requirements and laboratory results, for each:
   - Acetaminophen
   - Salicylate
6. For the following cholinergic/anticholinergic toxidrome agents, describe the clinical uses if any, the mechanism of action, the metabolites, the methods of analysis, and the laboratory results for each:
   - Antihistamines
   - Antimuscarinics
   - Antipsychotics
   - Organophosphates/carbamates
   - Tricyclic antidepressants
7. For the following drugs, describe the manifestations of intoxication, the metabolizing enzyme and metabolite, the pharmacological response, clinical uses if any, the antidote, and the screening tests and confirmatory methods for each:
   - Amphetamines/methamphetamines
   - Barbiturates
   - Benzodiazepines
   - Cannabinoid
   - Cocaine
   - Marijuana
   - Opioids
   - Phencyclidine
   - Synthetic opioids
8. List and describe five drugs used in drug-facilitated sexual assault, including drug classification, pharmacological effects, and methods of analysis.
9. For the following specimen types, state the advantages and disadvantages of each when used for drug analysis, and list a method of analysis for each:
   - Hair
   - Meconium
   - Saliva (oral fluid)
   - Sweat
10. Evaluate and analyze case studies related to clinical toxicology and toxic drug analysis.

Key Words and Definitions

Amphetamine A sympathomimetic amine that has a stimulating effect on the central and peripheral nervous systems.

Analgesics Agents that relieve pain without causing loss of consciousness.

Anticholinergic agent An agent that opposes the effects of impulses conveyed by adrenergic postganglionic fibers.

Antihistamines Antagonists of the H_1 or H_2 histamine receptors that are used to treat allergic reactions or gastric hyperacidity.

*The authors gratefully acknowledge the original contributions of William H. Porter, on which portions of this chapter are based.

†A more extensive review of the subject and additional references are found in: Langman LJ, Bechtel L, Holstege CP. Clinical toxicology (Chapter 35). In: Burtis CA, Ashwood ER, Bruns DE, eds. Tietz textbook of clinical chemistry and molecular diagnostics. St Louis: Elsevier, 2012:1109-88.

Key Words and Definitions—cont'd

Barbiturate Any of a class of sedative-hypnotic agents derived from barbituric acid or thiobarbituric acid and classified into long-, intermediate-, short-, and ultrashort-acting classes.

Benzodiazepines Any of a group of minor tranquilizers that have a common molecular structure and similar pharmacological activity, including antianxiety, sedative, hypnotic, amnestic, anticonvulsant, and muscle-relaxing effects.

Bezoar A concretion of foreign material found in the gastrointestinal tract or urinary tract.

Cholinergic toxidrome A toxidrome that represents the acute phase of cholinesterase inhibitor poisoning.

Clinical toxicology A subdivision of toxicology that involves the analysis of drugs, heavy metals, and other chemical agents in body fluids and tissues for the purpose of patient care.

Cocaine A crystalline alkaloid, obtained from leaves of Erythroxylon coca (coca leaves) and other Erythroxylon species, or by synthesis from ecgonine or its derivatives.

Confirmatory testing As used in programs that test for drugs of abuse, confirmatory tests are used to confirm a positive or sometimes negative result that had been presumptively classified as positive for a specific drug.

Crack cocaine The freebase form of cocaine that can be smoked.

Diuresis Increased excretion of urine.

Drug-facilitated sexual assault (DFSA) The use of (1) alcohol, (2) drugs, and/or (3) chemical agents to incapacitate an individual and facilitate sexual assault.

Drugs of abuse Drugs that are repeatedly and deliberately used in a way other than prescribed or socially sanctioned (i.e., a drug that is taken for nonmedicinal reasons).

Drug half-life ($t_{1/2}$) The length of time it takes for one-half of an administered drug to decrease due to a biological processes.

Enantiomer A molecule that exhibits stereoisomerism through the presence of one or more chiral centers (i.e., stereoisomers that are nonsuperimposable mirror images).

Ethylene glycol An ethylene compound with two hydroxy groups located on adjacent carbons. It is a common ingredient in antifreeze and is highly toxic if ingested.

Gamma-hydroxybutyric acid (GHB) A potent sedative, hypnotic, euphorigenic agent that is illicitly ingested for its pleasurable effects.

Intoxication A state of impaired mental or physical functioning resulting from ingestion of alcohol or drug.

Lysergic acid diethylamide (LSD) A derivative of an alkaloid found in certain fungi that has hallucinogenic properties.

Marijuana A crude preparation of the leaves and flowering tops of (male or female plants) Cannabis sativa, usually used in cigarettes and inhaled as smoke for its euphoric properties.

MDA (3,4-methylenedioxyamphetamine) A psychedelic drug of the phenethylamine and amphetamine classes of drugs.

MDMA (3,4-methylenedioxy-N-methylamphetamine) A drug of the phenethylamine and amphetamine classes of drugs. Known as "ecstasy."

Methadone A synthetic opioid analgesic, possessing pharmacologic actions similar to those of morphine and heroin and similar potential for addiction; used as an analgesic and as a narcotic abstinence syndrome suppressant in the treatment of heroin addiction.

Methamphetamine (Ritalin) A sympathomimetic amine closely related chemically to both amphetamine and ephedrine, having actions similar to those of amphetamine.

Methylphenidate (MPH) A central stimulant used in the treatment of attention-deficit/hyperactivity disorder, narcolepsy, and certain forms of depression.

Miosis Constriction of the pupil of the eye, resulting from a normal response to an increase in light or caused by certain drugs or pathological conditions.

Mnemonics A mnemonic or mnemonic device is any learning technique that aids information retention.

Opiate/Opioid Opiate refers to any of a group of naturally occurring (poppy plant) or semi-synthetic narcotic alkaloids with pharmacological actions and chemical structure similar to morphine. Opioid is a general term that is applied to all substances with morphine-like properties, regardless of origin or chemical structure.

Phencyclidine A potent veterinary analgesic and anesthetic, sometimes used as a drug of abuse by humans but capable of causing serious psychological disturbances.

Poison Any substance that, when relatively small amounts are ingested, inhaled, or absorbed, or when it is applied to, injected into, or developed within the body, has chemical action that may cause damage to structure or disturbance of function, producing symptoms, illness, or death.

Screening test An initial test, such as an immunoassay or a TLC, that is used to "screen" urine specimens to eliminate "negative" ones from further consideration and to identify presumptively positive specimens that then require confirmatory testing.

Sedative A drug that depresses activity of the central nervous system and reduces anxiety and induces sleep.

Toxidrome A syndrome caused by a dangerous concentration of toxins in the body.

Toxins Poisonous substances that are produced by living cells or organisms and is capable of causing disease when introduced into the body tissues and is often capable of inducing neutralizing antibodies or antitoxins.

Toxicology is a broad, multidisciplinary science whose goal is to determine the effects of chemical agents on living systems. Innumerable potential **toxins** inflict harm, including (1) pharmaceuticals, (2) herbals, (3) household products, (4) environmental agents, (5) occupational chemicals, (6) **drugs of abuse**, (7) drugs used in sexual attacks, and (8) drugs used by athletes for their performance-enhancing effects. Each year, millions of human exposure cases are reported to the American Association of **Poison** Control Centers. The Centers for Disease Control and Prevention has reported that poisoning (both intentional and unintentional) is one of the top 10 causes of injury-related death in the United States in all adult age groups.

This chapter provides a general overview of **clinical toxicology** and the laboratory services necessary to support the care of poisoned patients. Because a comprehensive discussion of all aspects of toxicology is beyond the scope of this chapter, the clinical significance and toxicity of only a select number of (1) common drugs, (2) drugs of abuse, and (3) other chemicals are discussed.

Basic Information

In practice, it is neither possible nor necessary to test for all of the hundreds or thousands of clinical toxins that may be encountered. In reality, up to 24 drugs or agents account for 80% or more of cases of **intoxication** treated in most emergency departments. The scope of clinical toxicology testing provided by the laboratory depends on the pattern of local drug use and on the available resources of the institution.

The value of drug and/or substance testing is well established (1) in the workplace, (2) for some athletic competitions, (3) to monitor drug use during pregnancy, (4) to evaluate drug exposure and/or withdrawal in newborns, (5) to monitor patients in pain management and drug abuse treatment programs, and (6) to aid in the prompt diagnosis of toxicity for a number of commonly encountered drugs or agents for which a specific antidote or treatment modality is required (Table 31-1). In many other instances of drug toxicity, the value of drug testing, especially on an emergency basis, is controversial.[13]

Clinical Considerations

To operate effectively, the laboratory should be closely associated with the healthcare team that is directly managing the patient. Through close and collaborative work, clinical information provided will help to guide appropriate ordering of tests and to ensure that interpretation of results is complete and accurate. For example, the team caring for the patient should provide the following information with the laboratory request:

1. The time and date of the suspected exposure along with the time and date of sample collection.
2. History obtained from the patient or from witnesses that might aid in identification of the toxin.
3. Assessment of the physical state of the patient at the time of presentation. Such information is useful for guiding test selection and interpretation of results.

Analytical Considerations

Because of the wide variety of drugs, no single analytical technique is adequate for broad-spectrum drug detection. Therefore, several analytical approaches in combination are generally required. Other critical issues include (1) speed of analysis, (2) turnaround time, and (3) availability of services. A drug analysis that requires several hours to complete or that is not available at all hours of the day may be of little value in a clinical emergency. Alternatively, a rapid test that may provide false information could result in erroneous diagnostic and therapeutic decisions.

TABLE 31-1 Antidote or Specific Treatment for Intoxication

Toxin	Antidote/Treatment
Acetaminophen	N-Acetylcysteine
Aluminum, iron	Deferoxamine
Anticholinergic agents	Physostigmine
Arsenic	Dimercaprol; 2,3-dimercaptosuccinic acid; d-penicillamine
Barbiturates	Multiple-dose oral activated charcoal; alkaline diuresis (phenobarbital only)
Benzodiazepines	Flumazenil
β-Blockers	Glucagon
Calcium channel blockers	Calcium; glucagon; high-dose insulin infusion
Carbamazepine	Multiple-dose oral activated charcoal; charcoal hemoperfusion
Carbon monoxide	Oxygen
Cyanide	Amyl nitrite, sodium nitrite, sodium thiosulfate; hydroxocobalamin
Digoxin	Anti-digoxin Fab fragments
Ethylene glycol, methanol	Fomepizole (4-methylpyrazol) or ethanol; hemodialysis
Isoniazid	Pyridoxine
Lead	Calcium disodium edetate; dimercaprol; 2,3-dimercaptosuccinic acid
Lithium	Hemodialysis
Mercury	Dimercaprol; 2,3-dimercaptosuccinic acid; d-penicillamine
Methanol	Fomepizole (4-methylpyrazol) or ethanol; hemodialysis; folate
Nitrites, nitrates	Methylene blue
Opioids	Naloxone
Organophosphate or carbamate	Atropine; pralidoxime (controversial for carbamates)
Salicylates	Bicarbonate; hemodialysis, activated charcoal, alkaline diuresis
Theophylline	Multiple-dose oral activated charcoal; hemodialysis
Tricyclic antidepressants	Bicarbonate; benzodiazepines

Clinical Evaluation

When a healthcare team initially evaluates a patient who presents with a potentially toxicologically induced problem, the final diagnosis is often determined by (1) reviewing the history, (2) performing a directed physical examination, (3) using ancillary tests (e.g., electrocardiogram, radiology), and (4) laboratory testing.

Toxic Syndromes

Toxic syndromes ("**toxidromes**") are clinical syndromes that are essential for the successful recognition of poisoning patterns. A toxidrome is a constellation of clinical signs and symptoms that suggests a specific class of poisoning. An important purpose of the secondary survey is to determine whether a specific toxic syndrome is present. The most commonly encountered toxidromes include (1) anticholinergic, (2) cholinergic, (3) opioid, (4) sedative-hypnotic, and

(5) sympathomimetic toxidromes (Table 31-2). Many toxidromes have several overlapping features. For example, anticholinergic findings are highly similar to sympathomimetic findings, with one exception being their effect on sweat glands. In this exception, **anticholinergic agents** produce warm, flushed dry skin, but sympathomimetic agents produce diaphoresis (purfuse perspiration). Toxidrome findings may also be affected by (1) individual variability, (1) comorbid conditions, and (3) co-ingestants. For example, tachycardia associated with sympathomimetic or anticholinergic toxidromes may be absent in a patient who is concurrently taking beta-antagonist medications. Additionally, although toxidromes may be applied to classes of drugs, one or more toxidrome findings may be absent for some individual agents within these classes. For instance, meperidine is an opioid **analgesic**, but it does not induce **miosis** (constriction of the pupil), which helps to define the "classic" opioid toxidrome. When accurately identified, the toxidrome may provide invaluable information for diagnosis and subsequent treatment, although the many limitations that impede acute toxidrome diagnosis must be carefully considered.

TABLE 31-2 Symptoms of the Important Toxidromes

Toxidrome	Symptom
Anticholinergic	Agitation
	Blurred vision
	Decreased bowel sounds
	Dry skin
	Fever
	Flushing
	Hallucinations
	Ileus
	Lethargy/coma
	Mydriasis
	Myoclonus
	Psychosis
	Seizures
	Tachycardia
	Urinary retention
Cholinergic	Diarrhea
	Miosis
	Bradycardia
	Bronchorrhea
	Emesis
	Lacrimation
	Salivation
	Urination
Opioid	Bradycardia
	Decreased bowel sounds
	Hypotension
	Hypothermia
	Lethargy/coma
	Miosis
	Shallow respirations
	Slow respiratory rate
Sedative-hypnotic	Ataxia
	Blurred vision
	Confusion
	Diplopia
	Dysesthesias
	Hypotension
	Lethargy/coma
	Nystagmus
	Respiratory depression
	Sedation
	Slurred speech
Sympathomimetic	Agitation
	Diaphoresis
	Excessive motor activity
	Excessive speech
	Hallucinations
	Hypertension
	Hyperthermia
	Insomnia
	Restlessness
	Tachycardia
	Tremor

Screening Procedures for Detection of Drugs

Screening procedures are designed for the relatively rapid and generally qualitative detection of drugs or other toxic substances. Screening procedures may be designed to detect a particular drug or drug class. In general, **screening tests** have adequate clinical sensitivity but lack specificity. T us a negative result may rule out with reasonable certainty the presence of clinically significant concentrations of a particular analyte. Because of possible interferences, a positive result should be considered "presumptive positive" and should be confirmed by an alternate procedure of greater specificity. Screening tests include simple visual color tests (spot tests) and immunoassays.

Spot Tests

Spot tests are qualitative procedures that are (1) rapid, (2) easily performed, and (3) non–instrument based. T ey are potentially valuable to rule out the presence of drugs or to suggest (but not prove) the presence of a drug of a particular group. In practice, spot tests have been largely replaced by rapid immunoassays that may be performed at the point of care or in the central laboratory. Two examples of such tests are the ferric chloride and Trinder tests for rapid identification of the patient with salicylate toxicity. Both involve simply applying a few drops of a prepared reagent to a small sample of a patient's urine and watching for a characteristic color change.[13] Both have been used for rapid point-of-care testing and should be followed by determination of serum salicylate concentrations to confirm toxicity and quantitate the salicylate concentration.

Determination of Anion Gap

A basic metabolic panel is recommended and is an important initial screening test for all poisoned patients. When

low concentration of serum bicarbonate is discovered on a metabolic panel, the clinician should determine whether an elevated anion gap exists. The formula most commonly used for the anion gap (AG) calculation is as follows:

$$AG = [Na^+] - [Cl^- + HCO_3^-]$$

The reference interval for this anion gap is accepted to be 8 to 16 mmol/L.[13] An increase in the anion gap, accompanied by a metabolic acidosis, represents an increase in unmeasured endogenous (e.g., lactate) or exogenous (e.g., salicylates) anions. A list of the more common causes is described using the classic MUDPILES **mnemonic** (Box 31-1). It is imperative that clinicians who admit poisoned patients initially presenting with an increased anion gap metabolic acidosis investigate the cause of that acidosis. Many symptomatic poisoned patients may have an initial mild metabolic acidosis upon presentation, caused by processes resulting in elevated serum lactate. However, with adequate supportive care, including hydration and oxygenation, the anion gap acidosis should improve. If, despite adequate supportive care, an anion gap metabolic acidosis worsens in a poisoned patient, the clinician should consider as potential causes (1) continued absorption of exogenous acids (e.g., salicylate, **ethylene glycol**, methanol), (2) formation of acidic metabolites (e.g., glycolic acid, toluene metabolites), and (3) cellular ischemia with worsening lactic acidosis (e.g., cyanide).

Electrocardiogram

Because numerous drugs cause changes in the electrocardiogram (ECG), interpretation of the ECG in the poisoned patient has been known to significantly facilitate appropriate (1) laboratory testing, (2) diagnosis, and (3) management of care.

Determination of Osmol Gap

The main osmotically active constituents of serum are (1) Na^+, (2) CL^-, (3)HCO_3^-, (4) glucose, and (5) urea. Several empirical formulas based on measurement of these substances have been used to estimate serum osmolality.[13] In practice, one has not shown itself to be superior to the others, yet each equation demonstrates significant differences in the osmol gap reference interval. Therefore, reference intervals must be validated on appropriate patient populations. Two commonly used formulas (in conventional and SI units) are presented here:

$$\begin{aligned}\text{OSMc (mOsm/kg)} = {} & 2\,\text{Na (mmol/L)} \\ & + \text{glucose (mg/dL)}/18 \\ & + \text{urea (mg/dL)}/2.8\end{aligned}$$

$$\begin{aligned}\text{OSMc (mOsm/kg)} = {} & 2\,\text{Na (mmol/L)} + \text{glucose (mmol/L)} \\ & + \text{urea (mmol/L)}\end{aligned}$$

or

$$\begin{aligned}\text{OSMc (mOsm/kg)} = {} & 1.86\,\text{Na (mmol/L)} \\ & + \text{glucose (mg/dL)}/18 \\ & + \text{urea (mg/dL)}/2.8 + 9\end{aligned}$$

$$\begin{aligned}\text{OSMc (mOsm/kg)} = {} & 1.86\,\text{Na (mmol/L)} \\ & + \text{glucose (mmol/L)} \\ & + \text{urea (mmol/L)} + 9\end{aligned}$$

The difference between the actual osmolality (OSMm), measured by freezing-point depression, and the calculated osmolality (OSMc) is referred to as delta-osmolality, or the osmol gap (OSMg).

$$OSMg = OSMm - OSMc$$

Elevated OSMg implies the presence of unmeasured osmotically active substances. Compounds that increase serum osmolality when present in significant concentrations include volatile alcohols such as (1) ethanol, (2) methanol, (3) isopropanol, (4) acetone, and (5) ethylene glycol. The calculation of OSMg is commonly used as a screen. However, it is important to remember that volatile alcohols are not detected when osmolality is measured with a vapor pressure osmometer. Therefore, for the purpose of determining the OSMg, only osmolality measurements based on freezing-point depression are acceptable.

What constitutes a normal osmol gap is widely debated. Large variability is seen in the normal population.[13] It would be expected that each 100 mg/dL (21.7 mmol/L) of ethanol (molecular weight = 46.068 g/mol) in serum results in an approximate increase of 21.7 mOsm/kg. However, this is not found to be the case. Applying a correction factor of 0.83 to the ethanol value will more closely approximate the contribution of ethanol to the OSMg. However, it has been observed that ethanol does not follow a completely predictable relationship with OSMg. In severe ethanol intoxication, OSMg is increased with increasing concentration, implying that something is present besides the alcohol.

A significant residual osmol gap (>10 mOsm/kg) after correction for ethanol suggests the possible presence of (1) isopropanol, (2) methanol, (3) acetone, or (4) ethylene glycol. This information, in conjunction with the presence or

BOX 31-1 Use of the MUDPILES Mnemonic to Remember the Common Causes of Increased Anion Gap

Methanol
Uremia
Diabetic ketoacidosis
Paraldehyde
Iron, inhalants (i.e., carbon monoxide, cyanide, toluene), isoniazid, ibuprofen
Lactic acidosis
Ethylene glycol, ethanol ketoacidosis
Salicylates, starvation ketoacidosis, sympathomimetics

TABLE 31-3 Laboratory Findings Characteristic of Ingestion of Alcohols

Alcohol	Serum Osmol Gap	Metabolic Acidosis with Anion Gap	Serum Acetone	Urine Oxalate
Ethanol	+	−	−	−
Methanol	+	+	−	−
Isopropanol	+	−	+	−
Ethylene glycol	+	+	−	+

absence of metabolic acidosis or serum acetone, is helpful to the clinician when specific measurements of alcohols other than ethanol are not available on an emergency basis (Table 31-3). Unfortunately, OSMg as a screening method is insensitive to low, but clinically significant, concentrations of ethylene glycol (<50 mg/dL) and methanol (<30 mg/dL). It must be realized that ketones (for example, in patients with diabetes) and substances administered to patients such as polyethylene glycol, mannitol (osmotic diuretic), and propylene glycol (solvents in some drug formulations) may increase serum osmolality.[13]

Use of Immunoassay

Different types of immunoassays are useful in screening specimens for drugs (see Chapter 15). Some immunoassays are relatively specific for a single drug, but in others, several drugs of a similar class are detected (e.g., **opiates**). The detection limit for various members of a class of drugs or the degree of cross-reactivity for similar drugs varies, and each manufacturer of immunoassay reagents should be consulted for specific information. These assays (1) are easy to perform, (2) are available for use on automated instrumentation, and (3) often are capable of providing "semiquantitative" results. Several portable noninstrumental immunoassay-based drug detection devices are available for use in point-of-care testing (POCT). For the vast majority of drugs of abuse, immunoassays are the methods of choice for initial screening. However, for more comprehensive drug screening, chromatographic procedures complement immunoassays.

Use of Planar Chromatography

Planar chromatography, commonly known as thin-layer chromatography (TLC), is a versatile procedure that requires no instrumentation and thus is operationally relatively simple and inexpensive (see Chapter 12). With this technique, a large number of drugs may be detected and it has been applied to the analysis of (1) serum, (2) gastric contents, or (3) urine. However, urine is the specimen of choice because most drugs and drug metabolites are present in urine in relatively high concentrations. However, application of TLC to drug screening requires considerable experience and skill on the part of the laboratorian to recognize drug and metabolite patterns and various color hues for detection; it has largely been replaced by other chromatographic techniques[3]

Use of Gas Chromatography

Gas liquid chromatography (GC) is (1) relatively rapid, (2) capable of resolving a broad spectrum of drugs, and is (3) widely used for qualitative and quantitative drug analysis.[11] Capillary columns are analytical columns that are commonly used for drug detection by GC (see Chapter 12). In many instances, nonderivatized drugs have good GC properties when capillary columns are used. However, derivatization to a less polar or a more volatile compound is often necessary. Common detectors for drug detection by GC are flame ionization and alkali flame ionization (nitrogen phosphorus) detectors. A GC coupled to a mass spectrometer (GC-MS) provides an analytical system with the greatest accuracy of identification. Numerous methods for general drug screening by GC-MS spectrometry have been published

Use of High-Performance Liquid Chromatography

High-performance liquid chromatography (HPLC) (see Chapter 12) has been applied to the complex challenge of comprehensive drug screening in biological fluids. Advantages of HPLC over GC include its usefulness in analyzing (1) polar compounds without derivatization (e.g., morphine, benzoylecgonine) and (2) thermally labile drugs (e.g., chlordiazepoxide). The advent of diode array detectors that provide a spectral scan of compounds as they elute from the column has greatly increased the discriminatory power of this technique. Analytical systems based on coupling of liquid chromatography (LC) with mass spectrometry (MS) (LC-MS or LC-MS/MS) are rapidly gaining in popularity.[13]

Use of Point-of-Care Devices

Numerous point-of-care (POC) drug test devices for urine (and oral fluid) are designed for easy, rugged, and portable use by nontechnical personnel. Although these devices are relatively simple to use, proper training of nonlaboratory users is important for optimal results (see Chapter 17). These noninstrumental immunoassay test devices are designed for use at the site of collection; results are available within minutes and are variously configured to detect only one drug or many drugs simultaneously. The assay principles of POC test devices are found in the package insert for each specific test kit.

Pharmacology and Analysis of Specific Drugs and Toxic Agents

The toxic consequences of several drugs and toxins are individually discussed in this section. They include (1) agents that cause cellular hypoxia, (2) alcohols, (3) analgesics (nonprescription), (4) agents related to anticholinergic toxidrome, (5) agents related to cholinergic toxidrome, (6) drugs of abuse, and (7) drugs used in sexual assault.

Agents That Cause Cellular Hypoxia

Carbon monoxide (CO) and methemoglobin-forming agents interfere with oxygen transport, resulting in cellular hypoxia. Cyanide interferes with oxygen use and therefore causes an apparent cellular hypoxia.

Carbon Monoxide

CO is a colorless, odorless, tasteless gas that is a product of incomplete combustion of carbonaceous material. Small amounts of CO are produced endogenously in the metabolic conversion of heme to biliverdin.

Toxic Effects

When inhaled, CO combines tightly with the heme Fe^{2+} of hemoglobin to form carboxyhemoglobin. The binding affinity of hemoglobin for carbon monoxide is about 250 times greater than that for oxygen. Moreover, the binding of carbon monoxide to a hemoglobin subunit increases the oxygen affinity for the remaining subunits in the hemoglobin tetramer. Thus at a given tissue PO_2 value, less oxygen dissociates from hemoglobin when carbon monoxide is also bound, shifting the hemoglobin-oxygen dissociation curve to the left. Consequently, carbon monoxide not only decreases the oxygen content of blood, it also decreases oxygen availability to tissue. This produces a greater degree of tissue hypoxia than would result from an equivalent reduction in oxyhemoglobin due to hypoxia alone. Carbon monoxide may also bind to other heme proteins, such as myoglobin and mitochondrial cytochrome oxidase a_3; this may limit oxygen use when tissue PO_2 is very low.[13]

Treatment for carbon monoxide poisoning involves removal of the individual from the contaminated area and administration of oxygen. The **drug half-life ($t_{½}$)** of carboxyhemoglobin in the body is variable. Low carboxyhemoglobin concentrations relative to the severity of poisoning may be observed if the patient was removed from the CO-contaminated environment several hours before blood sampling. Hyperbaric oxygen therapy for CO is highly debated, and current position papers have reported no evidence to support its use.

Analytical Methods

Carbon monoxide may be released from hemoglobin and then measured by GC, or it may be determined indirectly as carboxyhemoglobin by spectrophotometry. Gas chromatographic methods are accurate and precise even for very low concentrations of carbon monoxide. Spectrophotometric methods are (1) rapid, (2) convenient, (3) accurate, and (4) precise, except at very low concentrations of carboxyhemoglobin (<3%).

Gas chromatographic methods measure the carbon monoxide content of blood and are considered to be reference procedures. When blood is treated with potassium ferricyanide, carboxyhemoglobin is converted to methemoglobin, and carbon monoxide is released into the gas phase. Measurement of the released carbon monoxide may be performed by GC using various methods and detectors.[13] In clinical practice, CO binding capacity is determined after an aliquot of the blood specimen is treated with carbon monoxide to saturate the hemoglobin. The results are then expressed as percentage of carboxyhemoglobin:

$$\%\,HbCO = \frac{CO_{content}}{CO_{capacity}} \times 100$$

Spectrophotometric methods rely on the characteristic spectral absorption properties of carboxyhemoglobin. The most common are based on automated, multi-wavelength measurements of several hemoglobin species, and they are rapid and convenient. Spectrophotometric methods generally compare favorably with gas chromatographic procedures at carboxyhemoglobin concentrations greater than 2% to 3%, but their precision is poor below these concentrations. Therefore, they are sufficiently accurate and precise for measurement of carbon monoxide after exogenous exposure, but they are too insensitive to detect the increased endogenous production of carbon monoxide that occurs in hemolytic anemia.

Fetal hemoglobin and adult hemoglobin differ slightly in their spectral properties. Consequently, falsely high carboxyhemoglobin values of 4% to 7% may occur when blood from neonates is measured by some spectrophotometric methods by using fewer wavelengths. Moreover, erroneous results may occur with lipemic and icteric specimens and in the presence of methylene blue (see later section, "Methemoglobin-Forming Agents").

Cyanide

Cyanide consists of one atom of carbon triple-bonded to one atom of nitrogen (C≡N). Inorganic cyanides (also known as cyanide salts) contain cyanide in anion form (CN^-) and are used in numerous industries. Organic compounds that have a cyano group bonded to an alkyl residue are called nitriles. Iatrogenic cyanide poisoning may occur during use of nitroprusside.

Toxic Effects

Cyanide in serum readily crosses all biological membranes and avidly binds to heme iron (Fe^{3+}) in the cytochrome a-a_3 complex within mitochondria. When bound to cytochrome a-a_3, cyanide is a competitive inhibitor that causes decoupling of oxidative phosphorylation. Patients exposed to toxic concentrations of cyanide exhibit rapid onset of symptoms typical of cellular hypoxia, such as (1) flushing, (2) headache, (3) tachypnea, (4) dizziness, and (5) respiratory depression. Subsequently, cellular hypoxia progresses rapidly to (1) coma, (2) seizures, (3) complete heart block, and (4) death if the cyanide dose is sufficiently large. Hydroxycobalamin or the cyanide antidote kit should be administered as soon as cyanide poisoning is suspected.

Analytical Methods

After microdiffusion, whole blood CN^- is measured by spectrophotometry or by headspace gas chromatography.[13]

Methemoglobin-Forming Agents

The heme iron in hemoglobin is typically present in the ferrous state (Fe^{2+}). When oxidized to the ferric state (Fe^{3+}), methemoglobin is formed, and this form of hemoglobin does not bind oxygen. The principal physiological system that maintains hemoglobin iron in the reduced state is nicotinamide adenine dinucleotide (NADH)-methemoglobin reductase. A minor pathway for methemoglobin reduction involves nicotinamide adenine dinucleotide phosphate (NADPH)-methemoglobin reductase. Congenital methemoglobinemia may result from a deficiency of NADH-methemoglobin reductase or, more rarely, from hemoglobin variants (hemoglobin M) in which heme iron is both more susceptible to oxidation and more resistant to reduction by the methemoglobin reductase system.

Toxic Effects

An acquired (toxic) methemoglobinemia may be caused by various drugs and chemicals (Table 31-4). The normal percentage of methemoglobin is <1.5% of total hemoglobin. All symptoms associated with methemoglobinemia are consequences of hypoxia associated both with diminished O_2 content of blood and with decreased O_2 dissociation from hemoglobin species. The PO_2 is normal in these patients, and therefore so is the calculated hemoglobin oxygen saturation. Thus, a normal PO_2 in a cyanotic patient is a significant indication of the possible presence of methemoglobinemia. Direct measurement of methemoglobin is important in these cases. Specific therapy for toxic methemoglobinemia involves the administration of methylene blue. Methylene blue and sulfhemoglobin cause spectral interference in the measurement of methemoglobin with some co-oximeters but not with the Evelyn-Malloy method.

Analytical Methods

Methemoglobin is measured in blood manually or by taking automated multi-wavelength measurements with a co-oximeter. Methemoglobin interferes with the noninvasive pulse oximetry method, measuring the absorbance of light at 660 nm (oxyhemoglobin) and 940 nm (deoxyhemoglobin). Because methemoglobin is not stable at room temperature, specimens should be kept on ice or refrigerated but not frozen. The stability of methemoglobin at 4 °C has not been well studied. Some sources report significant decreases in methemoglobin concentration after 4 to 8 hours, whereas others describe little or no change after 24 hours. Freezing results in an increase in methemoglobin concentration.

TABLE 31-4 Examples of Acquired Causes of Methemoglobinemia

Drugs	Chemical Agents
Amyl nitrite	Aniline
Benzocaine	Amyl nitrite
Chloroquine	Butyl nitrite
Dapsone	Chlorobenzene
Nitroglycerin	Naphthalene
Phenacetin	Nitrates
Phenazopyridine	Nitrites
Primaquine	Nitrophenol
Sulfonamides	Nitrous oxide

Alcohols

Several alcohols are toxic and medically important. They include (1) ethanol, (2) methanol, (3) isopropanol and acetone, and (4) ethylene glycol.

Ethanol

Ethanol is the most widely used and often abused chemical substance. Consequently, measurement of ethanol is one of the more frequently performed tests in the toxicology laboratory. The principal pharmacological action of ethanol involves central nervous system (CNS) depression, and effects vary depending on the blood ethanol concentration (Table 31-5) and an individual's tolerance. A blood alcohol concentration of 80 mg/dL (0.08%) has been established as the per se limit for operation of a motor vehicle in North America.[13]

Ethanol is metabolized principally by liver alcohol dehydrogenase to acetaldehyde, which is subsequently oxidized to acetic acid by aldehyde dehydrogenase (Figure 31-1). The rate of elimination of ethanol from blood approximates a zero-order process. This rate varies among individuals, averaging about 15 mg/dL/h for males and 18 mg/dL/h for females. At both low (<20 mg/dL) and high (>300 mg/dL) ethanol concentrations, elimination becomes more nearly first-order; it is accelerated at high concentrations. The elimination rate is also influenced by drinking practices (e.g., alcoholics have increased elimination rates caused by enzyme induction).

When consumed with other CNS depressant drugs, ethanol exerts a potentiation or synergistic depressant effect. This occurs at relatively low alcohol concentrations, and numerous deaths have resulted from combined ethanol and drug ingestion.[13] Ethanol is a teratogen, and alcohol consumption during pregnancy can result in the birth of a baby with fetal alcohol spectrum disorder (FASD). FASD is an umbrella term that describes the variety of effects that occur in an individual whose mother drank alcohol during pregnancy. These effects may include (1) physical, (2) mental, (3) behavioral, and (4) learning disabilities with lifelong implications. They are, however, 100% preventable when a woman completely **abstains** from alcohol during her pregnancy.

Methanol

Methanol is used as a solvent in several commercial products and is sold in numerous consumer products such as de-icers and windshield washer fluids. Methanol poisoning can be lethal if not recognized early. Unfortunately, in some instances, the latent period is as long as 24 hours before toxicity is recognized, making laboratory identification of this poisoning critical.[13]

Methanol is oxidized by liver alcohol dehydrogenase (at about one-tenth the rate of ethanol) to formaldehyde. Formaldehyde in turn is rapidly oxidized by aldehyde dehydrogenase to formic

acid, which may cause serious acidosis and optic neuropathy, resulting in blindness or death. The mainstay of therapy for methanol toxicity includes (1) administration of ethanol or fomepizole as a competitive alcohol dehydrogenase inhibitor, (2) administration of either folate or folinic acid, and (3) dialysis.

Isopropanol and Acetone

Isopropanol is readily available to the general population, commonly as a 70% aqueous solution, for use as rubbing alcohol. It has about twice the CNS depressant action as ethanol. Isopropanol is rapidly metabolized by alcohol dehydrogenase to acetone, which is eliminated much more slowly. Therefore, concentrations of acetone in serum often exceed those of isopropanol during the elimination phase after isopropanol ingestion. Acetone has CNS depressant activity similar to that of ethanol, and because of its longer half-life, it may prolong the apparent CNS effects of isopropanol. Supportive care is the mainstay of treatment, with rare reports of dialysis in severe intoxication.

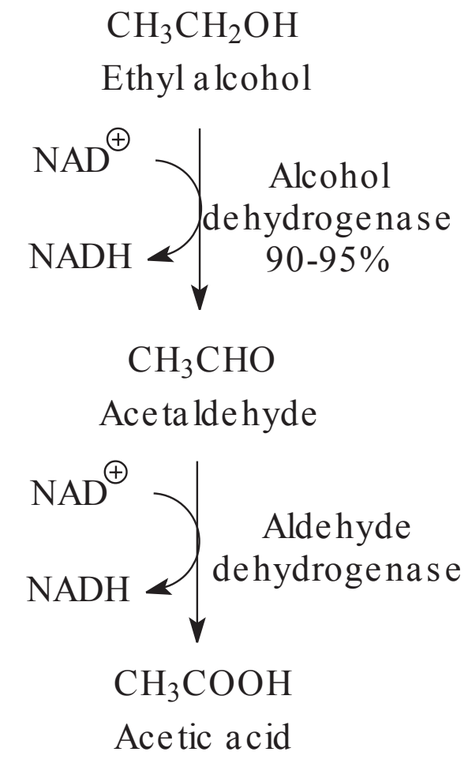

Figure 31-1 Metabolism of ethanol.

TABLE 31-5 Stages of Acute Alcoholic Influence/Intoxication

Blood Alcohol Concentration, g/100 mL or mg/dL	Influence	Clinical Signs/Symptoms
0.01-0.05	Subclinical	Influence/effects not apparent or obvious Behavior nearly normal by ordinary observation Impairment detectable by special tests
0.03-0.12	Euphoria	Mild euphoria, sociability, talkativeness Increased self-confidence; decreased inhibitions Diminution of attention, judgment, and control Some sensorimotor impairment Slowed information processing Loss of efficiency in finer performance tests Impairment of perception, memory
0.09-0.25	Excitement	Emotional instability; loss of critical judgment comprehension Decreased sensory response; increased reaction time Reduced visual acuity, peripheral vision, and glare recovery Sensorimotor incoordination; impaired balance Drowsiness
0.18-0.30	Confusion	Disorientation, mental confusion; dizziness Exaggerated emotional states (fear, rage, grief, etc.) Disturbances of vision (diplopia, etc.) and of perception of color, form, motion, dimensions Increased pain threshold Increased muscular incoordination; staggering gait; slurred speech Apathy, lethargy
0.25-0.40	Stupor	General inertia; approaching loss of motor functions Markedly decreased response to stimuli Marked muscular incoordination; inability to stand or walk Vomiting; incontinence of urine and feces Impaired consciousness; sleep or stupor
0.35-0.50	Coma	Complete unconsciousness; coma; anesthesia Depressed or abolished reflexes Subnormal temperature Impairment of circulation and respiration Possible death
0.45 +	Death	Death from respiratory arrest

Ethylene Glycol

Ethylene glycol, present in products such as antifreeze, may be ingested accidentally or for the purpose of inebriation or suicide. Ethylene glycol itself is relatively nontoxic, and its initial CNS effects resemble those of ethanol. However, metabolism of ethylene glycol by alcohol dehydrogenase (ADH) results in the formation of numerous acid metabolites, including oxalic acid and glycolic acid, which are responsible for much of the toxicity of ethylene glycol. Serum ethylene glycol concentrations associated with death from ethylene glycol ingestion have no correlation with severity of toxicity. It is thus impossible to define a serum ethylene glycol concentration associated with a high probability of death. However, the serum concentration of the metabolite glycolic acid correlates more closely with clinical symptoms and mortality. Because of the rapid elimination of ethylene glycol, its serum concentration may be low or undetectable at a time when glycolic acid remains elevated. Thus the determination of ethylene glycol and glycolic acid provides useful clinical and confirmatory analytical information in cases of ethylene glycol ingestion. The mainstay of therapy for ethylene glycol toxicity includes administration of ethanol or fomepizole as a competitive alcohol dehydrogenase inhibitor and dialysis.

Analysis of Ethanol

Serum, plasma, and whole blood are suitable blood-related specimens for the determination of ethanol. The venipuncture site should be cleansed with an alcohol-free disinfectant, such as aqueous benzalkonium chloride.

Serum/Plasma and Blood Ethanol

Alcohol distributes into the aqueous compartments of blood; because the water content of serum is greater than that of whole blood. Higher alcohol concentrations are obtained with serum as compared with whole blood. Experimentally, the serum-to-whole blood ethanol ratio is 1.18 and varies slightly with hematocrit. Therefore, laboratories that perform alcohol determinations should make clear the choice of specimen.

Because of the volatile nature of alcohols, specimens should be kept capped to avoid evaporative loss. Blood may be stored, when properly sealed, for 14 days at room temperature or at 4 °C, with or without preservative. For longer storage or for nonsterile postmortem specimens, sodium fluoride should be used as a preservative to prevent a decrease or occasionally an increase (via fermentation) in ethanol concentration.

To measure ethanol in serum/plasma, the enzymatic assay is the method of choice in many clinical laboratories. With this method, ethanol is measured by oxidation to acetaldehyde with NAD, a reaction catalyzed by ADH. With this reaction, the formation of NADH, measured at 340 nm, is proportional to the amount of ethanol in the specimen.

$$\text{Ethanol} + \text{NAD} \xrightarrow{\text{ADH}} \text{Acetaldehyde} + \text{NADH}$$

Under most assay conditions, ADH is reasonably specific for ethanol, with interferences by (1) isopropanol, (2) acetone, (3) methanol, and (4) ethylene glycol of typically <1%. Results obtained with these methods generally compare closely with gas chromatographic methods. However, spuriously increased results for ethanol have been described in the presence of high concentrations of lactate dehydrogenase (LD) and lactate, resulting from the production of NADH by LD.

Breath Ethanol

Statutory laws for driving under the influence of alcohol were originally based on the concentration of ethanol in venous whole blood. Because collection of blood is invasive and requires the participation of medical personnel, determination of alcohol in expired air (breath) has long been the mainstay of evidential alcohol measurements. Clinical interest in determination of breath alcohol at the point of care is growing. The fundamental principle for the use of breath analysis is that alcohol in capillary alveolar blood rapidly equilibrates with alveolar air in a ratio of approximately 2100:1 (blood/breath). This blood/breath ratio may actually be closer to 2300:1 but in any case is variable. Nevertheless, in the United States, evidential breath alcohol measurements are based on the ratio of 2100:1. To alleviate confusion and uncertainty surrounding conversion from breath to blood alcohol concentration, the traffic laws in many countries specify per se limits for blood and/or breath.

Before breath alcohol analysis, a deprivation period of at least 15 minutes is recommended to allow for clearance of any residual alcohol that may have been present in the mouth from (1) very recent drinking, (2) use of alcohol-containing mouthwash, or (3) vomiting of alcohol-rich gastric fluid. Duplicate tests, performed 3 to 10 minutes apart, typically must agree within 20 mg/dL (0.02%) as an additional safeguard against mouth alcohol contamination.

Determination of ethanol in expired air requires specialized breath alcohol analyzers. Several commercial evidential breath alcohol measurement devices are available. Breath alcohol devices also may be used for the medical evaluation of patients at the point of care (e.g., emergency department).

Urine Ethanol

Urine has been used as an alternative, less invasive specimen for determination of alcohol use. During the postabsorptive phase that follows alcohol ingestion, the concentration of alcohol in urine is roughly 1.3 times that in blood.[2] However, the use of urine alcohol measurements to estimate blood concentrations is discouraged because the ratio is highly variable, and, perhaps more important, because the urine alcohol concentration reflects an average of the blood alcohol concentration during the period in which urine is collected in the bladder. The detection of alcohol in urine represents ingestion of alcohol within the previous 8 to 12 hours.

Effects of Minor Metabolites

Ethyl glucuronide (EtG) and ethyl sulfate (EtS) are minor metabolites of alcohol. EtG is a phase II metabolite formed through UDP-glucuronosyltransferase, and EtS is formed directly by conjugation of the ethanol with sulfate group. In practice, it is possible to detect EtG in urine 80 hours

post alcohol consumption, and it is found even when small amounts of alcohol are consumed. Because of its long urinary elimination time and its specificity for ethanol exposure, its use as a marker of recent ethanol intake has been proposed. However, challenges associated with factors such as (1) establishing appropriate cutoff concentrations capable of distinguishing between drinking and nonbeverage sources of ethanol exposure, (2) sample stability, and (3) microbial activity substantially complicate accurate interpretation of results.

Analysis of Volatile Alcohols

Flame ionization GC remains the most common method used to detect and quantify volatile alcohols in biological samples.[2] Not only does it distinguish between (1) ethanol, (2) methanol, (3) isopropanol, and (4) acetone, it has the capability to measure concentrations as low as 10 mg/dL (0.01%). Specimens are prepared by a variety of methods; the two most common are direct injection and headspace analysis. Direct injection involves injection of a sample prepared by dilution with an aqueous solution of internal standard. However, repeated injection of this matrix into the GC may cause buildup on the injector and on the front of the analytical column, requiring frequent maintenance and column replacement. In practice, this problem is mitigated by the use of headspace injection. The volatility of the alcohols is used to separate them from the matrix. Specifically, the "Gas Law" states that at a given temperature, the amount of volatile substance in the air space above the liquid—headspace—is proportional to the concentration of the volatile alcohol in the solution. Therefore, the sample in the headspace allows calculation of the concentration in the specimen. Conversely, direct injection GC is the method of choice for ethylene glycol because it has a higher boiling point and is not as amenable to headspace analysis.[13]

Analgesics (Nonprescription)

Analgesics are substances that relieve pain without causing loss of consciousness.

Acetaminophen

Acetaminophen has analgesic and antipyretic actions. In normal doses, acetaminophen is safe and effective, but it may cause severe hepatic and renal toxicity when consumed in overdose quantities. Initial clinical findings in acetaminophen toxicity are relatively mild and nonspecific and include (1) nausea, (2) vomiting, and (3) abdominal discomfort. However, these conditions are not predictive of impending hepatic necrosis. Antidotal therapy with N-acetylcysteine (NAC) is most effective when administered before hepatic injury occurs, as signified by elevation of activities of aspartate aminotransaminase (AST) and alanine aminotransaminase (ALT). Thus the measurement of serum acetaminophen concentration becomes paramount for proper assessment of the severity of overdose and for appropriate decision making for antidotal therapy. The Rumack-Matthew nomogram relates serum acetaminophen concentration and time after acute ingestion to the probability of hepatic necrosis (Figure 31-2).

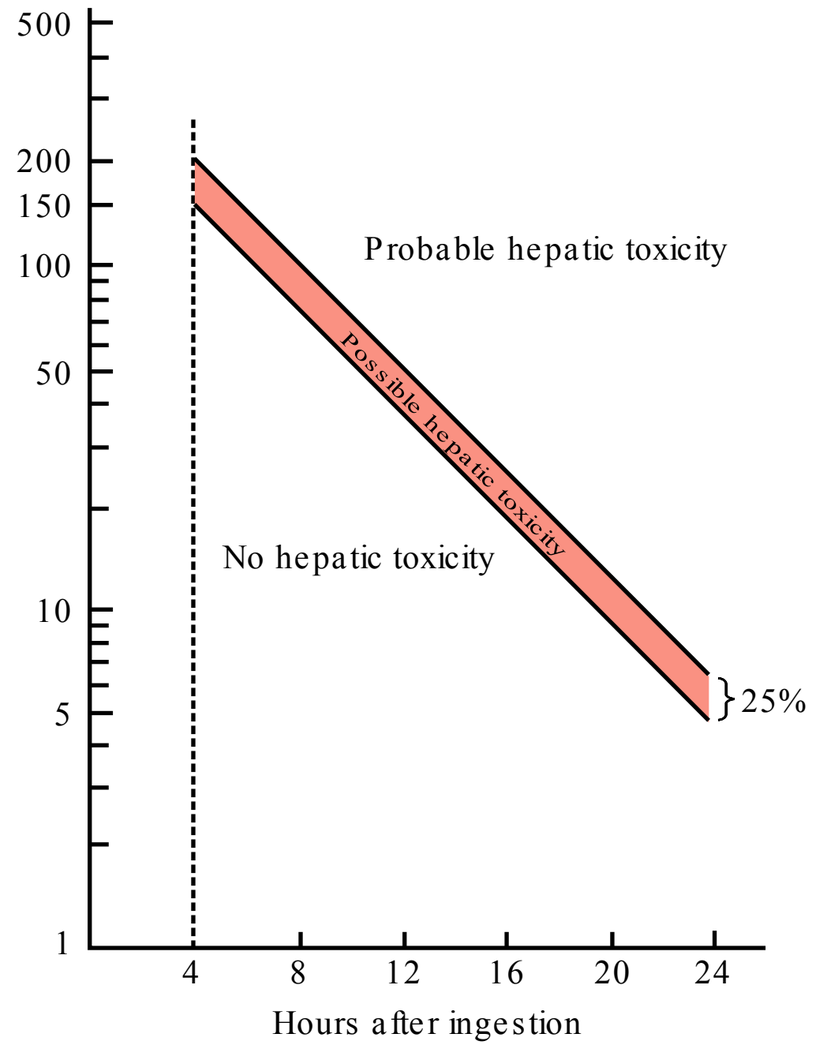

Figure 31-2 Rumack-Matthew nomogram. (From Rumack BH, Matthew H. Acetaminophen poisoning and toxicity. Pediatrics 1975;55:871-6. Reproduced by permission of Pediatrics.)

Acetaminophen is normally metabolized in the liver to glucuronide (50% to 60%) and sulfate (≈30%) conjugates. A smaller amount (≈10%) is metabolized by a cytochrome P450 mixed-function oxidase pathway that is thought to involve formation of a highly reactive intermediate (Figure 31-3), N-acetyl-p-benzoquinoneimine (NAPQI). This intermediate normally undergoes electrophilic conjugation with glutathione and then subsequent transformation to cysteine and mercapturic acid conjugates of acetaminophen. With acetaminophen overdose, the sulfation pathway becomes saturated; consequently, a greater portion is metabolized by the P450 mixed-function oxidase pathway. When the tissue stores of glutathione become depleted, arylation of cellular molecules by the benzoquinoneimine intermediate leads to hepatic necrosis. Specific therapy for acetaminophen overdose is administration of NAC, which acts as a glutathione substitute.

Many spectrophotometric methods are available for determination of acetaminophen.[13] In general, these methods are simple and relatively easy to perform but are subject to various interferences such as bilirubin or bilirubin byproducts absorbing at similar wavelengths. Some methods measure the nontoxic metabolites and the potentially toxic parent acetaminophen, and thus may produce especially misleading results. Therefore, only methods specific for parent acetaminophen should be used. Immunoassays are widely used for this purpose, as they are (1) rapid, (2) easily performed, and (3) accurate. A different spectrophotometric approach uses arylacrylamide amidohydrolase to hydrolyze acetaminophen (but not conjugates) to p-aminophenol and acetate. Subsequent formation of the absorbing species depends on the reaction of generated p-aminophenol with 8-hydroxyquinoline or o-cresol. Arylacrylamide amidohydrolase methods are susceptible

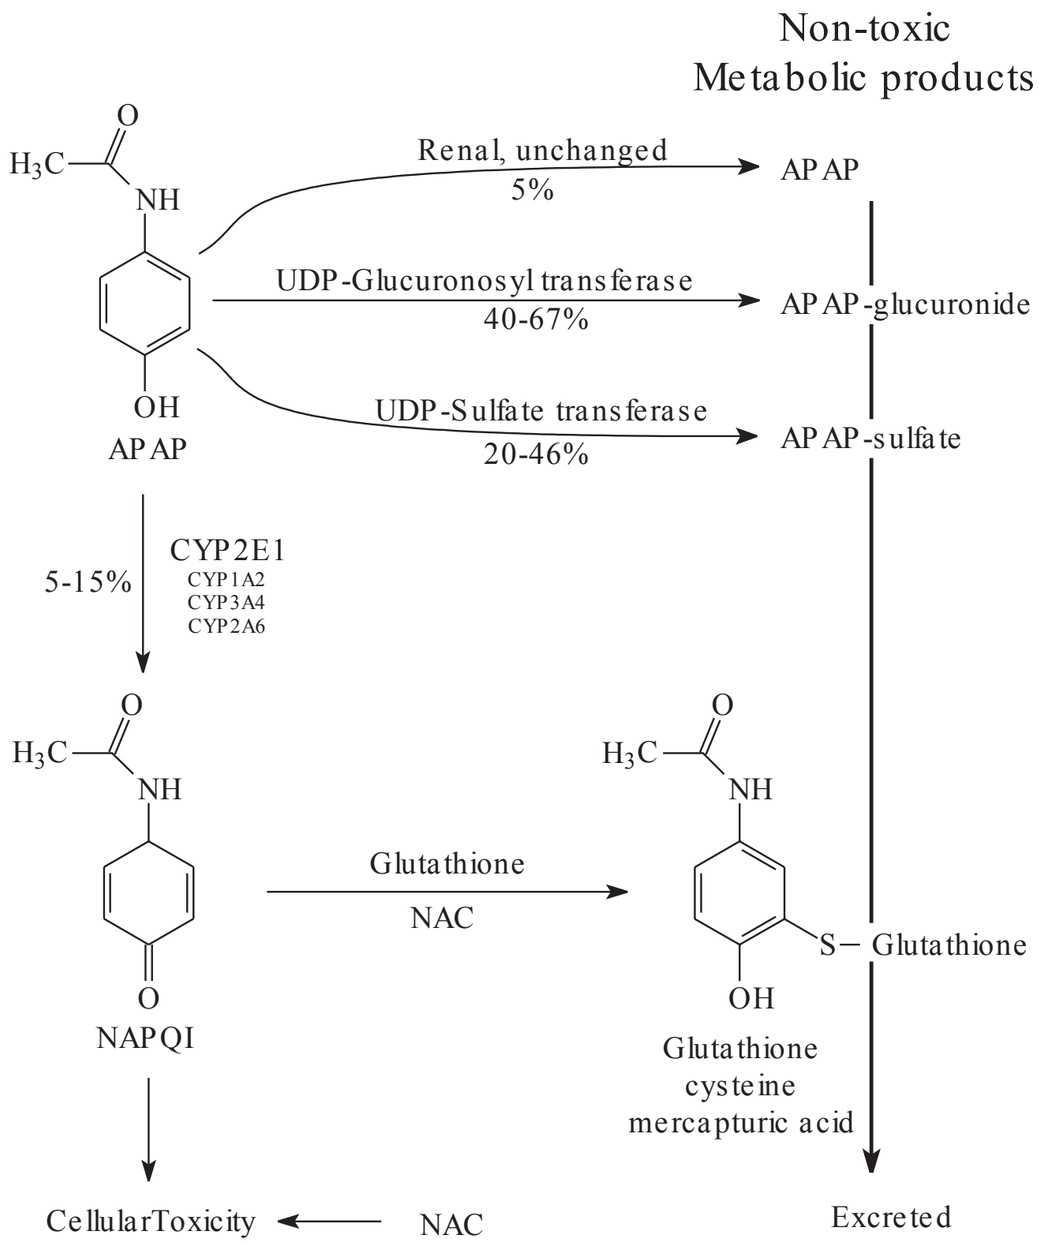

Figure 31-3 Pathways of acetaminophen metabolism. APAP (N-acetyl-p-aminophenol/acetaminophen), NAPQI (N-acetyl-p-benzoquinoneimine), and NAC (N-acetylcysteine).

to interference by (1) NAC, (2) bilirubin, and (3) immunoglobulin (Ig)M monoclonal immunoglobulins. A qualitative, one-step lateral flow immunoassay (cutoff of 25 µg/mL) may be suitable for point-of-care application, yet it has a low positive predictive value. Most chromatographic methods are very accurate and are considered reference procedures.

Salicylates

Acetylsalicylic acid (aspirin) is a salicylate that has (1) analgesic, (2) antipyretic, and (3) anti-inflammatory properties. Salicylates directly stimulate the central respiratory center, thereby causing hyperventilation and respiratory alkalosis. Moreover, salicylates cause uncoupling of oxidative phosphorylation. As a result, (1) heat production (hyperthermia), (2) oxygen consumption, and (3) metabolic rate may be increased. In addition, salicylates enhance anaerobic glycolysis but inhibit the Krebs cycle and transaminase enzymes, all of which lead to accumulation of organic acids and thus to metabolic acidosis.

After acute salicylate overdose, patients initially may be asymptomatic, especially if that product is enteric coated. Salicylate toxic patients may develop (1) nausea, (2) vomiting, (3) abdominal pain, (4) tinnitus (ringing of the ear), (5) tachypnea (rapid breathing), (6) oliguria (decreased urine output), and (7) altered mental status ranging from lethargy to coma. Individuals with chronic intoxication present in a similar fashion as those with acute exposures, yet such exposures typically are more insidious and therefore are often misdiagnosed.

Use of salicylate concentrations to guide management must be done cautiously and only in conjunction with careful evaluation of a patient's clinical status. Although toxic concentrations alone are of poor prognostic value, certain clinical findings predict a poor prognosis, including (1) pulmonary edema, (2) fever, (3) coma, and (4) acidosis. T e absorptive phase of salicylates is often unpredictable (delayed or erratic) as a result of (1) **bezoar** formation, (2) enteric-coated product, (3) gastric outlet obstruction, or (4) pylorospasm. T erefore, a specimen drawn soon after the original ingestion may not be reflective of the potential peak concentration. Initial serial concentrations should be obtained every 2 hours while the patient is monitored clinically. When the concentrations begin to decline and the patient's clinical status is improved, concentrations are measured less frequently.

Treatment for salicylate intoxication is directed toward (1) decreasing further absorption, (2) increasing elimination, and (3) correcting acid-base and electrolyte disturbances. Activated charcoal binds aspirin and prevents its absorption. Elimination of salicylate may be enhanced by alkaline **diuresis** and in severe cases by hemodialysis. Sodium bicarbonate may be given to alleviate metabolic acidosis. Indications for hemodialysis include (1) serum salicylate >1000 mg/L, (2) severe CNS depression, (3) intractable metabolic acidosis, (4) hepatic failure with coagulopathy, and (5) renal failure.

Classic methods for measurement of salicylate in serum are based on the method of Trinder (see the section, "Spot Tests"). T ese procedures rely on the reaction between salicylate and Fe^{3+} to form a colored complex that is measured at 540 nm. To lessen endogenous background interference, a protein precipitation step or a serum blank is necessary. Nevertheless, blank readings equivalent to about 20 to 25 mg/L are generally observed. Moreover, interference by (1) salicylate metabolites, (2) endogenous compounds, and (3) some drugs, especially structurally related drugs such as diflunisal (difluorophenyl salicylate), may occur. Azide, which is present as a preservative in some commercial control sera, also interferes. Despite these limitations, photometric methods continue to be successfully used to assess salicylate overdose. T e Trinder method results agreed very closely with those of a reference HPLC procedure.[10] Other methods for salicylate quantitation include fluorescent polarization immunoassay and a salicylate hydroxylase–mediated photometric procedure. T ese procedures are subject to some of the same interferences as the Trinder method, but the salicylate hydroxylase method is considered more specific and has been adapted to automated analyzers. Gas and liquid chromatographic methods are the most specific methods for salicylate, but their general availability, especially for emergency use, is limited and probably is not necessary. A qualitative, one-step lateral flow immunoassay (cutoff of 100 µg/mL) is commercially available for point-of-care application but has a low positive predictive value (0.47).

Agents Related to Anticholinergic Toxidrome

Agents related to anticholinergic toxidrome include (1) tricyclic antidepressants, (2) antipsychotics, and (3) **antihistamines**.

T ese agents have divergent therapeutic applications. However, in overdose, they often share similar anticholinergic and antihistaminic toxidromes as principal components of their overall toxic effects.

Tricyclic Antidepressants and Related Drugs

Tricyclic antidepressants (TCAs) are so named because of their three-ring structure (Figure 31-4). T ey represent a class of drugs frequently prescribed for the treatment of depression. T e N-demethylated metabolites of several tricyclic antidepressants are pharmacologically active and contribute variably to overall pharmacodynamic activity (see Chapter 30). Because TCAs have had a history of problems with toxicity, they have been largely supplanted by newer, less toxic agents. However, because of (1) their continued use as an inexpensive alternative to new-generation antidepressants, (2) their narrow therapeutic range, and (3) the nature of the illness for which they are typically prescribed, TCAs are frequently associated with severe or fatal toxicity.

T e therapeutic mechanism of tricyclic antidepressants is the blockade of neuronal reuptake of serotonin and/or norepinephrine. However, TCAs have many other pharmacological actions, including (1) anticholinergic; (2) antihistaminic; (3) α_1-receptor blocker actions; (4) inhibition of the GABA channel; and (5) of cardiac potassium ef ux and fast sodium channels. T ey apparently do not contribute to therapeutic effects, but they do contribute to adverse effects, both at therapeutic dosing and in overdose.

Analytical Methods

Tricyclic antidepressants are measured by chromatographic methods or by immunoassay. Immunoassays are rapid and relatively easy to perform but may be subject to interference by other drugs,[13] and they cannot necessarily be used to identify which TCA is being quantitated. In cases of overdose, qualitative identification (serum or urine) is sufficient because the severity of intoxication is more reliably indicated by an increase in the QRS interval than by the serum concentration.

Cyclobenzaprine, a tricyclic amine that is structurally very similar to amitriptyline (see Figure 31-4), is used as a centrally acting skeletal muscle relaxant. Similar to amitriptyline, cyclobenzaprine (1) causes sedation, (2) produces central and peripheral muscarinic blockade, and (3) potentiates adrenergic actions. In overdose, cyclobenzaprine may cause (1) a typical anticholinergic toxidrome, (2) cardiac arrhythmias, (3) hypotension, and (4) coma. The analytical distinction between amitriptyline and cyclobenzaprine is often difficult. Cyclobenzaprine cross-reacts with immunoassays for tricyclic antidepressants; however, it is possible to distinguish between them by using chromatographic methods.[13]

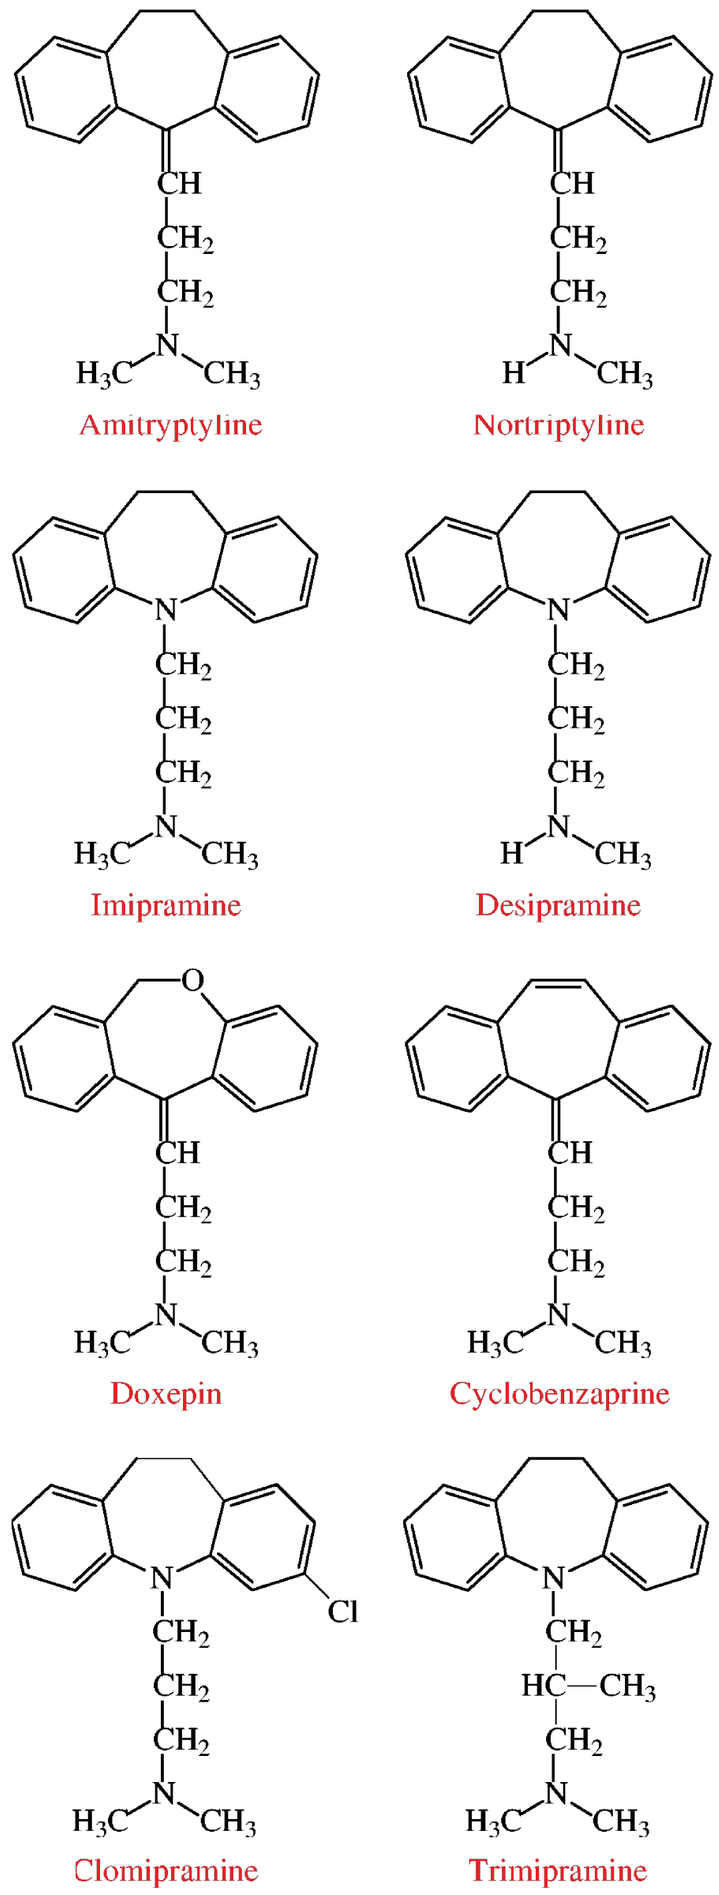

Figure 31-4 Structure of tricyclic antidepressants and related drugs.

Antipsychotic Drugs

Antipsychotic drugs are generally used for numerous psychiatric disorders. In addition to their psychotherapeutic effects, certain members of this group are used for other indications.[13]

Antipsychotic compounds are traditionally divided and subdivided according to their chemical structure (Table 31-6 and Figure 31-5).

T e principal manifestations of phenothiazine toxicity involve the CNS and the cardiovascular system. T e presentation for most of these drugs is related to their mechanisms of action, which include (1) dopamine blockade (CNS depression), (2) α_1-blockade (hypotension and miosis), (3) anticholinergic blockade (tachycardia), and (4) K-ef ux blockade (QT prolongation). Toxicity is strongly correlated with peak serum concentrations.

Neuroleptics are measured by chromatographic methods and by immunoassay. Chromatographically, GC methods with (1) nitrogen phosphorus (NP), (2) electron capture (EC), and (3) MS detectors are used, along with HPLC, LC-MS, and LC-MS/MS methods.[13]

TABLE 31-6 Examples of Classical and Atypical Antipsychotics

Antipsychotics	Examples
Classical Antipsychotics	
Phenothiazines	Chlorpromazine
	Promethazine
	Trichlorperazine
	Perphenazine
	Fluphenazine
	Thioridazine
	Mesoridazine
	Trifluoperazine
Thioxanthenes	Flupenthixol
	Zuclopenthixol
Dibenzoxazepine	Loxapine
Dihydroindole	Molindone
Butyrophenones	Droperidol
	Haloperidol
Diphenylbutylpiperidines	Pimozide
Benzamides	Sulpiride
Atypical Antipsychotics	
Dibenzodiazepine derivatives	Clozapine
	Olanzapine
Benzothiapine derivatives	Quetiapine
	Zotepine
Benzisoxazole derivatives	Risperidone
Benzothiazole piperazine	Ziprasidone
Imidazolindone derivatives	Setindole

Antihistamines

Antihistamines are medications that are popular among the general public for treatment of allergic reactions and as common sleep aids. Antihistamines are widely available, and many do not require a prescription. Histamine is released from mast cells and plays an important physiological role in immediate hypersensitivity and allergic responses. Histamine functions as a neurotransmitter in the CNS and stimulates gastric acid secretion. Currently available antihistamine drugs clinically antagonize H_1 and H_2 histamine receptors. First-generation liphophilic antihistamines, such as diphenhydramine (Benadryl), bind H_1 receptors, exhibit peripheral and central nervous system effects, and bind to muscarinic and adrenergic receptors, resulting in anticholinergic activity. The principal H_2 receptor response is stimulation of gastric acid secretion, whereas other actions of histamine such as (1) smooth muscle contraction, (2) vasodilation, (3) increased capillary permeability, (4) pain, and (5) itching are primarily mediated by H_1 receptors. Second-generation antihistamines, such as fexofenadine (Allegra), are highly specific for peripheral H_1 receptors and do not penetrate the CNS. Therefore, second-generation H_1 receptor antagonists display minimal **sedative** and anticholinergic effects. Individuals overdosed with first-generation H_1 antihistamines present clinically with CNS depression or stimulation and peripheral anticholinergic effects.

Commonly available antihistamines are detected qualitatively and quantitatively in blood and urine specimens. Methods of choice for their measurement include GC-MS/MS, and LC-MS/MS. However, the clinical necessity of quantitative serum antihistamine concentrations is questionable, as poor correlation has been noted among patient's (1) age, (2) dose, (3) blood concentration, (4) clinical effects, and (5) death. Antihistamines are detected by forensic laboratories as agents potentially used in facilitating sexual assault.

Although detection of antihistamines is not typically clinically relevant for the acutely toxic patient, it is important to note that very high concentrations of first-generation antihistamines, such as promethazine and diphenhydramine, have been documented to cross-react with urine drug immunomethods used for screening purposes. Therefore, physicians and medical review officers (MROs) should be aware of potential false-positive results from on-site drug testing devices, as well as immuno-screening methods for (1) **amphetamine**, (2) propoxyphene, and (3) tricyclic antidepressants.

Antimuscarinic Agents

Besides numerous pharmaceutical agents, several plant and mushroom species contain antimuscarinic compounds that mimic anticholinergic symptoms when ingested. Plants are commonly ingested or brewed as tea. Patients are clinically managed on the basis of clinical presentation, rather than by identification of ingested plants or drug-specific testing. Testing for atropine and scopolamine is performed by LC-MS methods.

Agents Related to Cholinergic Toxidrome

Agents inducing cholinergic toxidrome are diverse and act by producing uncontrolled acetylcholine transmission through inactivation of cholinesterase enzymes or direct stimulation of acetylcholine receptors. Acetylcholine is an essential neurotransmitter that affects (1) parasympathetic synapses (autonomic and central nervous systems), (2) sympathetic preganglionic synapses, and (3) the neuromuscular junction (see also prior section, "Toxic Syndromes"). Clinical manifestations in cholinergic toxidrome include (1) muscarinic, (2) nicotinic, and (3) central effects (see Table 31-2). The duration of acetylcholine action is controlled by acetylcholinesterase and butyrylcholinesterase/pseudocholinesterase (see Chapter 19). Acetylcholinesterase is found in (1) red blood cells, (2) nervous tissue, and (3) skeletal muscle. Butyrylcholinesterase is found in (1) plasma, (2) liver, (3) heart, (4) pancreas, and (5) brain.

Organophosphate and Carbamate Compounds

Organophosphate insecticides are toxic because they inactivate acetylcholinesterases that are required for hydrolyzing acetylcholine at nerve junctions. This inhibition is a consequence of phosphorylation of the serine hydroxyl group at the active site of the cholinesterase enzyme catalytic triad (Ser-Glu-His). Subsequent hydrolysis results in irreversible dealkylation of AChE. Although carbamates are structurally different from organophosphates, carbamates exert their toxicity at the active site of AChE but inhibit enzyme activity through carbamylation rather than phosphorylation of the serine hydroxyl group. Regeneration of

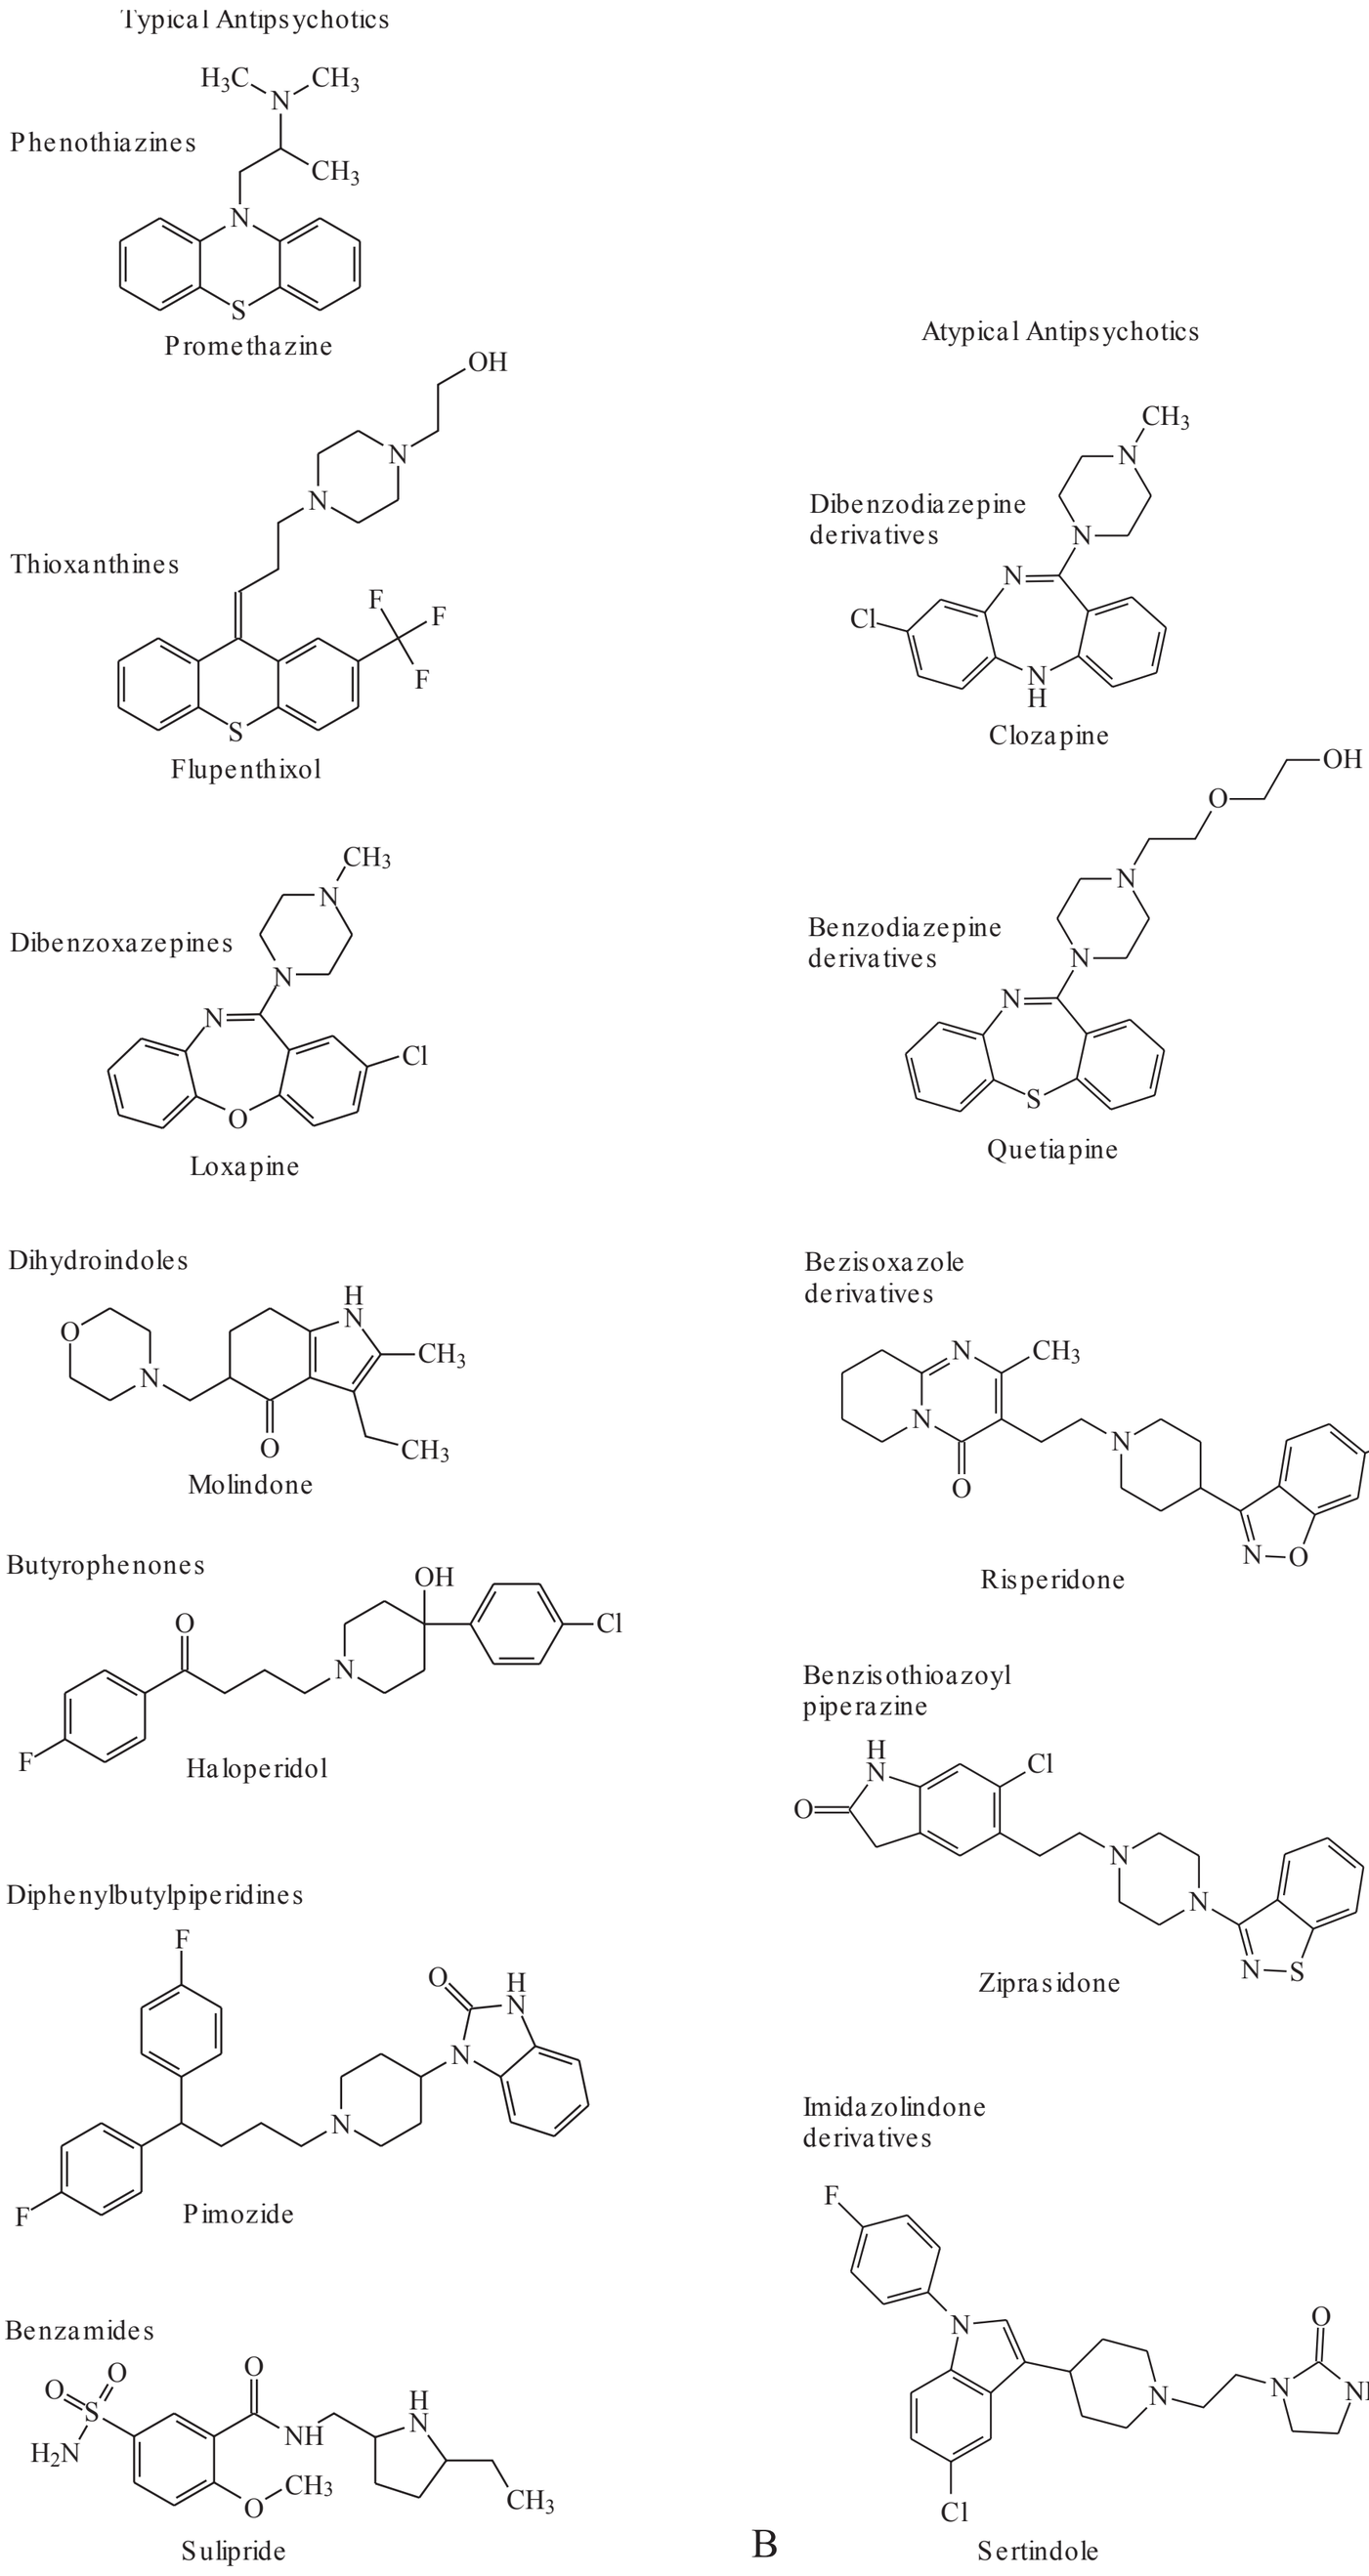

Figure 31-5 Classifcation and structure of select antipsychotic drugs. A, Typical antipsychotics. B, Atypical antipsychotics.

enzyme activity occurs in hours rather than days. Carbamates exhibit poor CNS penetration and have a shorter duration of action. In addition, their neurotoxicity is usually less severe.

Excess synaptic acetylcholine stimulates muscarinic receptors (peripheral and central nervous systems) and stimulates but then depresses or paralyzes nicotinic receptors. Activation of peripheral muscarinic receptors causes signs and symptoms described by the mnemonics SLUDGE (Salivation, Lacrimation, Urination, Defecation, GI distress, Emesi) or DUMBBELS (Diarrhea, Urination, Miosis, Bradycardia, and Bronchorrhea-bronchoconstriction, Emesis, Lacrimation, Sweating-salivation). Stimulation or paralysis of nicotinic receptors at the neuromuscular junction causes (1) muscle twitching, (2) cramping, (3) weakness, and (4) respiratory muscle paralysis. Stimulation of nicotinic receptors at sympathetic ganglia results in (1) hypertension, (2) tachycardia, (3) pallor, and (4) mydriasis. Thus, the actual signs and symptoms observed with these toxins depend on the balance of muscarinic and nicotinic receptor activation.

Diagnosis of organophosphate and carbamate toxicity depends mainly on (1) exposure history, (2) physical presentation, (3) clinical suspicion, and (4) laboratory support. Specific therapy for organophosphate and carbamate insecticide poisoning includes administration of atropine to block the muscarinic (but not the nicotinic) actions of acetylcholine. In addition, pralidoxime is given to reactivate cholinesterase in organophosphate poisoning. Treatment requires immediate attention and should not rely on **confirmatory testing** by the laboratory. Yet cholinesterase activity is often monitored by clinicians in occupational exposure, acute intentional and accidental exposure, and response to therapy.

Cholinesterase activity is measured to assess exposure and to monitor reactivation during treatment. Acetylcholinesterase and butyrylcholinesterase enzyme activities are typically monitored using spectrophotometric analyses (see Chapter 19). Acetylcholinesterase activity present at nerve junctions is similar to that present in red blood cells and is an appropriate index of neurotoxicity. This assay is more sensitive than serum cholinesterase activity and often is used to confirm exposure and to predict enzyme reactivation during treatment. Butyrylcholinesterase (pseudocholinesterase), also present in serum, is inhibited by these insecticides. The activity of butyrylcholinesterase declines then returns to normal more rapidly than is observed for the red cell enzyme. Serum butyrylcholinesterase is readily measured on hemolyzed samples and in clinical laboratories without isolation of red blood cells. However, interindividual variability is high; therefore pre-exposure activities are optimal when butyrylcholinesterase activities are interpreted. Because butyrylcholinesterases are synthesized in the liver, this assay is particularly sensitive to interferences associated with pregnancy and liver disease such as (1) acute and chronic hepatitis, (2) cirrhosis, and (3) malignancy. Thus, red cell cholinesterase activity theoretically should correlate more closely with the degree of neurotoxicity. In acute poisoning, symptoms generally begin when cholinesterase activity is inhibited by about 50% of the lower limits of the reference interval, and this degree of inhibition is of diagnostic value. However, the degree of cholinesterase inhibition generally does not correlate well with the clinical severity of poisoning. Interpretation of test results is made more difficult by considerable individual variability of reference activities. The presence of urinary organophosphate and carbamate metabolites is generally assessed by GC-MS and GC-MS/MS. These methods are labor-intensive and typically are reserved for monitoring chronic occupational exposure to specific agents rather than for emergency management of acute toxicity.

Drugs of Abuse

Many definitions exist for the term "drugs of abuse." For this chapter, this term is defined as "a drug that is repeatedly and deliberately used in a way other than prescribed or socially sanctioned (i.e., a drug that is taken for nonmedicinal reasons)." The spectrum of drugs tested includes (1) tricyclic antidepressants, (2) **barbiturates**, (3) **benzodiazepines**, (4) **methadone**, (5) **methylenedioxymethamphetamine (MDMA),** (6) **methylenedioxyethylamphetamine (MDEA),** (7) oxycodone, (8) amphetamine, (9) **cocaine**, (10) **marijuana**, (11) opiates, and (12) **phencyclidine**. Note: these last 5 drugs are known collectively as the SAMHSA (Substance Abuse and Mental Health Services Administration) or NIDA (National Institute on Drug Abuse).[5] They are the drugs for which tests are required under the Department of Transportation's (DOT) rule, 49 CFR Part 40, regulations.

Testing for drugs of abuse usually involves analyzing a single urine specimen for various drugs. It should be noted, however, that a single urine drug test detects only fairly recent drug use and does not differentiate casual use from chronic drug abuse. The latter requires sequential drug testing and clinical evaluation. Moreover, urine drug testing alone cannot determine (1) the degree of impairment, (2) the dose of drug taken, or (3) the exact time of use. Because of these and other limitations of testing for drugs in urine, integrating the use of alternate biological specimens for drug testing is a matter of growing interest (see later section on alternate specimens).

Several techniques have been used to mask or adulterate samples to avoid detection. These include (1) exchange of urine from a drug-free individual, (2) dilution of the urine specimen by excessive consumption of water, (3) dilution by addition of water to the specimen, and (4) use of a diuretic. Also, readily available adulterants, such as (1) detergent, (2) bleach, (3) salt, (4) alkali, (5) ammonia, (6) tetrahydrozoline, or (7) acid, may be added to the specimen after collection in an attempt to interfere with immunoassay screening procedures. Other adulterants specifically marketed to avoid drug detection include those that contain (1) glutaraldehyde, (2) nitrite, (3) chromate, and (4) a combination of peroxide and peroxidase.[13] These adulterants also interfere with immunoassays to a variable degree, and the oxidizing agents may result in destruction of morphine, codeine, and the principal metabolite resulting from marijuana use, thus interfering with their GC-MS or LC-MS confirmatory testing.

Direct observation of urine collection is the most stringent means to guard against specimen exchange or adulteration.

However, an individual's right to privacy and dignity must be weighed against the need for the highest degree of certainty of specimen integrity. Alternative measures to prevent specimen adulteration include (1) limitations on clothing or other personal belongings allowed in the specimen collection area, (2) addition of coloring agent to toilet water, and (3) inactivation of the hot water tap. In addition, several validity checks for specimen integrity may be made at the collection site and at the testing site. Validity testing criteria have been established by the U.S. Department of Health and Human Services (DHHS) for the drug testing program mandated for U.S. federal employees.[8] Numerous commercial reagents for validity testing are available in both test strip and liquid forms. Detailed information on the collection and processing analytes to be tested and on storage of specimens for drug testing has been presented in the federal rules for employee drug testing[8] and in the federal regulations promulgated by the Department of Transportation and the Nuclear Regulatory Commission. Testing programs for participants engaged in athletic competition typically are much more extensive.

Initial screening tests for the previously listed drugs are typically immunoassays (see Chapter 15). These assays are calibrated at established cutoff concentrations. Specimens yielding responses greater than the cutoff (threshold) value are considered "presumptively positive," whereas values below the cutoff are considered negative. Immunoassays may demonstrate limited and variable specificity within certain drug classes. Similar drugs may result in a positive test, for example, pseudoephedrine, present in cold medications, may produce a positive response in immunoassays designed to detect amphetamine and **methamphetamine**. Therefore, it is important that positive screening tests be confirmed by an alternate, more definitive test. The most widely accepted method for confirmatory testing is GC-MS; however, LC-MS/MS is also used and accepted.

In the following sections, the pharmacological and analytical aspects of commonly measured drugs will be discussed.

Barbiturates

The success of barbital in 1903 and phenobarbital (Figure 31-6) in 1912 led to the synthesis and testing of more than 2500 barbiturate derivatives, of which approximately 50 were distributed commercially. However, because of their low therapeutic index and high potential for abuse, they have been largely replaced by the much safer benzodiazepines. Nevertheless, barbiturates continue to be available.[13] The classification of barbiturates as (1) ultra-short-acting, (2) short-acting, (3) intermediate-acting, and (4) long-acting refers to the duration of effect, not to the elimination half-life (Table 31-7). The barbiturates produce all degrees of depression of the CNS, ranging from mild sedation to general anesthesia.

Analytical Methods

Screening

Numerous commercial immunoassays for barbiturates are available, and although the degree of cross-reactivity of other barbiturates varies with each assay, most have sufficient cross-reactivity to detect the major therapeutically used barbiturates.

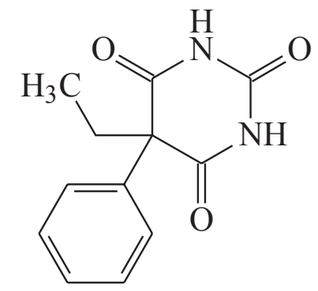

Figure 31-6 Structure of phenobarbital.

TABLE 31-7 Half-life and Significant Active Metabolites of Select Barbiturates

Drug	Half-life	Active Metabolite
Ultrashort-Acting		
Thiopental	6-46 hours	Pentobarbital
Methohexital	1.2-2.1 hours	
Thiamylal	0.6-0.8 hours initial 12-34 hours terminal	
Short-Acting and Intermediate-Acting		
Pentobarbital	15-48 hours	
Secobarbital	22-29 hours	
Butalbital	35-88 hours	
Aprobarbital	14-34 hours	
Amobarbital	15-40 hours (dose dependent)	
Butabarbital	34-42 hours	
Long-Acting		
Phenobarbital	2-6 days	
Mephobarbital	48-52 hours	Phenobarbital

Confirmatory Testing

Numerous confirmatory methods for barbiturates have been described. These include (1) GC with flame ionization detection, nitrogen phosphorous detection, and MS detection; (2) capillary electrophoresis-ultraviolet (UV) detection; (3) liquid chromatography using ultraviolet (LC-UV) detection; and (4) LC-MS.[13]

Benzodiazepines

Benzodiazepines include any of a group of compounds that have a common molecular structure and act similarly as depressants of the CNS. The prototype benzodiazepines are diazepam and nordiazepam (N-desmethyldiazepam) (Figure 31-7). Over 30 members of this group are presently used worldwide. Commonly used ones are listed in Table 31-8. As a class of drugs, benzodiazepines are among the most commonly prescribed drugs in the Western hemisphere because of their (1) efficacy, (2) safety, (3) low addiction potential, and (4) minimal side effects, and (5) because of the high public demand for sedative and anxiolytic agents. They have largely replaced barbiturates for sedative-hypnotic use because they (1) have fewer side effects, (2) cause fewer problems with liver enzyme induction, and (3) are safer in occurrences of overdose. New-generation sedative-hypnotics such as (1) zolpidem (Ambien), (2) eszopiclone (Lunesta), and (3) zaleplon (Sonata) modulate the $GABA_A$

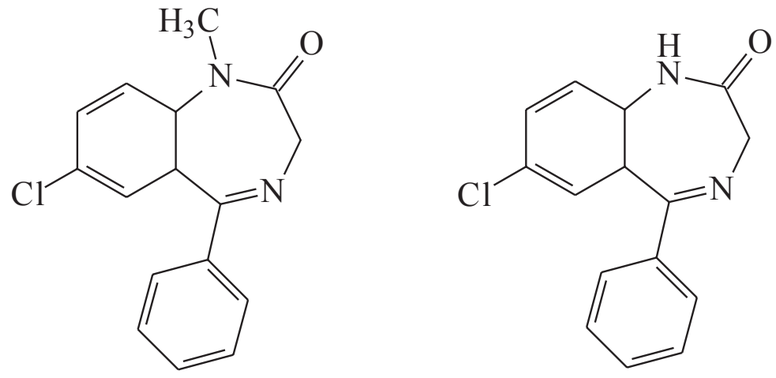

Figure 31-7 Structure of (A) diazepam and (B) nordiazepam.

receptor, as do benzodiazepines, yet they are structurally different, permitting unique physiological properties that will be discussed in a subsequent section (see "Drugs Used in Sexual Assault"). The benzodiazepines given by themselves or in combination with other drugs, particularly narcotic analgesics (opioids), are among the most widely abused drugs.

Benzodiazepines may be divided into three categories based on their onset time and elimination half-lives: (1)short-acting agents, (2) intermediate-acting agents, and (3) long-acting agents (see Table 31-8). These pharmacokinetic properties in part determine the primary clinical applications for some benzodiazepines.

Treatment of benzodiazepine toxicity is primarily supportive. Flumazenil may be used in select cases and is a competitive inhibitor of the benzodiazepine site on the GABA complex. It finds its greatest utility in the reversal of benzodiazepine-induced sedation from minor surgical procedures. However, flumazenil should not be administered as a nonspecific coma-reversal drug and should be used with extreme caution after intentional benzodiazepine overdose because it has the potential to precipitate withdrawal in benzodiazepine-dependent individuals and/or to induce seizures in those at risk.

TABLE 31-8 Half-life of Select Benzodiazepines

Drug	Half-life, hours	Significant Phase I Metabolites
Short-Acting		
Midazolam	1-4	α-Hydroxy-midazolam
Estazolam	10-24	3-Hydroxy-estazolam
Flurazepam	1-3	Hydroxy-ethyl-flurazepam
	47-100 (N-desalkyl-flurazepam)	N-desalkyl-flurazepam*
Temazepam	3-13	
Triazolam	1.8-3.9	α-Hydroxy-triazolam
Intermediate-Acting		
Flunitrazepam†	9-25	7-Amino-flunitrazepam
Long-Acting Agents		
Diazepam	21-37	Nordiazepam*
		Oxazepam*
		Temazepam*
Quazepam	39-53	3-Hydroxy-quazepam
		N-desalkyl-2-oxo-quazepam
		2-Oxo-3-hydroxy-quazepam
Alprazolam	6-27	α-Hydroxy-alprazolam
Chlordiazepoxide	6-27	Nordiazepam*
		Oxazepam*
Clonazepam	19-60	7-Amino-clonazepam
Clorazepate‡	2	Nordiazepam*

Analytical Methods

Benzodiazepines are measured through a variety of techniques. However, their structural diversity and wide variation in potency provide a challenge for laboratories seeking to detect all relevant members in one analytical scheme. Reviews of analysis of benzodiazepines have been published.[6,7,14] These cover the range of techniques used to screen for the presence of the class of drugs and to confirm the presence of one or more members.

Screening

Several commercial immunoassay systems are available for detection and screening for a wide variety of benzodiazepines and metabolites, but they differ in their ability to detect (1) the various benzodiazepines, (2) their metabolites, and (3) glucuronide conjugates.[6] Cross-reactivity in screening immunoassays of the various benzodiazepines and their metabolites varies considerably from manufacturer to manufacturer, and screening assays cannot be used to distinguish between the individual benzodiazepines. Most assays are calibrated to a common metabolite such as (1) oxazepam, (2) temazepam, or (3) nordiazepam. However, the large number of different functional groups that may be present on the benzodiazepine nucleus makes it difficult to detect all drugs in this class, and some compounds such as (1) midazolam, (2) chlordiazepoxide, and (3) flunitrazepam may not be detected by many assays. Other factors, such as low doses and short half-lives, make the detection of some benzodiazepines especially challenging. In the absence of sufficiently sensitive or specific immunoassays, direct analysis by a confirmatory method is warranted in suspected cases.

It should be noted that benzodiazepines may be identified and quantified in serum, but such quantitative information is not warranted in cases of benzodiazepine overdose because serum concentrations are not predictive of the severity of intoxication. However, a urine or serum immunoassay screening test for benzodiazepines is valuable in the evaluation of patients with an unknown cause of CNS depression.

Confirmatory Testing

Analysts need to be aware that the specimen type will dictate the target substance. Blood analyses invariably will target the parent benzodiazepine and perhaps the major active metabolite (e.g., nordiazepam for diazepam and other analogues metabolized to nordiazepam). This applies similarly to

analyses targeted for saliva. In urine, a metabolite is often the required target species.

Benzodiazepines and their metabolites have been extracted from biological specimens by liquid-liquid extraction (LLE) or solid-phase extraction (SPE). When urine specimens are analyzed by GC-MS, a hydrolysis step is necessary to cleave the glucuronide conjugates. Enzymatic hydrolysis is preferred over acid hydrolysis because some benzodiazepines are unstable and rearrange to form benzophenones.

Many benzodiazepines are analyzed without derivatization by GC; these include (1) diazepam, (2) nordiazepam, (3) flurazepam, and (4) alprazolam. Drugs that are more polar, including those with hydroxyl groups such as (1) oxazepam, (2) temazepam, and (3) lorazepam or a nitro group (clonazepam, nitrazepam), display poor chromatographic characteristics and require derivatization. Chlordiazepoxide is thermally unstable and may degrade at high temperatures in the GC. Some consider GC-MS as the definitive confirmatory method; however, LC with UV detection (240 nm) has been used to detect benzodiazepines and metabolites without derivatization. LC-MS and LC-MS/MS are becoming increasingly useful and popular methods for benzodiazepine parent drugs and their metabolites.

Cannabinoids

Cannabinoids are a group of compounds found in the marijuana plant Cannabis sativa. Cannabis is the most extensively abused illicit drug in the world. Cannabis has been used for centuries as a medicinal and a psychotropic agent. T e main psychotropic effects are (1) euphoria, (2) distorted perceptions, (3) relaxation, and (4) a feeling of well-being.

Delta-9-tetrahydrocannabinol (THC) is the primary psychoactive component of the C. sativa plant (Figure 31-8). It binds to the endogenous cannabinoid receptors, CB1 (neuronal) and CB2 (immune cells). T ese transmembrane receptors are G-protein–coupled receptors that mediate signal transduction through inhibition of adenylate cyclase and calcium ions, and through activation of potassium ion channels. T e distribution pattern of CB1 receptors in the CNS accounts for most of the clinical effects of THC such as those affecting (1) mood, (2) memory, (3) cognition, (4) pain, and (5) appetite. CB2 may regulate immune and inflammatory processes.

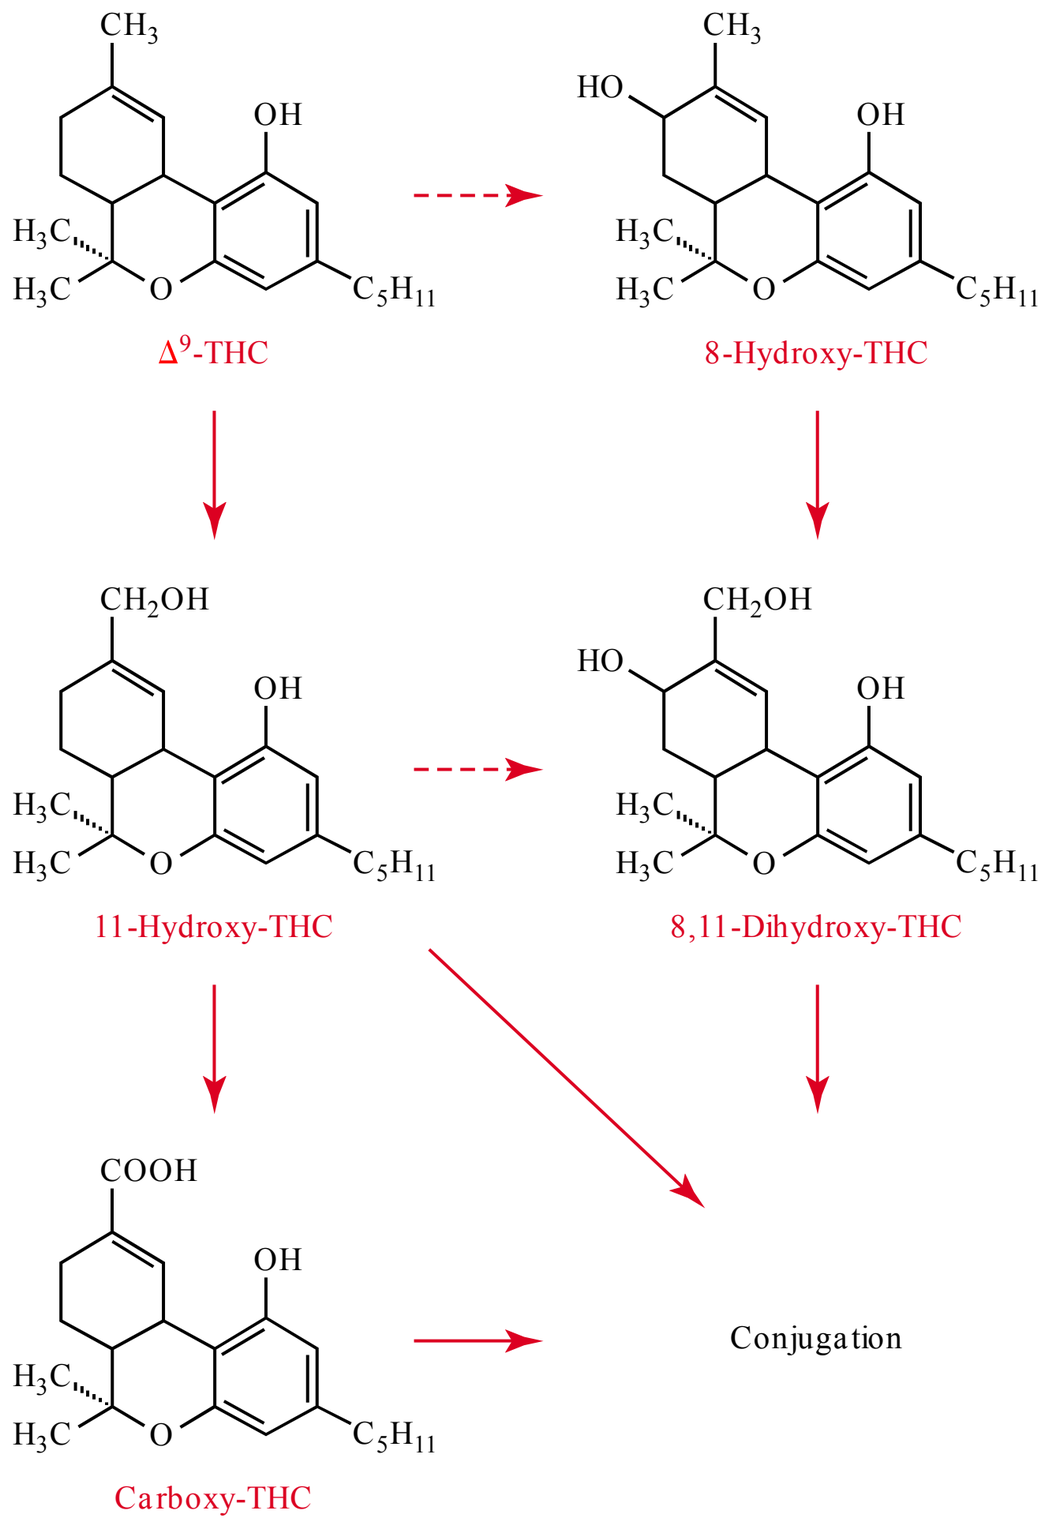

Figure 31-8 Principal metabolic route for delta-9-tetrahydrocannabinol (THC) in humans.

Pharmacological Response

When marijuana is smoked, THC diffuses into the plasma in seconds and is distributed into multiple phases. First, it distributes to highly vascularized tissues in minutes because of its lipophilic nature. THC then (1) is redistributed back into the bloodstream, (2) undergoes hepatic metabolism, and (3) slowly accumulates into less vascularized and fatty tissues. After cessation of marijuana smoking, THC and its metabolites are slowly released from fat stores.

T e main psychotropic effects after inhalation of marijuana occur within minutes and persist for several hours. T e peak plasma concentration of THC is dependent on the dose and occurs during the early acute phase (6 to 10 minutes). Numerous factors contribute to the variability in dose, such as (1) method of consumption, (2) depth of inhalation, (3) exposure frequency, and (4) cannabis potency. Onset of clinical symptoms and peak plasma concentrations after oral ingestion of THC is slower (2 to 6 hours) than after inhalation, primarily as the result of first-pass hepatic clearance. T e intensity of clinical effects described for smoked cannabis occurs during multiple phases. T ese phases are categorized as (1) acute (0 to 60 minutes), (2) postacute (60 to 150 minutes), and (3) residual (>150 minutes). T e ratio of THC to 11-nor-delta-9-tetrahydrocannabinol-9-carboxylic acid (THC-COOH) metabolite has been used to estimate the time of exposure to marijuana. T is approach may be useful in naive users but is unreliable in chronic abusers of marijuana.

Although marijuana is the most frequently used illicit drug, it does have some limited legitimate medicinal use. For example, dronabinol (Marinol) contains synthetic THC and is used to treat anorexia and nausea in patients with (1) acquired immunodeficiency syndrome (AIDS), (2) nausea and vomiting associated with chemotherapy, or (3) asthma and glaucoma. Measurement in urine of the principal THC metabolite, THC-COOH, present in cannabis but not in dronabinol has been proposed as a means to distinguish ingestion of marijuana from ingestion of Marinol.

Analytical Methods

An immunoassay method is typically used to screen for potential cannabinoid use in (1) workplace drug testing, (2) athlete drug testing, and (3) clinical specimens. A presumptive positive sample should be confirmed by quantitative GC-MS for at least THC-COOH. Confirmatory testing of quantitative concentrations of the parent compound, THC, is typically reserved for forensic samples.

Screening

Legitimate concern has been raised concerning the potential for false-positive results with "passive inhalation" from nearby users, or for use or consumption of hemp products causing positive results in cannabinoid screens and confirmatory analyses. Since 1998, the U.S. Federal Government has prohibited the importation of Cannabis sativa seeds and oil containing greater than 0.3% THC to reduce human exposure to THC. The concentration of THC consumed in drug use is 2% to 20%. Subsequent studies have suggested that these measures were successful in reducing potential positive cannabinoid drug screen results from dietary sources.

THC is metabolized by cytochrome liver enzymes to greater than 100 metabolites. The main active metabolite, 11-hydroxy-delta-9-THC, is further oxidized to the most abundant inactive THC-COOH (see Figure 31-8). Immunoassay screens have been designed to detect cannabis use in urine samples using antibody reagents developed against the inactive THC-COOH metabolite; these reagents cross-react with numerous other THC metabolites. Therefore the presence of multiple cannabinoid metabolites in a patient specimen will have an additive effect in immune-screen analyses, leading to screening results that estimate concentrations 1.5 to 8 times greater than the actual concentration of THC-COOH as determined by GC-MS.

A positive result from a urine cannabinoid screen or a positive result found by confirmatory testing does not indicate intoxication or degree of exposure. The window of detection for the urine concentration of THC-COOH varies among casual (2 to 7 days) and chronic abusers (up to 73 days) of marijuana and is dose dependent. Variables affecting the duration of detection include (1) dose, (2) frequency of exposure, (3) route of exposure, (4) body composition, (5) fluid excretion, and (6) method of detection. In practice, monitoring of abstinence is particularly challenging, as dilution of urine due to normal biological fluctuations (hydration) or ingested adulterants has caused a negative result one day and a positive on the next. To correct for hydration fluctuations, urine concentrations of THC-COOH are normalized per milligram creatinine in monitoring individuals who are resuming cannabis use. With the use of these normalized THC-COOH/creatinine concentrations, a ratio is calculated by comparing any normalized urine specimen (U2) with a previously collected normalized urine specimen (U1). "New use" is defined as a U2/U1 ratio $\geq$0.5 to 1.5 in urine specimens taken more than 24 hours apart and containing THC-COOH concentrations >15 ng/mL. Using the 1.5 cutoff rate results in decreased false-positive but increased false-negative decisions.

Confirmatory Testing

A positive screening result for THC obtained by immunoassay is confirmed by detection of THC-COOH by GC-MS/MS or LC-MS/MS analysis of the urine specimens.

Opiates and Opioids

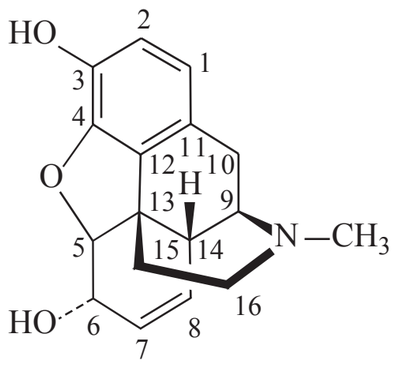
The term opioid describes compounds that encompass the natural and semi-synthetic opiates that include variations on the structure of morphine and fully synthetic opioids with minimal structural homology to the natural alkaloids (Figure 31-9). The defining characteristic of this class of drugs is their morphine-like activity stemming from interaction with opioid receptors. Other compounds that are referred to as "opioids" include receptor antagonists and mixed agonist/antagonists, as well as other opium-derived alkaloids such as papaverine.

Pharmacological Response

Opioids interact with the family of opioid receptors that are variably distributed throughout the body. Opioid receptor agonists typically produce analgesia, and antagonists block this response. Most opioids have both substantial addictive capacity and potentially life-threatening side effects. Thus the benefits of their use in non–end-stage patients must be carefully weighed against the chance of rather serious consequences. The development of tolerance and the risk of prescription diversion complicate even further the process of monitoring long-term opioid therapy for compliance and efficacy.[15]

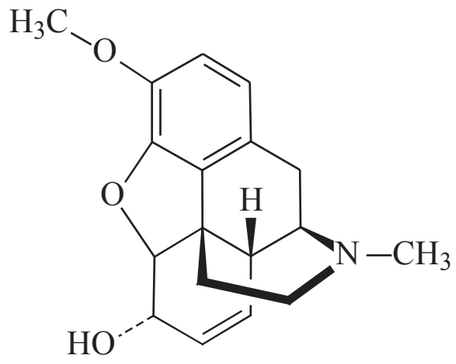
The metabolism of opioids is varied, but numerous biotransformations are common to these drugs. Several of the most commonly used opiates are formed in vivo by metabolism of other compounds, as seen with codeine demethylation resulting in conversion to morphine. This interconversion is a frequent source of confusion and must be considered when results of opiate screens are interpreted; specific details are provided below for key opioids with active metabolites.

One of the more important CYP cytochrome enzymes, CYP2D6, is particularly notable for its role in variable clinical response to opioids; it will be discussed in greater detail in a later section. Many additional CYP enzymes, including CYP3A and CYP2C and others, are involved in opioid metabolism. It is important to note that several of these enzymes are subject to substrate inhibition and/or induction. Substrate-dependent changes in metabolic activity are affected by (1) other drugs, (2) herbal supplements, and (3) endogenous compounds that are substrates of the same enzyme. For example, methadone concentrations may be lower than expected in a patient taking St. John's Wort—a noted CYP3A4 inducer—but higher in a patient ingesting a CYP3A4 inhibitor such as grapefruit juice.



Types of Opiates

Types of opiates include (1) natural opium alkaloids, (2) semisynthetic opiates, (3) fully synthetic opioids, and (4) opioid antagonists and mixed agonists/antagonists.



Natural Opium Alkaloids

Opiates are classified as phenanthrenes or benzylisoquinolines. The principal phenanthrenes are (1) morphine (10%

of opium), (2) codeine (0.5%), and (3) thebaine (0.2%). The principal benzylisoquinoline is papaverine (1%), which is a smooth muscle relaxant, and noscapine (6%).

Poppy seeds from the poppy plant Papaver somniferum contain morphine and to a lesser extent codeine. Because of first-pass metabolism, no pharmacological effect is experienced from poppy seed ingestion. Ingestion of bakery products containing poppy seeds leads to excretion of morphine (and codeine) in urine. In practice, caution is required when the results of a positive urine test for morphine and codeine are interpreted.

Morphine. Morphine is used as the basis of comparison for relative characterizations of the opioid class. Its major metabolites are glucuronide conjugates, including (1) inactive morphine-3-glucuronide (M3G; ≈60%), (2) active morphine-6-glucuronide (M6G; ≈10%), and (3) a small amount of morphine-3,6-diglucuronide mediated primarily by UGT2B7 (UDP-Glucuronosyltransferase-2B7), but also to a lesser extent by UGT1A3 (UDP-glucuronosyltransferase 1-3).[1,12] Note: The UGTs serve a major role in the conjugation and subsequent elimination of potentially toxic xenobiotics and endogenous compounds.

With long-term administration, and when morphine concentrations are high, a minor fraction is converted to hydromorphone (up to 2.5% of the urine morphine concentration). Therefore, glucuronides accumulate in serum to greater concentrations than morphine, and in patients with renal insufficiency, morphine glucuronides are thought to significantly contribute to opioid toxicity, as patients are unable to excrete the water-soluble metabolites. The detection time for morphine in urine is usually 48 to 72 hours, but this varies with individual differences in metabolism excretion and route and frequency of use.

Codeine. Because of its antitussive and analgesic properties, codeine is one of the most frequently prescribed opiates in the world; it is frequently combined with nonopiate analgesic agents such as aspirin and acetaminophen. Codeine has only about one-tenth the analgesic potency of morphine and is generally considered a prodrug.[3] The small fraction of codeine converted to morphine by CYP2D6 via O-demethylation is considered to be responsible for the analgesic effect. During the early phase of excretion, codeine and conjugates predominate, but after this time, morphine conjugates are the major product. Approximately three days after codeine use, morphine and its conjugates are the only metabolites detected.[3]

Genetic variation may play a significant role in the metabolism of codeine and several other opioids. More than 60 alleles have been described for CYP2D6, with resultant enzymatic activity ranging from essentially zero, in the case of null alleles, to many times higher than normal, in the case of amplified alleles (http://www.cypalleles.ki.se/cyp2d6.htm/; accessed on October 31, 2013). Thus, at the same codeine dose, patients with minimal CYP2D6 activity (poor metabolizers) would likely receive inadequate analgesia because of lack of conversion to morphine; however, patients with very high CYP2D6 activity would be at risk for adverse responses to excessive morphine. Without knowledge of the CYP2D6 genotype, these clinical presentations are confusing. Therefore, the possibility of pharmacogenetic effects is important to consider when (1) appropriate dosing, (2) patient compliance, and (3) potential diversion or illicit uses are assessed.

Semi-synthetic Opiates

Examples of semisynthetic opiates include (1) heroin, (2) hydrocodone, (3) hydromorphone, (4) oxycodone, and (5) oxymorphone.

Heroin. Heroin is a synthetic opiate that is made from morphine and is also called diacetylmorphine or diamorphine. It has an analgesic potency two to three times that of morphine because of its better penetration across the blood-brain barrier. This is penetration is the result of the two acetyl groups that enhance CNS distribution. Heroin is no longer legally produced in the United States, but it is still used elsewhere for fast-acting analgesia. Heroin itself is rarely found in body fluids because of its extremely short half-life (2 to 6 minutes). Given that acetylcodeine is a common contaminant of heroin, both morphine and low concentrations of codeine are frequently detected in urine after heroin use.[3]

A metabolite of heroin is 6-monoacetylmorphine (6-MAM). It is hydrolyzed to morphine, and although it has a longer half-life (6 to 25 minutes), it is detectable in urine only for about 8 hours after administration. Both 6-MAM and morphine are pharmacologically active, and 6-MAM is four to six times more potent than morphine. Because 6-MAM is a unique metabolite to heroin, its presence in the urine confirms that heroin was the opioid used.

Hydrocodone. Hydrocodone has about six times the potency and greater oral bioavailability than codeine[3] but it is thought to be more toxic than codeine. Similar to codeine, hydrocodone is metabolized by CYP2D6 to an active metabolite (hydromorphone) and therefore may be subject to pharmacogenetic variability in patients with abnormal CYP2D6 activity.

Hydromorphone. Oral hydromorphone is five to seven times more potent than morphine. Although it is used as an analgesic in its own right, hydromorphone is also an active metabolite of hydrocodone.[4] Similar to morphine, hydromorphone is metabolized in large part to a 3-glucuronide by UGT2B7, but also to a lesser extent by UGT1A3.[1,12] Hydromorphone lacks a free hydroxyl group at the 6-position. Two minor metabolites of hydromorphone—dihydromorphine and dihydroisomorphine—have demonstrated pharmacological activity, but their contribution may be minimal because of the small amount formed.[3]

Oxycodone. Oxycodone is a potent analgesic with high oral bioavailability that is frequently formulated in combination with aspirin or acetaminophen. Noncombination oxycodone is also available in immediate- and extended-release dosage forms. During illicit use, the pills may be (1) chewed, (2) crushed, (3) snorted, or (4) solubilized for IV injection to permit immediate availability of the entire dose, which is intended for extended release over a 12-hour period.[3]

Although its own strong analgesic activity precludes consideration of oxycodone as a prodrug, it is converted to the active metabolite, oxymorphone, through the activity of CYP2D6. This is conversion appears to be less of a concern for CYP2D6 poor metabolizers, in whom oxycodone itself still provides analgesia, than for ultra-rapid metabolizers.[3]

Oxymorphone. Oxymorphone provides potent analgesia with minimal interaction with CYP enzymes. Most oxymorphone is metabolized by UGT2B7 to the 3-glucuronide, which is a minor metabolite. 6-Hydroxyoxymorphone is an active analgesic with a steady-state area under the curve (AUC) similar to the parent compound. Oxymorphone is a metabolite of oxycodone that is formed via CYP2D6.

Fully Synthetic Opioids

Examples of fully synthetic opioids include (1) fentanyl, (2) meperidine, (3) methadone, (4) propoxyphene, and (5) tramadol.

Fentanyl. Fentanyl is a lipophilic drug with numerous routes of administration that is used in applications ranging from anesthesia to rapid management of breakthrough pain. It provides the structural backbone for a number of

opioids, including remifentanil and sufentanil. Norfentanyl, the primary metabolite, is generated by CYP3A and is inactive; the high potency of fentanyl and the clinical insignificance of its metabolites make it a preferred analgesic for patients with major organ failure. Transdermal fentanyl patches are used for longer-term administration among drug abusers, unfortunately, nonstandard application of the patch (e.g., chewing, extraction) carries substantial risk for overdose.

Meperidine. Originally synthesized as an anticholinergic, meperidine has analgesic potency comparable with or somewhat less than that of morphine. One major metabolite, normeperidine, also has analgesic activity. (1) It is thought to be responsible for the serotonergic toxicity of meperidine, (2) it is eliminated renally, and (3) its use results in seizure activity in patients with renal failure.

Methadone. A relatively long-acting opiate, methadone is used both for analgesia and in the treatment of opioid addiction. It is thought to provide (1) milder withdrawal, (2) somewhat lower potential for abuse, and (3) reduced exposure to the risks of illicit intravenous drug use. Substantial interindividual and intraindividual variability in metabolism and elimination has been noted. Both urine pH and seemingly self-inducible metabolism substantially influence the pharmacokinetics of this compound, as do commonly coadministered drugs such as benzodiazepines and antiretrovirals. Although a large fraction of methadone is excreted unchanged, measurement of a metabolite such as EDDP (2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine) in the setting of addiction treatment provides evidence of patient compliance rather than an exogenously spiked sample. EDDP excretion is less pH dependent than is clearance of the parent drug.[3] Use of the methadone/EDDP ratio to assess compliance has been suggested but is complicated by the pharmacokinetic variability already described.

Propoxyphene. A relatively weak analgesic, propoxyphene is less potent than codeine but carries significant risk of atypical adverse effects such as cardiac arrhythmia and seizure. The incidence of such negative responses is particularly high in the elderly. In November 2010, the FDA announced that medications containing propoxyphene were being withdrawn from the U.S. market.

Tramadol. Unlike most opioid agonists, tramadol has low abuse potential and therefore is unscheduled. It has low affinity for opioid receptors and mediates analgesia through opioid-independent regulation of neurotransmitter uptake; however, its main active metabolite (O-desmethyltramadol) is formed via CYP2D6 and is a potent opioid receptor agonist. These mechanisms are thought to work synergistically to provide greater total pain relief than the sum of each individual component. However, because of its effects on neurotransmission, tramadol has the potential to cause serotonergic toxicity. In fact, several synthetic phenylpiperidine opioids such as (1) tramadol, (2) methadone, (3) dextromethorphan, and (4) propoxyphene have been associated with increased risk of serotonin toxicity caused by weak reuptake inhibition of monoamines when used in combination with serotonin reuptake inhibitors, monoamine oxidase inhibitors, and amphetamine-type stimulants.

Opioid Antagonists and Mixed Agonists/Antagonists

These clinically useful compounds produce very different physiological responses, depending on the situation. For example, in opioid-naive patients, mixed agonists/antagonists (MAAs) provide μ-opioid receptor (MOR)-mediated analgesia with less risk of an adverse reaction, but the same dose in an opioid-tolerant patient may precipitate immediate withdrawal. In medical usage, coadministration of low-dose antagonists or MAAs alleviates minor opioid-induced side effects and appears useful in preventing opioid tolerance. In opioid addiction treatment, the addition of a low-dose antagonist to maintenance therapy seems to minimize subjective "feel-good" effects without substantially worsening withdrawal symptoms. Examples of opioid antagonists and mixed agonists/antagonists include (1) buprenorphine, (2) naloxone, and (3) naltrexone.

Buprenorphine. A semisynthetic derivative of thebaine, buprenorphine is an MOR partial analgesia. Low doses provide analgesia through MOR activation, but unlike full agonists, pain relief has a maximal threshold or "ceiling effect." Buprenorphine is available as sublingual tablets (with or without naloxone) for the treatment of opioid dependence. Buprenorphine is metabolized via N-dealkylation by CYP3A4 to the active compound, norbuprenorphine, both of which are further conjugated to inactive glucuronides by UGT1A1. CYP3A4 and UGT1A1 are subject to environmental and genetic variability, although the effects of these factors on buprenorphine are not well characterized. Only a small amount is found in urine, and it is usually detectable for 1 to 3 days.

Naloxone. Naloxone binds nonspecifically to all three opioid receptor types, with the greatest effect at MOR. Naloxone is commonly used in comatose patients as a therapeutic and diagnostic agent to (1) restore respiratory function, (2) protect the airway, and (3) improve level of consciousness, and (4) as an antidote for opioid intoxication. Its clinical efficacy lasts for as little as 45 minutes. Therefore, patients are at risk for recurrence of narcotic effect. This is particularly true for patients exposed to opioids with long elimination half-lives, such as methadone and sustained-release opioid products. Patients should be observed for re-sedation for at least 4 hours after reversal with naloxone. Because naloxone is renally eliminated, patients with renal dysfunction may have delayed re-sedation past 4 hours and therefore should be observed for a longer time.

Naloxone has been known to precipitate profound withdrawal symptoms in opioid-dependent patients. Its efficacy is much greater by intravenous administration as compared with oral and sublingual routes.

Naltrexone. Commonly used for the treatment of alcoholism, naltrexone is a potent antagonist of all three opioid receptors. Its combined formulation with opioid agonists is less common than are naloxone/opioid combinations; however, the greater oral bioavailability of naltrexone suggests that it may be useful in applications where poor oral delivery limits the utility of naloxone.

Analytical Methods

Many different immunoassay methods are used to screen for opiates. Gas chromatography (GC) with mass spectroscopic detection (GC-MS) is the technique of choice for confirmatory testing after a positive screening result.

Screening Assay

Given their ability to detect several opiates, immunoassays are the methods of choice to screen urine samples for their opiate content. Antibodies in opiate abuse screens commonly target morphine, and variability in cross-reactivity; thus some opiates or opioids (see Figure 31-9) with high abuse potential such as oxycodone are often poorly detected. For clinical application, a cutoff of 300 ng/mL morphine (or morphine equivalents) is commonly used to distinguish negative from positive urine specimens. Other general opiate screening methods are available, including thin-layer chromatography, but these techniques are more labor-intensive and may not provide adequate turnaround time for stat or emergency testing. In this setting, point-of-care devices are being used more frequently.

The cutoff concentrations used for drugs in federally regulated tests, in particular, opioids (2000 ng/mL), are too high to be of value in monitoring compliance of pain management patients or other clinical settings. Nonregulated testing of opioid cutoff concentrations (300 ng/mL) allows for a considerably more sensitive screening assay.[15] It is important for drug testing laboratories to communicate relevant aspects of the metabolic interconversion of opiates to physicians responsible for these programs. Monitoring compliance for oxycodone in pain management programs is problematic because of the low cross-reactivity of oxycodone in most opiate immunoassays. In this instance, a false-negative opiate immunoassay test may lead to an accusation of oxycodone diversion. Direct determination of oxycodone by a confirmatory method such as (1) GC-MS, (2) LC-MS, or (3) LC-MS/MS is more appropriate in monitoring compliance for this drug.[13]

Confirmatory Testing

For compound-specific confirmatory assays, GC-MS has historically been considered the method of choice. In addition, it is considered the reference method for determination of most natural and semi-synthetic opiates, particularly in forensic settings, although other detectors are available and have been used for GC applications. Despite the long-standing role of GC in opiate analysis, LC methods are common and are often analytically advantageous. One notable example is that LC provides the ability to analyze glucuronide-conjugated metabolites, as well as parent compounds. In addition, in practice, LC methods are used to measure polar metabolites without prior derivatization, and on-column extraction is possible with some LC systems. One trend in method development is the ability to quantitate/identify combinations of (1) morphine, (2) other opiates, and (3) opioids and their metabolites.[13]

Drugs of Abuse Related to the Sympathomimetic Syndrome

Several stimulants and hallucinogens chemically related to phenylethylamine are referred to collectively as amphetamine-type stimulants (ATSs). They are considered to be sympathomimetic drugs, as they mimic endogenous transmitters in the sympathetic nervous system. Amphetamine and methamphetamine (Figure 31-10) are CNS stimulant drugs that have limited legitimate pharmacological uses such as treatment for (1) narcolepsy, (2) obesity, and (3) attention-deficit hyperactivity disorders. They produce an initial euphoria and have a high abuse potential. Other sympathomimetic amines that have high potential for abuse include (1) ephedrine, (2) pseudoephedrine, and (3) phenylpropanolamine.

Amphetamine and Methamphetamine

These drugs have a stimulating effect on both the central and peripheral nervous systems. In the brain, a primary action is to elevate the concentrations of extracellular monoamine neurotransmitters such as (1) dopamine, (2) serotonin, and (3) norepinephrine. These drugs promote presynaptic release from the nerve endings rather than blockade of reuptake.[13] Amphetamine and methamphetamine are substrates for the dopamine, serotonin, and norepinephrine transporters.

Amphetamine and methamphetamine increase (1) blood pressure, (2) heart rate, (3) body temperature, and (4) motor activity, (5) relax bronchial muscle, and (6) depress the appetite. Abuse of these drugs may lead to (1) strong psychological dependence, (2) marked tolerance, (3) mild physical dependence associated with tachycardia, (4) increased blood pressure, (5) restlessness, (6) irritability, (7) insomnia, (8) personality changes, and (9) a severe form of chronic intoxication psychosis similar to schizophrenia. These unpleasant responses reinforce repetitive use of the drugs to maintain the "high." Tolerance and psychological dependence develop with repeated use of amphetamines. Long-term effects may include depression and impaired memory and motor skills, probably caused by a decrease in dopamine transporters and by damage to dopaminergic and serotonergic neurons.

The optical isomers of amphetamine and methamphetamine exhibit stereoselective pharmacological properties. The CNS activity of S(+) amphetamine (d-amphetamine) is three to four times greater than that of R(−) amphetamine (l-amphetamine), but the latter drug has more potent cardiovascular

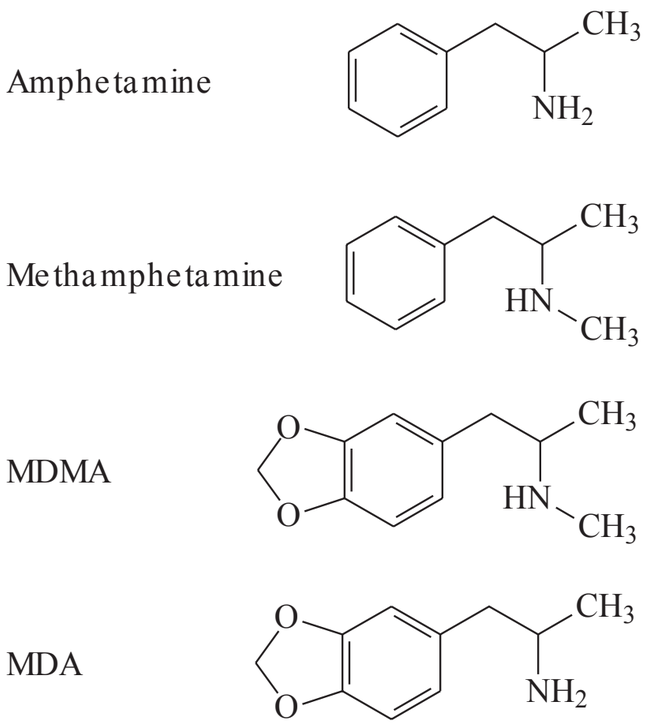

Figure 31-10 Select amphetamine-type stimulants.

effects than the former.[3] The CNS effects of S(+) methamphetamine (d-methamphetamine) are about 10 times greater than those of R(−) methamphetamine (l-methamphetamine), but the latter drug has greater vasoconstrictive properties than the former. Because of minimal CNS activity, low abuse potential, and vasoconstrictive properties, R(−) methamphetamine had been included in some nonprescription nasal inhalants (e.g., Vick's).

The main metabolic pathways of amphetamine and methamphetamine include (1) aromatic hydroxylation, (2) aliphatic hydroxylation, (3) N-demethylation, (4) oxidative deamination, (5) N-oxidation, and (6) conjugation of nitrogen. In addition to hepatic metabolism, amphetamine is eliminated as unchanged drug in urine. Elimination is dependent on urine pH.[3] Therefore, elimination half-life (renal excretion and hepatic metabolism) varies with urine pH from 7 to 14 hours at acid pH to 18 to 34 hours at alkaline pH.[13] These effects of urine pH on the elimination of unchanged amphetamines are a consequence of tubular reabsorption of nonionized amphetamine (pK_a, 9.9). Similarly methamphetamine is eliminated in urine in a pH-dependent manner, similar to that used for amphetamine.

Pharmacogenetics is thought to play a role in differences seen in the metabolism/elimination of these drugs. CYP2D6 is responsible for 4-hydroxylation of amphetamine and methamphetamine and N-demethylation of methamphetamine. However, the effects of methamphetamine are not reliably predicted from serum concentrations.

Ephedrine and Pseudoephedrine

These amines are diastereoisomers that possess two asymmetrical carbon atoms and exist as isomers designated as 1R,2S- and 1S,2R-ephedrine and 1R,2R- and 1S,2S-pseudoephedrine. The 1R,2S-ephedrine (ephedrine) and 1S,2S-pseudoephedrine (pseudoephedrine) isomers occur naturally in various plants of the Ephedra genus.

Ephedrine is both an α-adrenergic and a β-adrenergic receptor agonist. In addition, it enhances the release of norepinephrine from sympathetic neurons and is considered a mixed-acting sympathomimetic drug. Adverse effects such as (1) hypertension, (2) tremors, (3) myocardial infarction, (4) seizures, and (5) stroke have resulted in fatalities. Because of this, the FDA banned the sale of dietary supplements containing ephedra in 2004.

Pseudoephedrine is used primarily as a decongestant because of its vasoconstrictive properties (α-adrenergic action).[3] Pseudoephedrine is also used as a precursor for the illicit synthesis of methamphetamine. Because of this, the quantity per purchase of products containing these drugs is now restricted in many places.

PPA (Phenylpropanolamine)

PPA is a metabolite of ephedrine and pseudoephedrine and was once widely available in a number of nonprescription cold medications and diet control products. Adverse effects are similar to those described for ephedrine. In response to an FDA warning of increased risk of hemorrhagic stroke, PPA has been withdrawn from the market by most manufacturers.[3]

Designer Amphetamines

The terms "designer drugs" and "club drugs" originated in the 1980 and include derivatives of amphetamine-type stimulants such as (1) benzylpiperazine, (2) phenylpiperazine, and (3) pyrolidinophenone.[13] The moniker "club drug" does not imply that recreational use is restricted to this social environment. Most designer drugs (1) produce feelings of euphoria and energy and (2) a desire to socialize, (3) promote social and physical interactions, and (4) distort or enhance visual and auditory sensations. Designer drugs mistakenly have the reputation of being safe and several studies have revealed the increased risk of (1) serotonin syndrome, (2) hepatotoxicity, (3) neurotoxicity, and (4) psychopathology, and (5) the abuse potential of such drugs. Some of the more common designer amphetamines are listed in Box 31-2.

BOX 31-2 Designer Drugs Related to Phenylethylamine, Benzylpiperazine, Phenylpiperazine, and Pyrrolidinophenone[13]

Phenylethylamines
- 3,4-Methylenedioxymethamphetamine (MDMA; Ecstasy)
- 3,4-Methylenedioxyethylamphetamine (MDEA; "Eve")
- 3,4-Methylenedioxyamphetamine (MDA), which is also a metabolite of MDMA
- Paramethoxyamphetamine (PMA)
- Paramethoxymethamphetamine (PMMA)
- 2,5-Dimethoxy-4-methylamphetamine (DOM)
- 2,5-Dimethoxy-4-methylthioamphetamine (DOT)
- 4-Iodo-2,5-dimethoxyamphetamine (DOI)
- 2,5-Dimethoxy-4-bromo-amphetamine (DOB)
- 2,5-Dimethoxy-4-bromo-methamphetamine (MDOB)
- 3,4-(Methylenedioxyphenyl)-2-butanamine (BDB)
- N-Methyl-1-(3,4-methylenedioxy-phenyl)-2-butanamine (MBDB)
- 6-Chloro-3,4-methylenedioxymethamphetamine (Cl-MDMA)
- 3,4-Methylenedioxymethcathinone
- 4-Bromo-2,5-diemthoxy-phenylethylamine (2C-B)
- 2,5-Dimethoxy-4ethylthio-phenylethylamine (2C-T-2)
- 2,5-Dimethoxy-4 propylthio-phenylethylamine (2C-T-7)

Benzylpiperazines
- 1-Benzylpiperazine (BZP)
- 1-(3,4-Methylenedioxybenzyl)-piperazine (MDBP)

Phenylpiperazines
- 1-(3-Trifluoromethylphenyl)piperazine (TFMPP)
- 1-(3-Chlorophenyl)piperazine (mCPP)
- 1-(4-Methoxyphenyl)piperazine (MeOPP)

Pyrrolidinophenone
- α-Pyrrolidinopropiophenone (PPP)
- 4-Methoxy-α-pyrrolidinopropiophenone (MOPPP)
- 3,4-Methylenedioxy-α-pyrrolidinopropiophenone (MDPPP)
- 4-Methyl-α-pyrrolidinopropiophenone (MPPP)
- 4-Methyl-α-pyrrolidinohexanophenone (MPHP)

Methylphenidate (Ritalin)

Methylphenidate (MPH) is a phenethylamine derivative with psychostimulant properties similar to those of S(+) amphetamine. It is commonly used to treat attention-deficit hyperactivity disorder (ADHD) and narcolepsy.[3] Like many of its related amphetamine-type stimulants, it exists as an isomer, as (R,R)-methylphenidate (d-MPH) and as (S,S)-methylphenidate (l-MPH). The pharmacological actions of MPH are almost solely performed by the d-isomer. Diversion and abuse of methylphenidate have been increasing among children and adults because of its stimulant and purported aphrodisiac properties. In overdose, the clinical effects of methylphenidate are similar to those of amphetamines.

Analytical Methods

The initial screening test for amphetamines and related drugs is typically immunoassay. For confirmatory testing of a presumptive positive test, a quantitative drug measurement is performed using GC-MS.

Immunoassay. Most "amphetamine" immunoassays have been designed to detect amphetamine/methamphetamine; others have been designed to detect MDMA and MDA; and others to more broadly capture the ATS group—all with varying cross-reactivity. Not all amphetamine immunoassays were suitable for detection of the amphetamine-derived designer drugs PMA, PMMA, and MDEA, and especially not for the tryptamine, cathinones, and piperazine-derived substances. Alternatively, other chemically related compounds such as pseudoephedrine have been shown to produce positive results. Additionally, many psychotropic medications have been reported to interfere with immunoassays. Regarding methylphenidate, it should be noted that its detection by urine drug immunoassay is problematic, as it does not cross-react well with amphetamine immunoassays, and because of its low concentration.[3]

Confirmatory Methods. All positive immunoassay results should be confirmed by a second independent method. However, if the other designer amphetamines (see Box 31-2) are suspected, a negative amphetamine immunoassay screen cannot rule out the presence of these drugs. Fortunately, numerous GC- and LC-based methods for identification and quantitation of these drugs in biological samples have been described.[13]

Most published methods for analysis of members of the amphetamine class in (1) urine, (2) plasma, and (3) blood employ liquid-liquid extraction (LLE) or solid-phase extraction (SPE). Amphetamine-type stimulants are considered volatile and are lost during a dry-down or evaporation step during extraction. Also, because of their extreme volatility at the high temperatures encountered in GC-MS, derivatization before analysis lowers the limit of detection. Additionally, (1) the molecular weight of amphetamine-type stimulants, (2) the low intensity of their mass fragments in electron impact mode, and (3) the structural similarity of many endogenous and exogenous compounds result in a mass spectrum that is not highly characteristic. The issue of lack of specificity of the mass spectrum is resolved by derivatization. Although many derivatives are available for GC-MS use, the 4-CB derivative in the presence of ephedrine/pseudoephedrine may generate methamphetamine, which leads to the DHHS rule that amphetamine must also be detected before a positive methamphetamine result can be reported. The poor UV absorption properties of this class of drugs make it an unsuitable candidate for HPLC with UV detection, and it has no native fluorescence and no significant oxidative electrochemical properties at low voltages. However, LC-MS and LC-MS/MS have been gained in popularity.[13] Other prescription drugs that are metabolized to amphetamine or methamphetamine are listed in Table 31-9. Care must be taken in interpreting the results of drug screens.

Cocaine

Cocaine is an alkaloid found in Erythroxylon coca, which grows principally in (1) the northern South American Andes and to a lesser extent in (2) India, (3) Africa, and (4) Java. In clinical medicine, it is used for local anesthesia and vasoconstriction in nasal surgery, and to dilate pupils in ophthalmology. Cocaine abuse has a long history, and it iss still one of the most common illicit drugs of abuse.

Cocaine is sold on the street in two forms: (1) a hydrochloride salt (powder) and (2) a free-base product known as **crack cocaine**. The hydrochloride salt form of cocaine is administered by nasal insufation ("snorting") or, less frequently, intravenously. Crack is a free-base form and comes as a rock crystal that is heated and its vapors inhaled. The term refers to the crackling sound heard when it is heated.

It should be noted that "crack" cocaine is not to be confused with "free-basing," which is a process in which the user purifies cocaine HCl by mixing an aqueous solution of cocaine with baking soda or ammonia and adding diethyl ether, thereby extracting the free form of the drug into the organic solvent. However, because of the extremely flammable nature of diethyl ether, and therefore the risk of igniting any remaining ether, free-basing is no longer a common practice.

Chemically, cocaine is methylbenzoylecognine (COC). Its metabolism is complex (Figure 31-11) and occurs via both nonenzymatic hydrolysis and enzymatic transformation in the plasma and liver, producing both active and inactive metabolites. COC is rapidly metabolized to benzoylecgonine (BE) and ecogonine methyl ester, both of which are inactive. It should be noted that cocaethylene, produced when cocaine and ethyl alcohol are used simultaneously, possesses the same CNS

TABLE 31-9 Prescription Drugs That Are Metabolized to Amphetamine or Methamphetamine

Drug	Chemical Name	Drugs Detected
Adderall	Amphetamine	Amphetamine
Dexedrine	d-Amphetamine	d-Amphetamine
Deprenyl	Selegiline	l-Methamphetamine
		l-Amphetamine
Didrex	Benzphetamine	Methamphetamine
		Amphetamine

stimulatory activity as cocaine in experimental animals. Norcocaine (NC) is of clinical interest because of its conversion to potentially hepatotoxic metabolites: hydroxyl-norcocaine and then norcocaine-nitroxide.

BE has a half-life longer than that of COC. It is the most commonly monitored analyte in urine for determination of COC use. BE is further metabolized to minor metabolites such as m-hydroxybenzoylecgonine (m-HOBE), which has been shown to be an important metabolite in the meconium of cocaine-exposed babies. Anhydroecgonine methyl ester (AEME; methyl ecgonidine) has been identified as a unique COC metabolite after smoked COC ("crack") administration. Anhydroecgonine ethyl ester (AEEE; ethyl ecgonidine) has been identified in COC smokers who also use ethyl alcohol.

Pharmacological Response

Cocaine has cardiovascular effects and is a potent CNS stimulant that elicits a state of increased alertness and euphoria with actions similar to those of amphetamine but of shorter duration. These CNS effects are thought to be largely associated with the ability of cocaine to block dopamine reuptake at nerve synapses, thereby prolonging the action of dopamine in the CNS. It is this response that leads to recreational abuse of cocaine. Cocaine also blocks the reuptake of norepinephrine at presynaptic nerve terminals; this produces a sympathomimetic response. Sudden death due to cardiotoxicity may occur after cocaine use.[13] Death may also occur after the sequential development of hyperthermia, agitated delirium, and respiratory arrest. Excited delirium and extreme physical activity may lead to (1) rhabdomyolysis, (2) acute renal failure, and (3) disseminated intravascular coagulopathy.

The CNS and cardiovascular effects of cocaine exhibit acute tolerance; its effects are more pronounced when the concentration of cocaine in blood is increasing than when it is at a decreasing concentration (clockwise hysteresis). Thus, it is difficult to correlate isolated blood concentration values with psychomotor effects.[13]

COC is frequently used with other drugs, most commonly ethanol. This combination produces greater euphoria and an enhanced perception of well-being relative to COC. CE appears to be equipotent to COC with regard to dopamine transporter affinity but is less potent than cocaine pharmacologically. As a consequence, large amounts of COC and ethanol may be ingested, placing users at greater risk for toxicity than if either drug is used alone. The longer elimination half-life of CE may contribute to its toxicity. Additionally, with simultaneous administration of COC and ethanol, the production of NC may be increased, along with the potential for toxicity. It has been suggested that simultaneous COC and ethanol use carries an 18- to 25-fold increase in risk for immediate death over that associated with COC alone.

Analytical Methods

The half-life of COC is 0.5 to 1.5 hours, whereas the half-life of BE is 4 to 7 hours. Thus, BE is the analyte of choice in screening for cocaine use. The initial screening test for cocaine use is the immunoassay detection directed against the primary metabolite BE.[13]

Most confirmatory assays offer quantification of both parent drug and metabolite. Numerous methods have been described for measurement of COC and various metabolites. GC techniques for analysis of COC and its metabolites require derivatization, especially of polar metabolites.

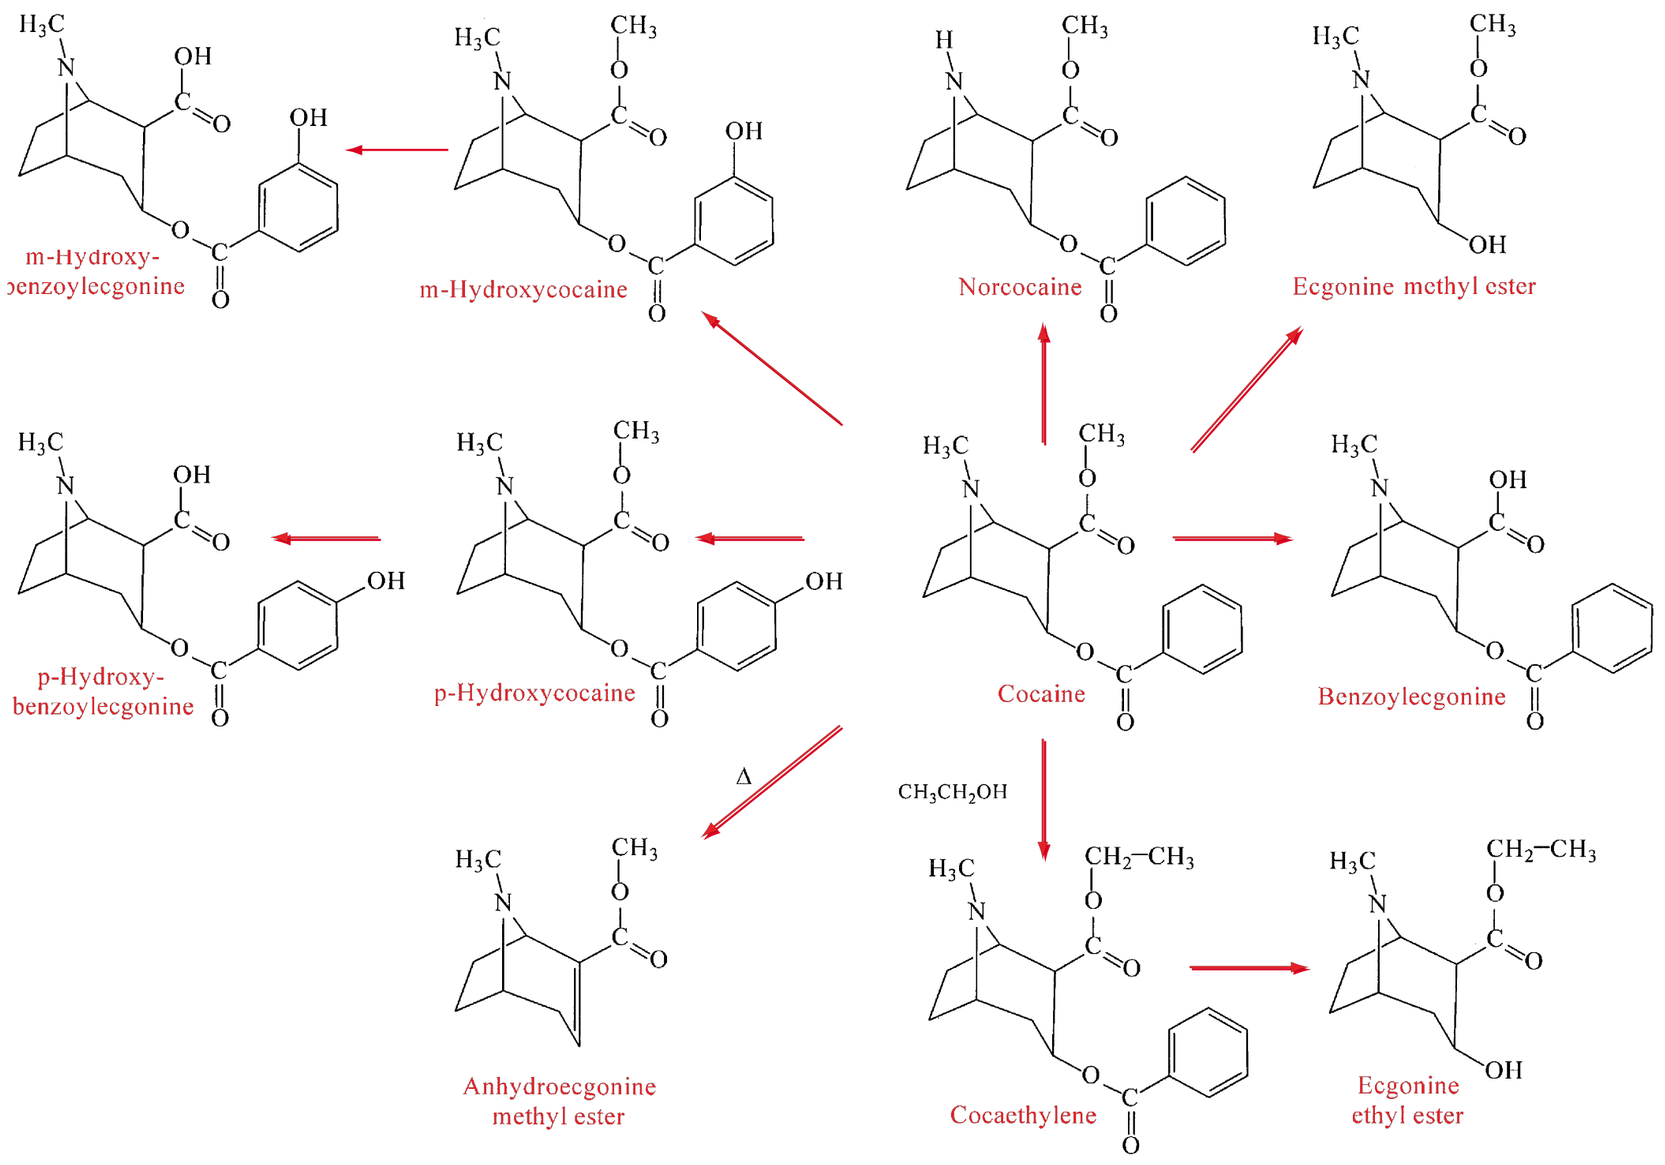

Figure 31-11 Metabolism of cocaine.

GC-MS is the method of choice for many laboratories.[13] However, some reports have suggested that AEME is not a truly unique indicator of smoked cocaine use because it has been reported to be produced in the injector port of a GC at high temperatures. With an LC method, high temperatures are not present in the injector or in any other part of the LC; therefore, AEME is not generated, and its presence identifies a smoked route of COC use. Additionally, LC methods measure simultaneously many of the more polar potentially significant secondary metabolites such as (1) CE, (2) NC, (3) AEME, and (4) AEEE. For these reasons, LC-MS/MS methods are gaining in popularity.[13]

Lysergic Acid Diethylamide (LSD)

Lysergic acid diethylamide (LSD) is an extremely potent psychedelic ergot alkaloid derived from the fungus Claviceps purpurea, which grows on wheat and other grains.

Pharmacological Response

LSD shares structural features with serotonin (5-hydroxytryptamine), a major CNS neurotransmitter and neuromodulator. The drug LSD binds to serotonin receptors in the CNS and acts as a serotonin agonist. The principal psychological effects of LSD are (1) perceptual distortions of color, sound, distance, and shape; (2) depersonalization and loss of body image; and (3) rapidly changing emotions from ecstasy to depression or paranoia.

Popular dosage forms include (1) powder, (2) gelatin capsule, (3) tablet, (4) LSD-impregnated sugar cubes, (5) filter paper, and (6) postage stamps. The drug is rapidly absorbed from the GI tract, and its effects (1) begin within 40 to 60 minutes, (2) peak at about 2 to 4 hours, and (3) subside by 6 to 8 hours. The elimination half-life is about 3 hours. The metabolism of LSD in humans is incompletely understood, but 2-oxo-3-hydroxy-LSD is present in urine at concentrations 10- to 43-fold greater than those of LSD. N-demethyl-LSD and other metabolites are present in urine specimens but at concentrations less than or equal to those of LSD. Iso-LSD is not a metabolite but is formed by nonenzymatic epimerization of LSD during synthesis or storage of urine at alkaline pH and elevated temperature.

Analytical Methods

Because of the very high potency of LSD and its subsequent rapid and extensive metabolism, only about 1% to 2% of the drug is excreted unchanged in urine. Thus, detection of LSD presents an especially difficult analytical challenge. Even with sensitive assays, the detection window for LSD is generally only 12 to 24 hours. The detection window may be extended, perhaps twofold to threefold, by including 2-oxo-3-hydroxy-LSD in the confirmatory test, while using sensitive techniques such as (1) GC-MS-MS, (2) LC-MS-MS, or (3) LC-MS. To avoid degradation of LSD and 2-oxo-3-hydroxy-LSD or epimerization of LSD to iso-LSD, urine specimens should be protected from (1) sunlight, (2) bright fluorescent light, and (3) elevated temperature at alkaline pH.

Drugs Used in Sexual Assault

Drug-facilitated sexual assault (DFSA) is defined as the use of (1) alcohol, (2) drugs, and/or (3) chemical agents to incapacitate an individual and facilitate sexual assault. In addition to alcohol, the drugs most often implicated in drug-facilitated sexual assault include (1) benzodiazepines, (2) choral hydrate, (3) nonbenzodiazepine sedative-hypnotics, (4) **gamma-hydroxybutyric acid (GHB)**, (5) 1,4-butanediol, (6) γ-butyrolactone, (7) dextromethorphan, (8) ketamine, and (9) nonprescription medications such as antihistamines and anticholinergics. These drugs share similar characteristics that are desired by an assailant such as (1) fast onset, (2) colorlessness, (3) tastelessness, and (4) easy access. Similar clinical effects permit the victim to be easily incapacitated. They include (1) impaired judgment, (2) confusion, (3) reduced inhibitions, (4) sedation, (5) hypnosis, (6) loss of muscle coordination, and (7) sometimes anterograde amnesia. These effects are intensified when these agents are coadministered willingly or involuntarily with other psychotropic medications that produce CNS depression, most notably ethanol. This or involuntarily administration is a commonly reported occurrence. Because of the amnesic properties of these drugs, victims often may not report their sexual assault for several days. Therefore, sensitive analytical techniques are necessary to detect these drugs and their metabolites in urine or hair samples after a single dose.

Benzodiazepines

It is estimated that 8% of sexual assault cases are positive for benzodiazepines. Benzodiazepines that have been reported in sexual assault victims are (1) diazepam, (2) triazolam, (3) temazepam, and (4) clonazepam (see benzodiazepine section above for more details). Flunitrazepam (Rohypnol) has achieved significant public awareness. It is a fast-acting sedative-hypnotic categorized as a Schedule I drug in the United States. Because it is still licensed for use in Europe, Asia, and Latin America, sexual predators are able to acquire this drug through illegal trafficking. Sexual assault predators use flunitrazepam because (1) it is easily dissolved into a beverage, (2) it is relatively tasteless and odorless, (3) it quickly incapacitates their victims, and (4) routine drug screens do not detect its presence.

Pharmacological Effects

Flunitrazepam is more potent than diazepam because of its slower dissociation from the GABA receptor. It is rapidly absorbed and distributed into tissues upon oral administration. Onset of its (1) sedative, (2) amnesic, (3) hypnotic, and (4) disinhibitory effects occurs within 20 to 30 minutes. Flunitrazepam has a long half-life (up to 25 hours), permitting an extended window of detection in blood and urine.[3] Although the effects of flunitrazepam occur rapidly when it is used alone, it is often co-ingested with alcohol, which amplifies its effects.

Analytical Methods

Detection of flunitrazepam (Rohypnol) is especially challenging because of the low doses and the low degree of

cross-reactivity of most immunoassays with the principal urinary metabolite, 7-aminoflunitrazepam, although specific immunoassays have been developed. As with other benzodiazepines, prior glucuronidase hydrolysis may improve immunoassay detection. Direct analysis or confirmatory testing of 7-aminoflunitrazepam by GC-MS or LC-MS/MS is indicated in suspected cases.

Choral Hydrate

Chloral hydrate is classified as a sedative and as a hypnotic. The CNS depressant effects of chloral hydrate are believed to be due to its active metabolite trichloroethanol.

Pharmacological Effects

The clinical diagnosis of chloral hydrate intoxication is difficult to differentiate from (1) alcohol, (2) benzodiazepine, and (3) barbiturate intoxication, as all share similar clinical effects. The exact mechanism of action of chloral hydrate has not been determined. The elimination half-life of choral hydrate is very short (4 minutes), but the half-life of its metabolite trichloroethanol is 6 to 10 hours.[3] If co-ingested with alcohol, the metabolism of chloral hydrate may be seriously impaired. Because both ethanol and chloral hydrate are metabolized by CYP2E1 and alcohol dehydrogenase, co-ingestion not only may exacerbate their clinical effects but also may prolong their duration of action.

Analytical Methods

Chloral hydrate is not detected on routine drug screens. Chloral hydrate and its metabolite trichloroethanol (TCE) are detected with the use of LC-MS and capillary gas chromatography with electron-capture detection (GC-ECD), or GC-flame ion detection (GC-FID).

Nonbenzodiazepine Sedative-Hypnotics

A new generation of sedative-hypnotics are available that are structurally different from benzodiazepines (Figure 31-12). They include (1) zopiclone, (2) eszopiclone (Lunesta), (3) zolpidem (Ambien), and (4) zaleplon (Sonata). As a group, they are prescribed as sleep aids through a prescription for a Schedule IV drug. However, they are also used in DFSAs as they are (1) readily prescribed, (2) easily shared, and (3) sold illegally. The rapid onset and amnesic properties of this class of drugs result in (1) disinhibition, (2) passivity, and (3) retrograde amnesia, making it a favored DFSA drug. These drugs require only a low dosage to cause an effect and are rapidly metabolized. CNS-depressant effects are additive when they are co-administered with other psychotropic medications such as (1) anticonvulsants, (2) antihistamines, (3) ethanol, and (4) other drugs that produce CNS depression.[13]

Pharmacological Effects

The pharmacological effects of these agents result from their interaction with a specific subtype of $GABA_A$ receptor complex. These drugs modulate the $GABA_A$ receptor chloride channel by binding to the benzodiazepine (BZ) receptors in the brain without binding to peripheral BZ receptors. Therefore, these drugs have fewer muscle relaxant properties.

Analytical Methods

Although these drugs do not cross-react with most benzodiazepine immunoassays, specific reagent systems (ELISA) directed against the nonbenzodiazepine hypnotics are available. Screening and confirmatory testing are performed by GC-MS or LC-MS/MS.

Four Carbon (C4) Compounds

Gamma-Hydroxybutyric acid (GHB) and its synthetic precursor compounds, 1,4-butanediol (1,4-BD) and γ-butyrolactone (GBL), are Schedule I agents in the United States, and availability is restricted in numerous other countries. GHB is an odorless and colorless liquid, or it can be obtained as an off-white powder that easily dissolves in liquids. When ingested, it has CNS depressant effects, resulting in sedation and hypnosis.

Pharmacological Effects

GHB is a naturally occurring substance that is produced in the brain. It is metabolized to GABA by multiple endogenous enzymes. Consumption of GHB, or the synthetic GHB precursor compound 1,4-BD or GBL, will promote GABA activity. In addition to increased metabolism to GABA, GHB has direct effects on the CNS by binding GHB-specific receptors and $GABA_B$ receptors.

GHB is rapidly metabolized ($t_{1/2}$ ≈30 minutes).[3] Onset of its effects occurs in approximately 15 to 30 minutes and the duration of response is short, typically 1 to 3 hours for a normal dose (1 to 5 g) and 2 to 4 hours with excessive doses.[13]

Analytical Methods

GHB is not detected on immunoassay-screens but can be identified with the use of GC-FID or GC-MS. Because GBH is metabolized rapidly, timely sample collection is an important

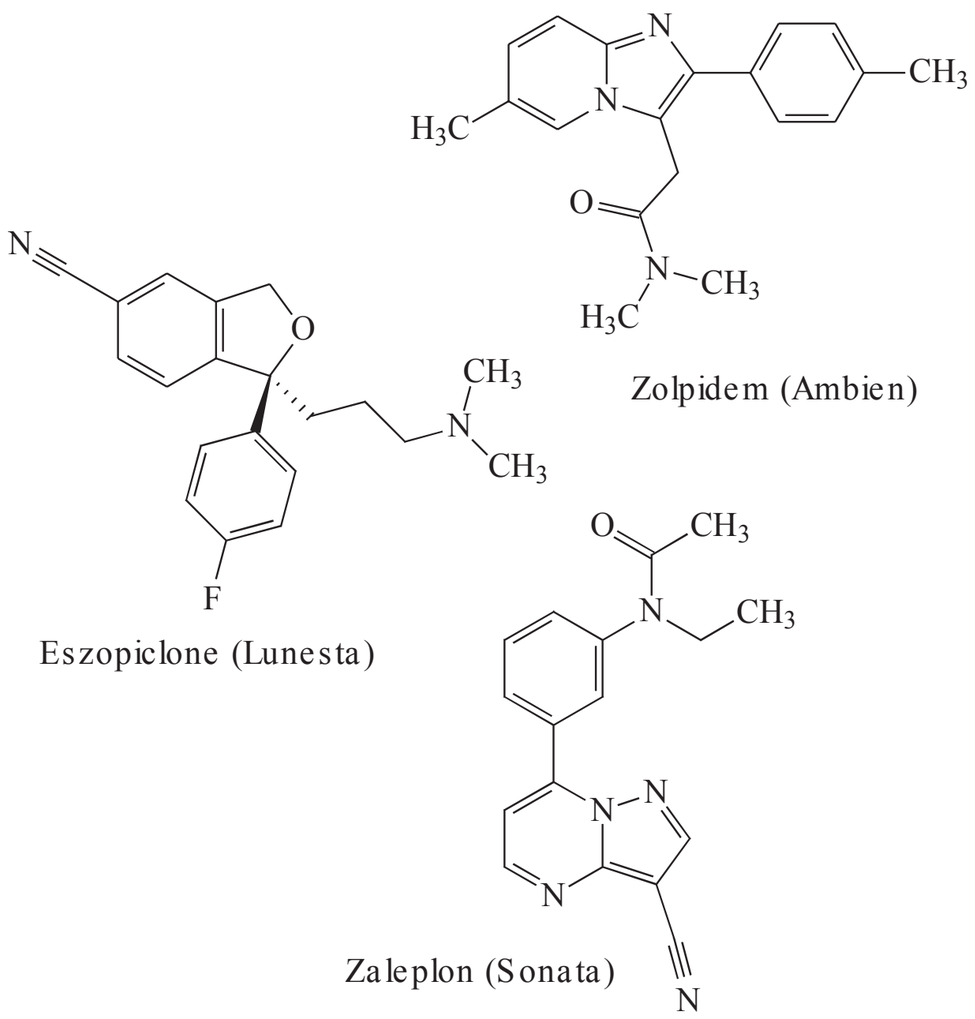

Figure 31-12 Chemical structures of the nonbenzodiazepine sedative-hypnotics (zolpidem, eszopiclone, zaleplon).

facet of GBH assay. Plasma samples should be collected within 6 to 8 hours after ingestion, and urine samples within 10 to 12 hours. Endogenous concentrations of GHB are typically 1.0 mg/L[3] and after exogenous exposure may return to normal levels within 8 to 12 hours after ingestion.

Dextromethorphan

Dextromethorphan (DXM) is structurally related to the opioids, but it does not bind to opioid receptors at normal dose. The (1−) isomer of dextromethorphan, levorphan (not available in the United States), is a potent opioid analgesic and is an example of the stereoselective nature of opioid receptor binding. DXM lacks analgesic activity but does have antitussive activity comparable with that of codeine. DXM is present in (1) numerous over-the-counter (OTC) cough medications, often in combination with (2) antihistamines, (3) nasal decongestants, (4) guaifenesin, (5) aspirin, and (6) acetaminophen. At high doses, DXM binds opioid receptors to produce (1) miosis, (2) respiratory depression, and (3) CNS depression. High doses may also cause (1) lethargy, (2) agitation, (3) ataxia, (4) nystagmus, (5) diaphoresis, and (6) hypertension.[3]

Pharmacological Effects

Dextromethorphan is metabolized to dextrophan by CYP2D6. Dextrophan may be responsible for the more pleasant psychotropic effects of high-dose dextromethorphan, whereas the parent drug may cause (1) dysphoria, (2) sedation, and (3) ataxia. Thus, poor metabolizers (deficient in CYP2D6 activity) may be less prone and extensive metabolizers more prone to continue the abuse of dextromethorphan.[13] Dextrophan and to a lesser degree DXM bind to PCP- and ketamine-binding sites on the NMDA receptor; this may account for their similar psychotropic actions (see phencyclidine and ketamine sections).

Analytical Methods

Clinically approved doses of DXM are not detected by most clinical opiate immunoassays, but larger doses may cross-react. ELISA assays are available to detect DXM and its major metabolite, dextrorphan. Because most preparations contain dextromethorphan as the bromide salt, excessive ingestion of dextromethorphan may result in bromide poisoning and in a negative serum aniongap. The presence of DXM or dextrophan in a sample is confirmed by GC-MS or LC-MS/MS.[13] Dextrophan is the **enantiomer** of levorphanol, a potent opioid agonist available in the United States (Levo-Dromoran). Unless chiral analytical techniques are used, these enantiomers are not resolved.

Ketamine and Phencyclidine

Ketamine and phencyclidine (PCP) are potent analgesics and general anesthetics. PCP is listed as a Schedule II drug in the U.S. Federal Controlled Substance Act and is not approved for human use. Ketamine is a Schedule III drug that is commonly used as an anesthetic in pediatric medicine for short surgical procedures. Both drugs have been used illicitly in human cases of drug abuse, as well as in cases of drug-facilitated sexual assault. They are sold under a variety of names and are available as a colorless, odorless liquid or as a white powder.

Pharmacological Effects

Ketamine and PCP share similar structural features and pharmacological actions. They are classified as dissociative anesthetics because they produce rapid-acting (1) dissociation of perception, (2) consciousness, (3) movement, and (4) memory.[13] The effects are dose dependent and vary between individuals. An anesthetic dose produces profound analgesia, but the individual is awake yet incapacitated, with limited voluntary limb movement. The mechanism of action for these compounds consists of complex integration of neurological pathways. They bind and antagonize the excitatory glutaminergic system by binding to NMDA receptors. They also (1) decrease GABA transmission, (2) disrupt cortical activity, and (3) increase dopamine and norepinephrine synaptic reuptake.[13]

Analytical Methods

Initial screening is typically done by immunoassay. Immunoassays for PCP are generally reliable; however, false positives have been reported because of high concentrations of (1) dextromethorphan, (2) diphenhydramine, and (3) thioridazine. Immunoassay-positive specimens should be confirmed using GC-MS or LC-MS techniques. Note, these techniques will also detect norketamine and dehydronorketamine, the active metabolites of ketamine.[13]

Athletes and Drug Testing

"Doping" in athletic competitions has a history of abuse in a variety of sports for centuries. Regulation of performance-enhancing substances was initiated in 1967 in response to the death of Danish cyclist, Knud Jensen, at the 1960 Olympic Games in Rome. After decades of global reform between governments and sporting agencies,[16] the World Anti-Doping Agency (WDA) was established in 1999. Approximately 30 facilities around the world are accredited for detecting drug use among competitive athletes. Prohibited drugs are substances or methods that conform to two of three criteria: (1) performance enhancing, (2) may endanger the athlete's health, (3) go against the spirit of the sport. "In-competition" testing was established to detect drugs such as (1) stimulants, (2) narcotics, (3) cannabinoids, and (4) glucocorticosteroids in specimens taken at the time of a competition to temporarily enhance performance.

"Out-of-competition" testing is performed to detect substances and methods such as (1) anabolic-androgenic steroids, (2) hormones, (3) hormone modulators, (4) oxygen transfer enhancement, and (5) genetic manipulations. These compounds and methods are used by an athletic for their performance-enhancing effects. In practice, they have a gradual onset to allow for more intense and efficient training, and their use is then abruptly discontinued before competition begins.[16]

Detection of Drugs of Abuse Using Other Types of Specimens

Blood, serum, and urine samples are typically collected for the purpose of determining exposure to various agents. However, sampling of blood is considered invasive, and collection of urine may require some invasion of privacy and loss of dignity. In addition, urine specimens are subject to adulteration or manipulation to evade detection. For these reasons, alternate biological specimens have been investigated as alternative types of samples for drug analysis. They include (1) meconium, (2) oral fluid, (3) hair, and (4) sweat.

Meconium

The first intestinal discharge from newborns is meconium, which is a viscous, dark green substance contains (1) intestinal secretions, (2) desquamated squamous cells, (3) lanugo hair, (4) bile pigments, (5) blood, (6) pancreatic enzymes, (7) free fatty acids, (8) porphyrins, (9) interleukins, (10) phospholipase A_2, and (11) bile acids. Meconium begins to form during the second trimester and continues to accumulate until birth; drugs taken by the mother can be detected in the meconium of the newborn.

Illicit drug use during pregnancy is a major social and medical issue. Drug abuse during pregnancy is associated with significant perinatal complications, including a high incidence of (1) stillbirth, (2) meconium-stained fluid, (3) premature rupture of the membranes, (4) maternal hemorrhage (abruptio placentae or placenta previa), and (5) fetal distress. In the neonate, conditions that contribute to increases in the rates of mortality and morbidity include (1) asphyxia, (2) prematurity, (3) low birth weight, (4) hyaline membrane disease, (5) infection, (6) aspiration pneumonia, (7) cerebral infarction, (8) abnormal heart rate and breathing patterns, and (9) drug withdrawal.

In practice, identification of the drug-exposed mother or her neonate is not easy. Maternal admission of the use of drugs is often inaccurate principally because of denial about addiction or fear of the consequences stemming from such admission. Likewise, many infants who have been exposed to drugs in utero may appear normal at birth and show no overt manifestations of drug effects. Drug testing, on the other hand, is an objective means of determining drug exposure in both mother and infant. Thus, drug testing is necessary in infants to document proof of the infant's exposure to illicit drugs. Urine testing of the mother or newborn will detect only recent drug use (within a few days before birth), and urine collection from newborns may be problematic.

Meconium testing has some limitations. For example, meconium is usually passed by full-term newborns within 1 to 2 days; however, low-birth-weight infants may have delayed passage (median age of 3 days). Thus, meconium collection is missed completely, or significant delay is seen in detection of intrauterine drug exposure.

In the clinical laboratory, meconium is an unfamiliar matrix; it is a sticky material that is difficult to process. Meconium drug screening has been adapted to various analytical techniques, including (1) radioimmunoassay, (2) enzyme immunoassay, and (3) fluorescence polarization immunoassay. As with any immunoassay-based drug screen, confirmatory testing by MS is necessary.

TABLE 31-10 Drugs and Metabolites of Significance in Meconium

Drug Class	Confirmation Compound
Cocaine	Cocaine
	Benzoylecgonine
	Cocaethylene
	m-Hydroxybenzoylecgonine
Opiates	Morphine
	Codeine
	6-Monoacetylmorphine (6-MAM)
	Hydromorphone
	Hydrocodone
	Oxycodone
Cannabinoids	9-Carboxy-11-nor-delta-9-THC
	11-Hydroxy-delta-9-tetrahydrocannabinol
	8,11-Dihydroxy-delta-9-tetrahydrocannabinol
Amphetamines	Amphetamine
	p-Hydroxyamphetamine
	Methamphetamine
	MDMA
	MDA
	MDEA
Ethanol	Fatty acid ethyl esters
PCP	PCP

A variety of (1) GC-MS, (2) LC-MS, and (3) LC-MS/MS methods and their advantages and disadvantages have been described. Confirmatory assays for meconium are more difficult than those for urine. Recovery of drugs from meconium is low (10% to 50%). Some debate continues as to which are the most appropriate drug analytes that should be measured in meconium; Table 31-10 attempts to summarize current knowledge.[9,13] Meconium drug testing is far less standardized than urine drug testing. Assay cutoff limits and units (ng/g meconium or ng/mL extract) may vary; suitable reference or control materials are not yet available.

A word of caution, interpretation of meconium data should be approached carefully. For example, some investigators believe that tremendous, and potentially inappropriate, value has been placed on meconium results. On occasion, decisions about treatment or custody of the infant have been based solely on meconium drug screen results. It is critical to remember that a positive test could indicate drug exposure. However, a negative result does not rule it out. It is clear that additional work is necessary to address these important issues and to improve our understanding of the disposition of drugs in meconium.

Oral Fluid (Saliva)

Reports concerning the appearance of organic solutes in oral fluid have been included in the scientific literature for longer than 70 years. Analysis of saliva for drugs was

first done almost 30 years ago for the purpose of therapeutic drug monitoring. It has since been evaluated for use in forensic toxicology, with recognition of its advantages over other biological matrices. Most studies on saliva in humans use whole saliva. It should be noted that the term "oral fluid" is now preferred for the specimen collected from the mouth.

Several advantages are associated with monitoring oral fluid as contrasted with monitoring plasma or serum concentrations. For example, collection of oral fluid is considered to be a noninvasive procedure, direct observation is possible minimizing risk of adulteration, and some of the risks associated with drawing of blood are avoided. Furthermore, for the patient, the (1) fear, (2) anxiety, and (3) discomfort that may accompany the drawing of blood are diminished. One significant disadvantage of oral fluid is that the window of detection is about equivalent to that of blood or serum and is short compared with that of urine. Another disadvantage is the small volume of sample collected. The problem of small sample size is usually overcome by using methods that simultaneously extract multiple drug groups.

In principle, oral fluid drug concentration is related to plasma free drug concentration; therefore oral fluid has the potential to show a relation between behavior/impairment and drug concentration, making it a possible medium for monitoring drug intoxication or for conducting therapeutic drug management. Since disposition of drugs in oral fluid is dependent upon chemical and metabolic processes appropriate interpretation is required.[5] In recent years, great interest has been expressed in the use of oral fluid testing for (1) roadside drug screening, (2) monitoring the compliance of individuals on drug maintenance programs, and (3) workplace drug testing. Low concentrations of drugs and metabolites necessitate sensitive screening methods, which typically are immunoassays. Again, low concentrations of drugs have necessitated that confirmatory methods be equally sensitive. Many confirmatory methods have been developed for oral fluid testing of abused drugs, including (1) GC-MS, (2) LC-MS, and (3) LC-MS/MS.[13]

Hair

For longer than 30 years, hair has been analyzed for trace metals, including (1) lead, (2) arsenic, and (3) mercury (see Chapter 32). This was achieved with the use of atomic absorption spectroscopy (see Chapter 9). Subsequently, interest in analysis of hair for the purpose of detecting drug use has increased.[13]

Hair is advantageous as a biological specimen for drug analysis because (1) it is easily obtained, (2) it is obtained with less embarrassment, and (3) it is not easily altered or manipulated to avoid drug detection. Hair also differs from other human materials used for toxicological analysis in that it has a substantially longer detection window (months to years) depending on the length. The rate of hair growth depends on (1) anatomical location, (2) race, (3) sex, and (4) age. Once deposited in hair, drugs are very stable, and analysis can be performed even after centuries.

The exact mechanism by which chemicals are incorporated into hair is still being studied. It has been suggested, however, that passive diffusion may be augmented by binding of the drug to intracellular components of hair cells such as the hair pigment melanin. Factors that may affect how efficiently drugs are incorporated into hair are not well established but may include (1) rate of hair growth, (2) anatomical location of hair, (3) hair color (melanin content), and (4) hair texture (thick or fine, porous or not). These factors are determined by genetic factors and by the effects of various hair treatments. For example, in vitro studies suggest that melanin pigment plays an important role in drug binding. Studies have demonstrated that after the same dosage is given, dark hair incorporates much more of the drug than is incorporated by light hair. This may lead to biases in hair testing for drugs of abuse.[13]

Drugs, when deposited in hair, are generally present in relatively low concentrations; thus sensitive analytical techniques are required for detection. Immunoassay procedures have been modified for use with hair. For confirmatory testing, GC-MS is generally the method of choice; however, various GC-MS/MS or LC-MS/MS methods have been used.[13] External exposure to drugs causes them to be detected in hair; one of most crucial issues facing hair analysts today is technical and false positives. The need to distinguish between passive exposure (environmental contamination) and active consumption is fundamental; consequently, decontamination procedures for hair are compulsory. These usually involve a washing step.

Sweat

Drugs may be excreted in sweat, and sweat analysis may provide an alternative detection technique. Sweat patch collection devices that resemble an adhesive bandage may be worn for several days to several weeks. During this time, a drug, if present, accumulates in the absorbent pad in the patch, while water vapor escapes through the semi-permeable covering. Thus sweat drug testing offers the possibility of monitoring drug use over extended periods without the need for frequent collection of urine.[13] Sweat drug excretion may also be an important mechanism by which drugs enter hair.

Review Questions

1. The best specimen type used to determine whether a neonate has been exposed to drugs drug during the second or third trimester of her pregnancy is:
   a. fetal oral fluid.
   b. meconium.
   c. fetal hair.
   d. newborn infant urine.
2. The antidotal therapy for acetaminophen overdose is:
   a. forced alkaline diuresis.
   b. inhibition of the GABA channel.
   c. pralidoxime.
   d. N-acetylcysteine.

3. The best advantage of using high-performance liquid chromatography (HPLC) over gas chromatography (GC) for comprehensive drug screening for a broad range of chemicals is that:
   a. HPLC does not require a derivatization step.
   b. HPLC can be performed at the individual's bedside.
   c. GC gives diverse color hues and requires considerable technical skill.
   d. GC drug testing methods are subject to many types of interference.
4. The principal pharmacological action of ethanol is:
   a. binding to heme iron in the cytochrome complex within mitochondria.
   b. respiratory acidosis.
   c. central nervous system depression.
   d. increased metabolism of GABA.
5. A phenethylamine derivative that has properties similar to amphetamine and is used to treat attention-deficit hyperactivity disorder and narcolepsy is:
   a. methylphenidate.
   b. methamphetamine.
   c. pyridoxime.
   d. ephedrine.
6. To confirm heroin use, testing of which of the following urinary metabolites is considered unique and specific for this drug?
   a. morphine
   b. codeine
   c. meperidine
   d. 6-Monoacetylmorphine
7. For assessment of drugs of abuse, the most widely accepted laboratory method for drug confirmation is:
   a. immunoassay.
   b. gas chromatography-mass spectrometry.
   c. HPLC.
   d. reflectance photometry.
8. An example of an agent that induces the cholinergic syndrome when present in overdose amounts would be a(n):
   a. tricyclic antidepressant.
   b. antihistamine.
   c. organophosphate compound.
   d. barbiturate.
9. The correct formula for determining osmol gap is:
   a. measured cations − measured anions
   b. calculated osmolality − measured osmolality
   c. measured osmolality − calculated osmolality
   d. measured anions − measured cations
10. An increased anion gap value associated with acidosis likely indicates:
    a. methanol overdose.
    b. overuse of antihistamines.
    c. carbon monoxide inhalation.
    d. treatment of opioid overdose with naloxone.

CHAPTER

32 Toxic Metals*

Thomas P. Moyer, Ph.D.

Objectives

1. Define the following terms:
   - Adverse Reaction to Metal Debris
   - Argyria
   - Berylliosis
   - British anti-Lewisite
   - Cardiomyopathy
   - Chelation therapy
   - Dimercaprol
   - Mees' lines
   - Penicillamine
   - Beryllium
   - Cadmium
   - Chromium
   - Cobalt
   - Copper
   - Gadolinium
   - Lead
   - Platinum
   - Selenium
   - Silicon
   - Silver
   - Thallium
   - Titanium
   - Vanadium
2. List three factors that must be demonstrated before a diagnosis of metal toxicity is made.
3. Describe the location and classification of essential and nonessential metals in the periodic table, including row, column, and characteristics of these metals.
4. For the following metals, list common uses, physiological significance (if any), metabolism, therapeutic uses (if any), physiological effects of overexposure, therapy (if any), and methods of analysis:
   - Aluminum
   - Antimony
   - Arsenic
   - Manganese
   - Mercury
   - Nickel
5. Describe the specimen requirements for quantification of metal, including special collection procedures, how results are reported, and possible inferences.
6. Evaluate and analyze case studies involving metal overexposure and analysis.

Key Words and Definitions

Adverse Reaction to Metal Debris (ARMD) A condition characterized by severe hip pain that results from metal release when the ball and joint of the prosthesis used in a hip replacement are both metal.

Argyria A permanent ash gray discoloration of the skin, conjunctiva, and internal organs that results from long-continued use of silver salts.

ATSDR Agency for Toxic Substances and Disease Registry

Berylliosis A hypersensitivity response to beryllium, usually involving the lungs and less often the skin, subcutaneous tissues, lymph nodes, liver, or other structures. Two varieties are distinguished: acute b. and chronic b. Called also beryllium poisoning.

Cardiomyopathy A general diagnostic term designating primary noninflammatory disease of the heart muscle.

CERCLA Comprehensive Environmental Response, Compensation, and Liability Act. (see **SARA** and **Superfund**).

Chelation therapy Administration of chelating agents to remove metals from the body.

Mees' lines Lines of discoloration across the nails of the fingers and toes.

Minamata disease A condition characterized by symptoms of alkyl mercury poisoning that were seen between 1953 and 1958 among individuals who ate seafood from a bay in Japan that was polluted with alkyl mercury compound.

NIOSH U.S. National Institute for Occupational Safety and Health

OSHA U.S. Occupational Safety and Health Administration

Pneumoconiosis Deposition of large amounts of dust or other particulate matter in the lungs.

SARA Superfund Amendments and Reauthorization Act. The Superfund Amendments and Reauthorization Act (SARA) amended the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) on October 17, 1986.

*A more extensive review of this subject and additional references are found in Moyer TP. Toxic metals. In: Burtis C, Ashwood E, Bruns D, eds. Tietz textbook of clinical chemistry and molecular diagnostics, 7th edition. St Louis: Saunders Elsevier, 2012:1189–205.

Key Words and Definitions—cont'd

Superfund A program of the U.S. Government to clean up the nation's uncontrolled hazardous waste sites. Under the Superfund program, abandoned, accidentally spilled, or illegally dumped hazardous waste that poses a current or future threat to human health or the environment is cleaned up.

Toxic metals Metals that are elements with high molecular weight and generally toxic in low concentrations to plant and animal life. Note: The International Union of Pure and Applied Chemistry (IUPAC) considers the term "heavy metal" to be both meaningless and misleading and recommends that it no longer be used.

Threshold limit value (TLV) The maximum concentration of a chemical allowable for repeated exposure without producing adverse health effects.

WHO World Health Organization.

Metals have been recognized as toxins for centuries. For example, arsenic (As) poisoning was a favored way to dethrone royalty in the Renaissance era, and mercury (Hg) poisoning was common in eighteenth century Europe, where it was used in the generation of felt from beaver pelts to make the popular top hat. T is resulted in behavioral changes and common use of the phrase "mad as a hatter."

T is chapter explores these and other **toxic metals** and the role of the clinical laboratory in diagnosing and monitoring toxicity associated with exposure to them.

Assessment of Metal Poisoning

Important questions to address when metal toxicity is considered are listed in Box 32-1. T ese questions are addressed generally in the first section of this chapter. In the second section, the unique characteristics of the more common metals known to be associated with toxicity are discussed.

Prevalence of Metal-Based Toxicity

As the twenty-first century begins, one would might assume that metal toxicities would be thoroughly known and avoidable. However, humans still encounter elemental toxins, and chronic, low-concentration exposure occurs more frequently in individuals than in large population groups. Concern continues regarding low-concentration exposure to lead and the effect that such exposure has on mental development in the young. As is common in our environment, individuals are occasionally exposed because of lack of knowledge of the household products they are using. Many insecticides contain As as an active ingredient, the most common source of exposure causing peripheral neuropathy among patients who have been unwittingly exposed. Another problematic metal is cadmium (Cd), which is used to manufacture brightly colored paint pigments. Painters who fail to use adequate respiratory protection have been known to experience significant exposure. It is also significantly present in tobacco products. Studies indicate that apoptotic pathways are initiated by metals such as As, Cd, chromium (Cr), nickel (Ni), and beryllium (Be), and possibly lead (Pb), antimony (Sb), and cobalt (Co).

Although rare, manufacturing errors have caused the production of products that contain toxic metals. For example, in the early 1960s, a Canadian beer brewery accidentally contaminated a large lot of its product with Co. T e product was sold to and consumed by the public, resulting in an outbreak of renal disease and **cardiomyopathy**. In this type of situation, the Public Health Service is often called in to identify the cause of an outbreak of unusual symptoms. T e clinical laboratory should be prepared to support these types of investigations.

BOX 32-1 Pertinent Questions Relative to Metal Toxicity

1. Is the metal of concern toxic?
2. What is the prevalence associated with the metal of concern?
3. What are the signs and symptoms of exposure to that metal?
4. Is the degree of exposure known?
5. Are adequate analytical techniques available to analyze the metal?
6. Are appropriate body fluids and tissues and analytical techniques available to identify and quantify the metal?

Diagnosing Toxicity

Confirming the diagnosis of metal toxicity is difficult because signs and symptoms are similar to those of a number of non–element-dependent diseases. Consequently, diagnosis of metal toxicity requires demonstration of all of the following factors: (1) A source of metal exposure must be evident, (2) the patient must demonstrate signs and symptoms typical of the metal, and (3) abnormal metal concentration in the appropriate tissue or body fluid must be evident.

In clinical practice, analysis of toxic elements should always be considered in the clinical work-up of the patient with (1) renal disease of unexplained origin, (2) bilateral peripheral neuropathy, (3) acute change in mental function, (4) acute inflammation of the nasal or laryngeal epithelium, or (5) a history of exposure. Certain elements should be considered as the (1) active, (2) causative, or (3) deficient agents in specific circumstances (Table 32-1).

Classification of Metals

Some metals are essential for life (see Chapter 27), but if their concentration in one's body exceeds a certain threshold, toxicity may develop. Also, some nonessential metals are toxic even at low concentrations. Review of the periodic table provides some insight into the determination of a metal's potential toxicity (Figure 32-1).

TABLE 32-1 Conditions That Result from Various Metal Toxicities

Metal	Condition
Aluminum	Dialysis, encephalopathy, or dementia
Arsenic	Bilateral pain radiating from feet to legs or peripheral neuropathy, or unexplained impaired renal function
Cadmium	Impaired renal function in aerosol painters
Cobalt	Pulmonary edema, allergy, hemorrhage, renal failure, or neurologic impairment
Copper-zinc deficiency	Impaired wound healing
Gadolinium	Nephrogenic systemic fibrosis
Lead	Children younger than 2 years living in older homes, or unexplained gastric upset, anemia, or impaired renal function at any age
Mercury	Acute changes in behavior, impaired speech, visual field constriction, hearing loss, and somatosensory disorders
Manganese	Onset of parkinsonism in individuals younger than age 50
Selenium (deficiency)	Patients undergoing total parenteral nutrition
Thallium	Acute hair loss
Zinc (deficiency)	Burn patients exhibiting erythema

Elements in rows 3 and 4 of groups 1 and 2 of the periodic table are essential elements. The gastrointestinal tract and the dermis are very effective in regulating the body burden of these compounds. Consequently, patients rarely experience toxicity from one of these elements unless the element is injected directly into the vascular system. Elements in groups 6 through 12 in row 4 are essential for life but are required at low concentrations; many are protein cofactors required for enzymatic activity. The gastrointestinal tract and the dermis regulate intake to some degree, but overload will induce passive diffusion that leads to excessive concentrations and toxicity. Elements in rows 5 and below are classified as nonessential (or if essential, are required at picomolar concentrations or less). As one moves from right to left across the periodic table, the elements become more prevalent and therefore have greater potential to induce toxicity. Elements in groups 13 through 16 in rows 4 through 6 are of particular interest as toxins because they have electron configuration that allows them to bond covalently with sulfur. This is characteristic has been identified as a significant factor in the mechanism of action of this group of metals. These metals include (1) As, (2) Cd, (3) Pb, (4) Hg, and (5) thallium (Tl), which are toxins of considerable concern. Elements in group 17 (halides) are essential for life but are toxic when present in excess. The inert elements that constitute group 18 are toxic in the gas phase because they can cause anoxia; their inert characteristic is the very cause of their toxicity.

Occupational Monitoring

Employees are frequently monitored when working in an environment where exposure to toxic metals is a possibility. The most common form of monitoring involves quantification of airborne concentrations of metals in the production process. **Threshold limit values (TLV)** for airborne concentrations and time interval exposure concentrations are specified by the U.S. National Institute for Occupational Safety and Health (**NIOSH**). TLVs are air quality standards developed by the American Conference of Governmental Industrial Hygienists (ACGIH). They are the model for many other air quality limits such as the permissible exposure limits (PELs) of the Occupational Safety and Health Administration (**OSHA**). They are defined generally as the maximum concentration of a chemical allowable for repeated exposure to ensure worker safety without producing adverse health effects.

Workers may also be monitored by quantification of biological samples. The most common sample used is a random urine sample, and results are expressed in concentration units for the metal of interest per gram of creatinine to normalize for excretion volume variances. Cd, Cr, and Pb have defined urine excretion concentrations set by a U.S. federal agency to ensure worker safety.[15-17] Additional technical and regulatory information about toxic metals is available at the OSHA website at http://www.osha.gov/SLTC/metalsheavy/index.html/; (accessed November 5, 2013).

The World Health Organization (**WHO**) and OSHA have defined blood concentrations for Pb that are designed to warn employers when workers are overexposed. Safety limits for other metals have been set by professional organizations, such as the American Conference of Governmental Hygienists.[7]

Analytical Methods

Analytical techniques used to measure metals in biological fluid include (1) atomic absorption spectrometry with flame (AA-F) or electrothermal atomization furnace (AA-ETA), (2) inductively coupled plasma emission spectroscopy (ICP-ES), (3) inductively coupled plasma mass spectrometry (ICP-MS), and (4) high-performance liquid chromatography–inductively coupled plasma mass spectrometry (LC-ICP/MS). These techniques are specific and sensitive and provide the clinical laboratory with the capability to measure a broad array of metals at clinically significant concentrations. For example, ICP-MS and ICP-ES are used to measure several metals simultaneously.[2] Photometric assays are available but require large volumes of sample and have limited specificity. Spot tests are also available but should be considered obsolete because they are error prone, often yielding false-positive results.

Specific Metals

Certain metals are known to be toxic when humans are exposed to elevated concentrations; five metals are listed in the top 20 of the 2007 **CERCLA** (Comprehensive Environmental Response, Compensation, and Liability Act) Priority List of Hazardous Substances (http://www.atsdr.cdc.gov/SPL/index.html/; accessed November 5, 2013).[12] They include As (No. 1), Pb (No. 2), Hg (No. 3), Cd (No. 7), and Cr (No. 18). Other metals of concern include (1) aluminum (Al), (2) Be, (3) Co, (4) copper (Cu), (5) gadolinium (Gd), (6) iron (Fe), (7) manganese (Mn), (8) Ni, (9) platinum (Pt), (10) selenium (Se), (11) silicon (Si), (12) silver (Ag), and (13) Ti. The Agency

IUPAC Periodic Table of the Elements

INTERNATIONAL UNION OF
PURE AND APPLIED CHEMISTRY

Notes

- IUPAC 2011 Standard atomic weights abridged to four significant digits (Table 4 published in Pure Appl. Chem. 85, 1047-1078 (2013); http://dx.doi.org/10.1351/PAC-REP-13-03-02. The uncertainty in the last digit of the standard atomic weight value is listed in parentheses following the value. In the absence of parentheses, the uncertainty is one in that last digit. An interval in square brackets provides the lower and upper bounds of the standard atomic weight for that element. No values are listed for elements which lack isotopes with a characteristic isotopic abundance in natural terrestrial samples. See PAC for more details.
- "Aluminum" and "cesium" are commonly used alternative spellings for "aluminium" and "caesium."
- Claims for the discovery of all the remaining elements in the last row of the Table, namely elements with atomic numbers 113, 115, 117 and 118, and for which no assignments have yet been made, are being considered by a IUPAC and IUPAP Joint Working Party.

For updates to this table, see iupac.org/reports/periodic_table/. This version is dated 1 May 2013.

for Toxic Substances and Disease Registry (**ATSDR**) provides toxicological profiles for many of these.

Several of these metals are also considered essential trace elements and are discussed in Chapter 27. Risk assessments for essentiality versus toxicity for Cr, Cu, iodine (I), Fe, Mn, molybdenum (Mo), Se, and zinc (Zn) have been performed by several U.S. governmental and private organizations.

Aluminum

Under normal physiological conditions, the usual daily dietary intake of Aluminum (Al) is 5 to 10 mg, which is completely excreted. T is excretion is accomplished by filtration of Al from the blood by the glomerulus of the kidney. Patients in renal failure lose this ability and are candidates for Al toxicity. T e dialysis process is not highly effective in eliminating Al and can be a significant source of exposure. Furthermore, it is common practice to administer Al-based gels orally to patients in renal failure to reduce the amount of phosphate absorbed from their diet to avoid excessive phosphate accumulation. A small fraction of this Al may be absorbed, and patients in renal failure accumulate this Al. After dialysis, albumin is sometimes administered to replace that which is removed during dialysis. A note of caution, some albumin products have high Al content resulting from the pharmaceutical purification process of passing the product through Al silicate filters.

As a consequence of Al intake, it (1) accumulates in blood if not filtered by the kidney; (2) binds firmly to proteins, such as transferrin; and (3) is rapidly distributed throughout the body. Deposition of Al in bone interrupts physiological calcium exchange; the calcium in bone becomes unavailable for resorption into blood—a process under the physiological control of parathyroid hormone (PTH) and 1,25-dihydroxy vitamin D (see Chapter 39). T e normal physiological action of PTH on bone is blunted in patients with renal failure because their renal cells are not synthesizing the 1,25-dihydroxy vitamin D required for normal PTH action. It is typical for patients in renal failure to have high serum PTH values and low serum calcium; this represents secondary hyperparathyroidism—the normal physiological response to vitamin D deficit. Deposition of Al at the bone mineralization front and its binding to parathyroid calcium receptors interfere with this physiological process. Clinical guidelines suggest that patients with no signs or symptoms of osteomalacia or encephalopathy are likely to have serum Al concentrations <20 μg/L and PTH whole molecule concentrations 150 to 300 ng/L—typical for secondary hyperparathyroidism associated with renal failure. Patients with osteomalacia or encephalopathy typically have serum Al concentrations >60 μg/L, and PTH concentrations <65 ng/L indicating Al-related bone disease. Patients with serum Al concentrations >20 and <60 μg/L were identified as candidates for likely onset of Al-related bone disease; these patients required aggressive efforts to reduce their daily Al exposure. Efforts to reduce Al intake include (1) switching from Al-containing phosphate binders to calcium-containing phosphate binders, (2) ensuring that dialysis water contains less than 10 μg/L of Al, and (3) ensuring that albumin used during postdialysis therapy is Al-free.

Al has been implicated as a factor in Alzheimer's disease (AD) because Al accumulates in the neurofibrillary tangle of patients with AD. Although a cause-and-effect relationship between accumulation of Al in brain and AD has not been conclusively demonstrated,[1] studies have clearly shown an increased concentration of Al in the brain. It is probable that accumulation of Al in the neurofibrillary tangle of AD patients is a secondary finding associated with the disease but not directly related to the cause. T e neurofibrillary tangle has a higher than normal affinity for Al that may explain increased accumulation of Al in brain tissue of Alzheimer's patients.

Antimony

Compounds containing antimony (Sb) have been known since ancient Egyptian times and were used as cosmetics by the women of that era. In the sixteenth century, Sb preparations were thought to be wonder drugs that in the nineteenth century were prescribed for a number of conditions. Today antimony compounds are used to treat parasitic diseases such as (1) leishmaniasis, (2) schistosomiasis, and (3) bilharziasis.

Workplace exposure to Sb dust over a period of years leads to **pneumoconiosis**. T e size of the dust particles of Sb trioxide significantly increases the occurrence of pneumoconiosis, with smaller particles being more dangerous. T e workers at greatest danger are those in underground facilities and in metal production. Smoking may also contribute to respiratory problems. Other conditions of damage to the liver and spleen resulting from antimony exposure are (1) lymphocytosis, (2) eosinophilia, and (3) reduction in leukocyte and platelet counts. It is important to remember that when intoxication occurs with metallic Sb, the effect is caused not only by Sb, but also by the lead, arsenic, and other metals that may accompany it.

Ars e nic

Arsenic (As) is one of the most widely known toxic metals, having gained notoriety from its extensive use by Renaissance nobility as an antisyphilitic agent and an antidote against acute arsenic poisoning. T is agent was memorably used in the well-known tale "Arsenic and Old Lace" as a means of terminating undesirable acquaintances. Currently, As is still a dangerous toxicant, as evidenced by the Bangladesh incident wherein several hundred persons were poisoned by drinking ground water contaminated with As leaching from bedrock. As mentioned earlier, As is listed as the No. 1 toxicant on the 2011 U.S. CERCLA Priority List of Hazardous Substances (http://www.atsdr.cdc.gov/SPL/index.html/; accessed November 5, 2013), and it is still used extensively in insecticides.

Arsenic exists in numerous toxic and nontoxic forms. Toxic forms include (1) the inorganic species As^{3+}, also denoted as As(III); (2) the more toxic As^{5+}, also known as As(V), and their partially detoxified metabolites; (3) monomethylarsine (MMA); and (4) dimethylarsine (DMA). Detoxification occurs in the liver as As^{5+} is reduced to As^{3+} and then is methylated to MMA and DMA. (T e structures of these and related As species are shown in Figure 32-2.)

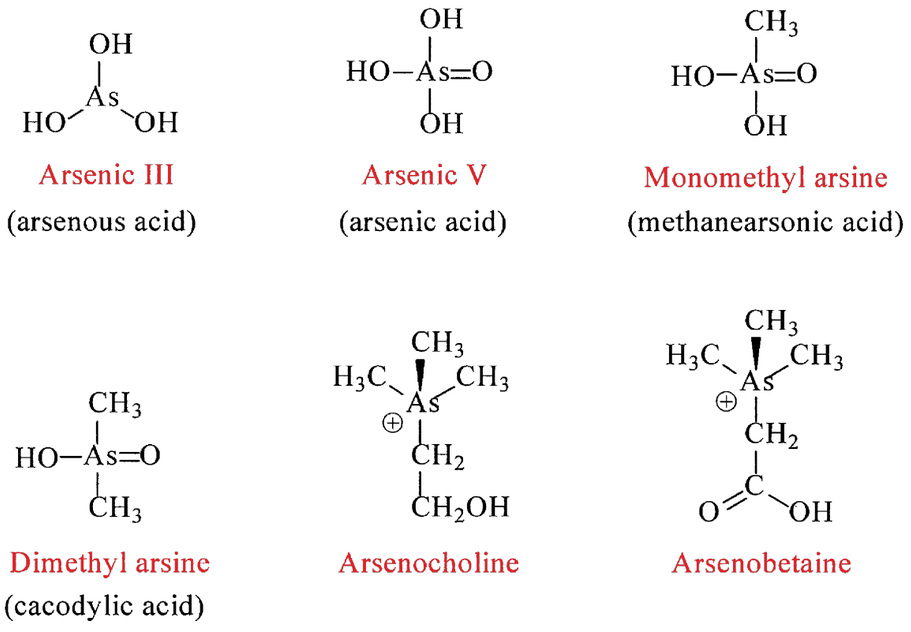

Figure 32-2 Structures of arsenic species.

As a result of detoxification, As^{3+} and As^{5+} are found in the urine shortly after ingestion, whereas MMA and DMA are the species that predominate longer than 24 hours after ingestion. Urinary As^{3+} and As^{5+} concentrations peak in urine at approximately 10 hours and return to normal 20 to 30 hours after ingestion. Urinary MMA and DMA concentrations normally peak at about 40 to 60 hours and return to baseline 6 to 20 days after ingestion. In a large U.S. population study, for all participants aged >6 years, dimethylarsinic acid and arsenobetaine made the greatest contribution to the quantity of total urinary arsenic. Arsenobetaine was the primary contributor to high total urinary arsenic concentrations (see further discussion on this later).[3]

The half-life of inorganic As in blood is 4 to 6 hours, and the half-life of the methylated metabolites is 20 to 30 hours. Blood concentrations of As are elevated for only a short time after administration, after which As rapidly disappears into the large body phosphate pool. Abnormal blood As concentrations in the 5 to 50 ng/mL range can be detected shortly after exposure. Nontoxic forms of As are present in many foods. Arsenobetaine and arsenocholine are the two most common forms of organic As that are found in food. The foods that most commonly contain significant concentrations of organic As are shellfish and other predators in the seafood chain (e.g., cod, haddock). In a large U.S. population study, for all participants aged >6 years, dimethylarsinic acid and arsenobetaine made the greatest contribution to the total urinary arsenic. Arsenobetaine was the primary contributor to high total urinary arsenic concentrations.[3] Arsenic excretion in healthy individuals who have ingested arsenobetaine-containing foods is >120 μg per 24-hour specimen. After ingestion, arsenobetaine and arsenocholine undergo rapid renal clearance to become concentrated in the urine. Arsenobetaine and arsenocholine are completely excreted within 1 to 2 days after ingestion, and no residual toxic metabolites are present. The apparent half-life of organic As is 4 to 6 hours. Consumption of seafood before collection of a urine sample for As testing is likely to result in an elevated concentration of As in the urine.

The toxicity of As is due to three different mechanisms, two of which are related to energy transfer. Firstly, As avidly binds to dihydrolipoic acid, a necessary cofactor for pyruvate dehydrogenase. Absence of the cofactor inhibits the conversion of pyruvate to acetyl coenzyme A—the first step in gluconeogenesis. Secondly, As competes with phosphate for reaction with adenosine diphosphate (ADP), resulting in formation of the lower-energy adipic acids (ADPAs) rather than adenosine triphosphate (ATP). Thirdly, As also binds with any hydrated sulfydryl group on protein, distorting the three-dimensional configuration of the protein, thus causing it to lose activity.

British antilewisite (BAL) is an effective antidote for treating As intoxication; the active agent in BAL is dimercaprol, a sulfydryl-reducing agent. This suggests that the primary mechanism of action of the toxicity of As is related to sulfydryl binding. Arsenic also interferes with the activity of several enzymes of the heme biosynthetic pathway. Arsenic is also a known carcinogen, as evidence suggests increased risk of bladder, skin, and lung cancers, as well as lung cancer associated with smoking, following consumption of water with high As contamination.

Of note is the fact that As compounds are also used for therapeutic reasons. For example, arsenic compounds have been used for decades in the management of protozoal infections such as trypanosomiasis. A preparation of arsenic trioxide called Fowler's agent was used in the nineteenth century as a health tonic and for a variety of ailments ranging from skin disease to leukemia. Arsphenamine was used intravenously to treat (1) syphilis, (2) yaws (a tropical infection of the skin, bones, and joints), and some (3) protozoal infections. Arsenic is still a key ingredient of certain herbal remedies, and arsenic trioxide is currently used in the management of refractory promyelocytic leukemia.

To distinguish among toxic inorganic species and nontoxic organic species of As of seafood origin, high-performance liquid chromatography (HPLC) techniques have been developed.[3] A typical finding in a urine specimen with total 24-hour excretion of As of 350 μg/24 h is that more than 95% is present as the organic nontoxic seafood species, and less than 5% is present as the inorganic toxic species. Such a finding indicates that the elevated total As concentration was likely due to ingestion of seafood.

Hair analysis is frequently used to document time of As exposure. Arsenic circulating in the blood will bind to protein by formation of a covalent complex with sulfydryl groups of the amino acid cysteine. Because As has a high affinity for keratin, which has high cysteine content, the As concentration in hair or nails is greater than in other tissue. Several weeks after exposure, transverse white striae, called **Mees' lines**, may appear in the fingernails; this event is caused by denaturation of keratin by metals such as (1) As, (2) Cd, (3) Pb, and (4) Hg. Because hair grows at a rate of approximately 0.5 cm/mo, hair collected from the nape of the neck can be used to document recent exposure. Axillary or pubic hair is used to document long-term (6 months to 1 year) exposure. Hair As >1 μg/g dry weight indicates excessive exposure. Blood is the least useful specimen for identifying As exposure because blood As concentrations are elevated for only a short time after administration and rapidly disappear into the large body phosphate pool. This occurs because the body treats As like phosphate, incorporating it wherever phosphate would be incorporated.

Absorbed As is rapidly circulated and distributed into tissue storage sites. Abnormal blood As concentrations are detected for only a few hours (<4 hours) after ingestion. T is test is useful only to document an acute exposure when the As is likely to be >20 ng/mL for a short time. Typically, serum As is <4.0 ng/mL.

Arsenic has been accurately analyzed by ICP-MS. T e specimen is prepared in dilute acid containing gallium as an internal standard and is aspirated directly into the argon plasma. Mass response from the argon plasma is monitored for As (75 m/z), gallium (70 m/z), and $^{16}O^{35}Cl$ (51 m/z) to allow for correction for $^{40}Ar^{35}Cl$ (75 m/z) interference. T e operator must be aware of the potential for interference from argon chloride. A correction is made by accounting for chloride by measuring 51 m/z and subtracting that residual from 75 m/z. Urine is the sample of choice for As analysis because As is excreted predominantly by the kidney, where it becomes concentrated.

Beryllium

Beryllium (Be) metal and alloys and Be ceramics are used in a wide range of applications, including (1) dental appliances, (2) golf clubs, (3) nonsparking tools, (4) wheelchairs, (5) satellite and spacecraft manufacture, (6) circuit board production, and (7) the nuclear power industry, as well as in (8) weapons as a neutron modulator.

T e general population is exposed to low concentrations of Be through food and drinking water; these exposures are of no clinical consequence. T e major route by which Be enters the body is via the respiratory tract, and industrial exposure usually occurs from inhalation and ingestion of Be dust. Inhaled Be compounds are cleared very slowly from the lungs. Soluble compounds are absorbed to a much greater degree than others, such as Be oxide, which is much less soluble. Beryllium salts are strongly acidic when dissolved in water, and this is thought to have a major toxic effect on human tissue. Absorbed Be accumulates in the skeleton. Renal clearance is very slow.

Acute exposure to Be (1) is rare, (2) is usually caused by an industrial accident or explosion, and (3) typically results in chemical pneumonitis. Chronic Be exposure in the workplace has led to occupational health concerns because of its potential to cause a progressive and potentially fatal respiratory condition called chronic Be disease (CBD). T is disease, also known as **berylliosis**, is characterized by the formation of granulomas resulting from an immune reaction to Be particles in the lung. To reduce the number of workers currently exposed to beryllium in the course of their work at the U.S. Department of Energy (DOE) facilities or among its contractors, the DOE has established a chronic beryllium disease prevention program (CBDPP) to minimize the concentrations of, and the potential for, exposure to beryllium, and has put forth medical surveillance requirements to ensure early detection of the disease.

Studies have suggested that the size of the Be particles affects not only the site of deposition but also the amount deposited. T is in turn may influence the clearance rate and thus the time of contact between immune cells and Be. Several years ago, researchers noted that blood and lung cells from CBD patients proliferated when exposed to Be in culture. T is assay has been refined and is offered as the Be lymphocyte proliferation test (BeLPT) (http://www.hss.doe.gov/nuclearsafety/techstds/docs/specification/SPEC11422001.pdf/; accessed on November 4, 2013). Unfortunately, because of the nature of the test and variability from laboratory to laboratory, the BeLPT has been known to produce false-negative and problematic results. Efforts are under way by several groups to standardize the assay. Despite these issues, the BeLPT in bronchoalveolar cells is part of the current "gold standard" diagnosis for CBD. Quantification of Be in serum or urine is not useful in making this diagnosis. Air analysis (TLV) is the preferred method of exposure evaluation.

Cadmium

Cd is a byproduct of zinc and lead smelting. It is used (1) in industrial electroplating, (2) in the production of rechargeable batteries, (3) as a common pigment in organicbased paints, and (4) in tobacco products. Breathing the fumes of Cd vapors leads to nasal epithelial deterioration and pulmonary congestion resembling chronic emphysema. Spray painting of organic-based paints without the use of protective breathing apparatus is a common source of chronic exposure. Auto repair mechanics represent a work group that has significant opportunity for exposure to Cd.

T e toxicity of Cd resembles that of As, Hg, and Pb in that it attacks the kidney. Patients suffering from Cd toxicity typically present with renal dysfunction with proteinuria of slow onset (over a period of years). Chronic exposure to Cd causes accumulated renal damage.[15] Breathing the fumes of Cd vapors leads to nasal epithelial deterioration and pulmonary congestion resembling chronic emphysema. Cadmium toxicity is expressed via formation of protein-Cd adducts that change the conformational structure of the protein, causing it to denature. T is protein denaturation occurs at the site of highest concentration—in the alveoli if exposure is due to dust inhalation—and in the proximal tubule of the kidney because this is a major route of excretion.

NIOSH regulations mandate that employees exposed to Cd in the workplace must be monitored with the use of quantification of the urinary concentrations of Cd and creatinine, with results in μg of Cd expressed per gram of creatinine. T is is based on the finding that renal damage caused by Cd exposure is detected by increased Cd excretion relative to creatinine. Cadmium excretion >3 μg Cd/g of creatinine indicates significant exposure to Cd. Results >15 μg Cd/g of creatinine are considered indicative of severe exposure. T e urinary concentration of Cd is a more specific measure of Cd exposure than are other markers of renal function, such as (1) β_2-microglobulin, (2) retinol-binding protein, and (3) N-acetyl glucosaminidase. Normal blood Cd concentration is less than 5 ng/mL, and most concentrations are in the interval of 0.5 to 2 ng/mL. Moderately increased blood Cd (3 to 7 ng/mL) may be associated with tobacco use. Acute toxicity is observed when the blood concentration exceeds 50 ng/mL. Usual daily excretion of Cd is less than 3 μg/d. Collection of urine samples

using a rubber catheter has been known to result in elevated results because latex rubber contains trace amounts of Cd that are extracted as urine passes through it. Brightly colored plastic urine collection containers should be avoided because the pigment in the plastic may be Cd-based. Cadmium concentrations also increase with age and may be involved with senescence. Cadmium is usually quantified by atomic absorption spectrometry, but it also has been accurately quantified by ICP-MS.

Chromium

Occupational exposure to Cr represents a significant health hazard.[16] Chromium is used extensively (1) in the manufacture of stainless steel, (2) in chrome plating, (3) in the tanning of leather, (4) as a dye for printing and textile manufacture, (5) as a cleaning solution, (6) as an anticorrosive in cooling systems, and (7) in metallic orthopedic implants.[9]

The toxic form of Cr is Cr^{6+} [Cr(VI)], which is rare; a strong oxidizing environment is required to convert the common form Cr^{3+} [Cr(III)] to Cr^{6+}, as might be found when Cr^{3+} is exposed to high temperatures in the presence of oxygen or during high-voltage electroplating. Inhalation of the vapors of Cr^{6+} causes erosion of the epithelium of the nasal passages and produces squamous cell carcinomas of the lung. Cr^{6+} is highly lipid soluble and readily crosses cell membranes, whereas Cr^{3+} is rather insoluble and does not readily cross membranes. Clinically, monitoring biological specimens for Cr^{6+} is neither practical nor clinically useful to detect Cr toxicity because the instant it enters a cell, it is reduced to nontoxic Cr^{3+}. Instead, monitoring the air at the manufacturing site for Cr^{6+} is the usual way to test for Cr^{6+} exposure.

Quantification of total Cr in urine can be used to assess exposure to total Cr. NIOSH has proposed <30 μg chromium/g creatinine as the concentration of concern when employees are monitored, but this concentration does not indicate that the specific exposure was to Cr^{6+}. The presence of chromium in erythrocytes is suggestive of exposure to Cr^{6+} within the past 120 days, because Cr^{6+} crosses biological membranes but Cr^{3+} does not.[13] Increased serum chromium concentrations are observed in association with orthopedic implants made from chromium alloys. ICP-MS is the preferred technology for quantification of Cr in body fluids.

Total hip replacement is a successful treatment for advanced joint disease; more than 1 million total hip replacements are surgically inserted worldwide each year.[9] Bearing surfaces such as ceramic on ceramic and metal on metal (MoM) have become the dominant forms in the prosthesis market, with the expectation that these forms could be used in younger, more active individuals, and wear would no longer be an issue. Although these patients benefit from joint replacement with improved mobility and quality of life, implant-specific local and systemic adverse effects due to hypersensitivity to the metal or hyperreactivity due to the wear of MoM surfaces affect a small number of implant recipients.[9] Metal implants made up of various combinations of (1) Al, (2) Cr, (3) Co, (4) Fe, (5) Mg, (6) Mo, (7) Ni, and/or (8) V, wear as the result of continuous motion at the MoM surfaces, resulting in release of microparticles into the surrounding tissues. These microparticles can corrode, resulting in the release of metal ions into the systemic circulation.

DeSmet and coworkers have provided data relating serum and joint synovial fluid concentrations to orthopedic implant status.[6] Joint fluid concentrations of metal ions were at least an order of magnitude higher than those measured in the serum. The median serum Cr concentration in the patients with documented MoM wear were approximately ten times higher than those in patients without MoM wear. Joint fluid Cr concentration correlates with serum Cr concentrations; significantly elevated serum Cr in the context of severe joint pain associated with hip implant is known as **Adverse Reaction to Metal Debris (ARMD).**

Serum Cr analysis is useful for evaluation of implant wear. All patients with an orthopedic implant will have Cr concentrations higher than individuals without implants. Patients experiencing implant joint pain with serum Cr >15 ng/mL or Co >10 ng/mL are likely to have significant implant deterioration.

Preanalytical handling of the specimen for Cr analysis is critically important. Many specimen collection products contain Cr in the rubber stopper or O-rings to add plasticity to the rubber. Special rubber was created to manufacture evacuated blood collection tubes suitable for use in trace metal testing. Attention to detail during specimen collection is essential for achieving successful and clinically valid testing. Blood for Cr testing should be collected in tubes that are approved by the U.S. Food and Drug Administration (FDA) for trace metal testing.

Cobalt

Co is widely distributed in the environment and is the essential cofactor in vitamin B_{12}. Quantification of active vitamin B_{12} (see Chapter 27) is the usual way to assess nutritional status. Cobalt deficiency has not been reported in humans. Exposure to Co is of growing concern among patients with metallic orthopedic implants.[6,9]

Cobalt is found in metal alloys that (1) are very hard, (2) have high melting points, and (3) are resistant to oxidation. Cobalt is not highly toxic, but large exposures will produce (1) pulmonary edema, (2) allergy, (3) nausea, (4) vomiting, (5) hemorrhage, (6) renal failure, and (7) neurologic impairment. Occupational exposure occurs during production and machining of these metal alloys and has been known to result in interstitial lung disease. Cardiomyopathy and renal failure are symptomatic of acute Co exposure. These symptoms were discovered in an incidence of mass population exposure to Co when beer contaminated with the metal was consumed. Chronic exposure may cause (1) pulmonary syndrome, (2) skin irritation, (3) allergy, (4) gastrointestinal irritation, (5) nausea, (6) cardiomyopathy, (7) hematological disorders, and (8) thyroid abnormalities. Cobalt exposure alone may not lead to toxicity and must be considered within the context of exposure to multiple metals.

Quantification of urinary Co is an effective means of identifying individuals with excessive exposure. For example, the National Health and Nutrition Examination Survey

(NHANES/; http://www.cdc.gov/nchs/nhanes.html/; accessed November 5, 2013) reported that the geometric mean of cobalt excretions in a large population was 0.54 μg/g creatinine in children and 0.34 μg/g creatinine in adults. Serum cobalt concentrations are increased above normal (>1 μg/L) in patients with orthopedic implants made from cobalt alloys. Cobalt is quantified in biological tissues by atomic absorption spectrometry or by ICP-MS.

DeSmet and coworkers have provided data relating serum and joint synovial fluid concentrations to orthopedic implant status.[6] Joint fluid concentrations of metal ions were at least an order of magnitude higher than those measured in the serum. T e median serum Co concentration in the patients with documented MoM wear were 5 to 20 times higher than those in patients without MoM wear. As with Cr, joint fluid concentration of Co correlates with serum Co concentration, and significantly elevated serum Co in the context of severe joint pain associated with hip implant is known as Adverse Reaction to Metal Debris (ARMD).

Copper

T e homeostasis and analysis of Cu are discussed in Chapter 27. Copper ingestion has been known to cause serious toxicity, and exposure may be caused by common pesticides. Copper arsenate is one of the active agents in marine antifouling paints and in the wood preservative used with green "treated" wood. Copper arsenate wood products have been taken off the market in the United States because of this concern. Ingestion of copper produces (1) severe gastrointestinal pain with erosion of the epithelial layer of the gastrointestinal tract, (2) hemolytic anemia, (3) centrilobular hepatitis with jaundice, and (4) renal damage. T e classical presentation of Cu toxicosis is represented by the genetic disease of Cu accumulation known as Wilson's disease. T is disease is typified by hepatocellular damage (increased transferases) and/or changes in mood and behavior caused by accumulation of Cu in central neurons.

Evaluation of serum and urine copper concentration is useful in diagnosing Wilson's disease (see Chapter 18). Because most Cu circulating in blood is bound to ceruloplasmin, and ceruloplasmin formation is decreased in Wilson's disease, serum copper concentration is less than the reference interval for serum (Cu, 0.7 to 1.4 μg/mL), and urinary Cu concentrations are increased to 15 to 60 μg/L. Increased hepatic Cu >2.0 (adjusted for age and reported as the hepatic iron index) is diagnostic for Wilson's disease. Increased serum Cu is observed in patients prescribed estrogen. Excess Zn ingestion interferes with absorption of copper and leads to copper deficiency, which is characterized by myeloneuropathy.

Gadolinium

Gd is a chemical element found in image contrast agents that are used during magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) procedures. T ese agents have come under scrutiny by the FDA (http://www.fda.gov/; accessed November 5, 2013) because gadolinium-based contrast agent (GBCA) is thought to be involved in nephrogenic systemic fibrosis (NSF), a debilitating disorder characterized by (1) edema, (2) plaques, (3) discoloration, and (4) severe thickening of the skin, resulting in contractures and immobility. In addition to GBCA exposure, proposed contributing factors and associations with NSF include (1) renal insufficiency, (2) pharmaceutical erythropoietin usage, (3) hypocalcemia acidosis, (4) low serum albumin concentrations, and (5) high serum ferritin concentrations. Exposure to GBCA during a condition of low glomerular filtration rate (GFR) appears to be the most consistent risk factor. Because GBCA is excreted by the kidney, exposure is prolonged in patients with renal insufficiency. It is thought that extended exposure permits transmetallation to occur; this allows free gadolinium to come in contact with proteins and other cellular components. Although several different attempted therapies have been administered, some leading to moderate disease regression, no known cure is uniformly effective.

Iron

T e homeostasis and analysis of iron (Fe) are reviewed in Chapter 28. Iron supplements are used frequently to maintain an adequate body burden of Fe. Occasionally, ingestion exceeds the needed daily requirement, resulting in Fe toxicity. For example, ingestion of more than 0.5 g of Fe has been known to produce severe irritation of the epithelial lining of the gastrointestinal tract, resulting in hemosiderosis, which may develop into hepatic cirrhosis. T e presence of Fe >350 μg/dL or transferrin >125 micromole/L in serum corroborates this diagnosis.

Lead

Lead (Pb) is a metal commonly found in the environment that is an acute and a chronic toxin. It is present at high concentration (up to 35% w/w) in many paints manufactured before 1972. T e Pb content of paints intended for household use was limited to <0.5% in 1978, but Pb is still found in paint products intended for nondomestic use and in artists' pigments. Ceramic products for use in homes available from noncommercial suppliers such as local artists have been known to contain significant amounts of Pb. Also, lead is leached from the ceramic products by weak acids such as vinegar and fruit juices. Leaded crystal contains up to 10% Pb, which is leached during long-term storage of acidic fluids such as fruit juice. Lead is also found (1) in dirt from areas adjacent to homes painted with Pb-based paints and (2) on highways, where it has accumulated from the use of leaded gasoline in automobiles. Use of leaded gasoline has diminished significantly since the introduction of unleaded gasoline, which has been required in personal automobiles in the United States since 1978. Lead is also found in soil near abandoned industrial sites where Pb may have been used. Water transported through Pb or Pb-soldered pipe contains some Pb, with higher concentrations found in water that is weakly acidic. Some foods such as moonshine distilled in Pb pipes and some traditional home medicines also contain Pb. Exposure to Pb from any of these sources by (1) ingestion, (2) inhalation, or (3) dermal contact has been known to cause significant toxicity.

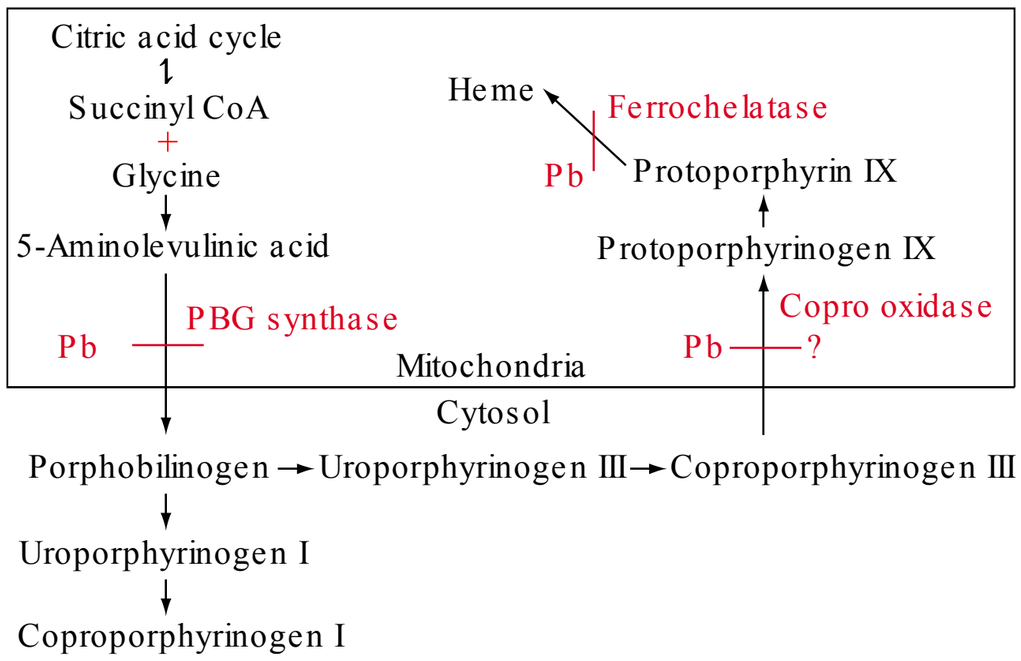

Figure 32-3 Erythropoietic effects of lead.

A typical diet in the United States contributes approximately 3 µg of Pb per day, of which 1% to 10% is absorbed. Children may absorb as much as 50% of the dietary intake. The fraction of Pb absorbed is enhanced by nutritional deficiency. Most of the daily intake is excreted in the stool after direct passage through the gastrointestinal tract. Although a significant fraction of the absorbed Pb is rapidly incorporated into bone and erythrocytes, Pb is ultimately distributed among all tissues. Lipid-dense tissues, such as the central nervous system, are particularly sensitive to organic forms of Pb. Erythrocyte turnover of Pb occurs within approximately 120 days. Lead is ultimately excreted in bile or urine.

Lead expresses its toxicity by several mechanisms that are described graphically in Figure 32-3. It avidly inhibits amino levulinic acid dehydratase (ALAD), which is an enzyme that catalyzes the synthesis of heme from porphyrin. Inhibition of ALAD causes accumulation of protoporphyrin in erythrocytes (see Chapter 29), which is a significant marker for Pb exposure. Anemia caused by lack of heme is frequently observed in Pb toxicity. Lead also is an electrophile that avidly forms covalent bonds with the sulfhydryl group of cysteines in proteins. Thus proteins in all tissues exposed to Pb will have Pb bound to them. Keratin in hair contains a high fraction of cysteine relative to other amino acids and actively binds Pb. Consequently, hair analysis for Pb is a good marker for exposure. Some proteins become labile as Pb binds with them because Pb causes the tertiary structure of the protein to change. Cells of the nervous system are particularly susceptible to this effect. Some Pb-bound proteins change their tertiary configuration sufficiently that they become antigenic. Renal tubular cells are particularly susceptible to this effect because they are exposed to relatively high Pb concentrations during clearance.

The development of Pb toxicity follows a progressive pattern. Figure 32-4 describes this progression through a series of symptoms.[4] The finding that Pb contributes significantly to decreased intellectual capability in the very young is of particular concern. Young children are particularly prone to the effects of Pb because they have greater opportunity for exposure. For example, in older homes that have been previously treated with Pb-based paints, Pb-laden paint chips and dust accumulate on the floor where they are likely to be ingested by children.

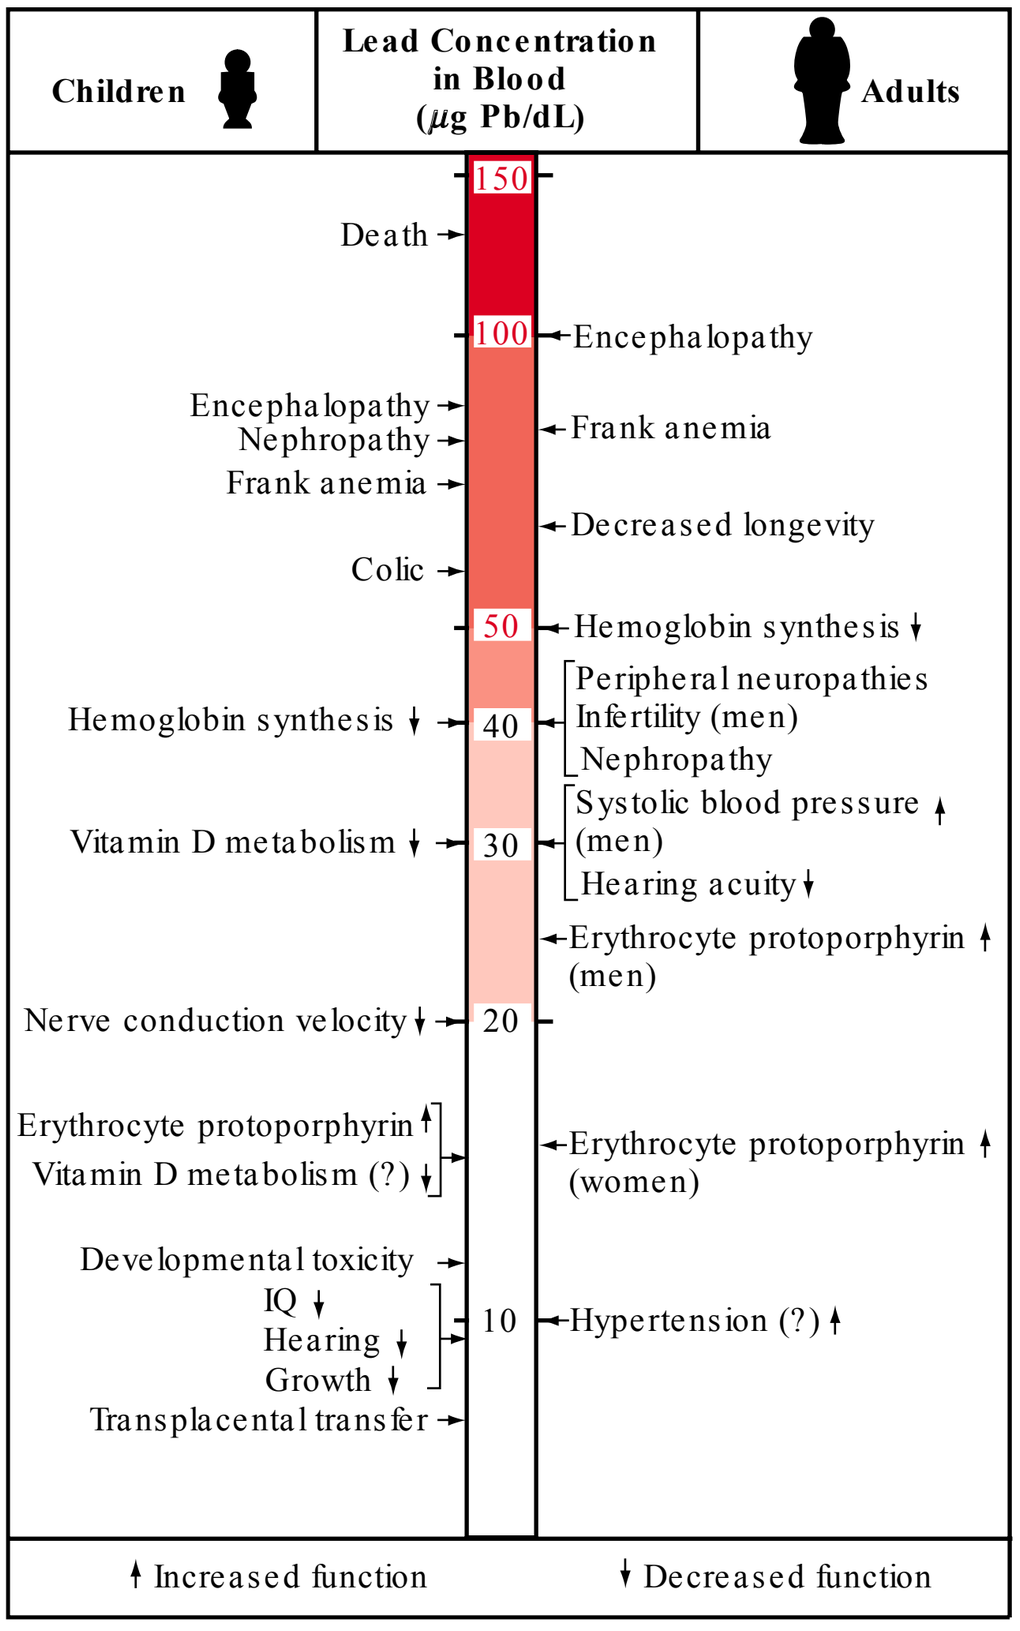

Figure 32-4 Effects of inorganic lead on children and adults (lowest observable adverse effect concentrations). (From Royce SE, Needleman HL, eds. Case studies in environmental medicine: lead toxicity. Washington, DC: U.S. Public Health Service, ATSDR, 1990.)

The definitive test for Pb toxicity is measurement of blood Pb. Over the past 3 decades, studies have shown an inverse relationship between blood Pb concentrations and children's IQ at increasingly lower Pb concentrations. In response, the Centers for Disease Control and Prevention (CDC) has continued to lower the upper limit of normal for children, which is now stated at less than 10 µg/dL, with 5 per µg/dL the reference concentration at which the CDC recommends that public health actions be initiated. (http://www.cdc.gov/nceh/lead/; accessed November 5, 2013). It is important to note that the median blood Pb concentration in children fell from 15 µg/dL in 1978 to 2 µg/dL in 1999. Consequently, renewed interest in determining safe blood Pb concentrations resulted in additional studies. Preliminary data have revealed an inverse relationship between Pb concentrations and children's IQ even at blood Pb concentrations <10 µg/dL. On the basis of these findings, New York State has recommended that blood lead concentrations for children be lowered to <5 µg/dL (www.health.state.ny.us/environmental/lead/; accessed November 5, 2013).[14]

The WHO has defined blood Pb concentrations >30 µg/dL in adults as indicative of significant exposure. Lead concentrations >60 µg/dL require **chelation therapy** (administration of chelating agents to remove metals from the body). In 2000, CDC recommended that, as a preventive health measure, blood Pb concentrations in exposed workers be reduced to <25 µg/dL by the year 2010. Similar to the situation seen in children, adult blood Pb concentrations have dropped to a mean value of 1.4 µg/dL for ages 20 to 49 and a mean value of 1.9 µg/dL for ages 50 to 69. Studies have shown a number of adverse health effects in adults exposed to Pb at concentrations below existing regulatory exposure limits. These include hypertension, adverse reproductive outcomes, and subtle central nervous system problems.

Although erythrocyte protoporphyrin concentrations are not a sensitive indicator of low-concentration Pb exposure, they are definitive markers for significant Pb exposure. For example, an erythrocyte protoporphyrin concentration greater than 60 µg/dL is a significant indicator of Pb exposure[17] (see Chapter 29). Serum activities of ALAD are also a useful indicator of medium to high concentrations of Pb exposure; however, they do not correlate with low concentrations of Pb exposure. Serum Pb analysis is of very limited utility because Pb concentrations are abnormal only for a short time after exposure. The National Health and Nutrition Examination Survey (NHANES) reported a median urine excretion of 3 µg/L lead or 2.4 µg lead per g creatinine in a large population (http://www.cdc.gov/; accessed November 5, 2013). Quantification of urine excretion rates before or after chelation therapy has been used as an indicator of Pb exposure. Normally, the hair Pb content is lower than 5 µg/g; hair Pb concentration >5 µg/g indicates significant Pb exposure. Blood Pb concentrations have the strongest correlation with toxicity.

Avoidance of continued exposure to Pb is paramount when blood Pb concentrations exceed acceptable limits. Oral dimercaprol has become a standard therapy and is being used in the outpatient setting for all except those with the most severe Pb poisoning. Although chelation therapy is effective in reducing blood Pb concentrations, a 2003 study indicated that chelation therapy given to preschool children with Pb concentrations in the range of 20 to 44 µg/dL showed no beneficial effect on tests of cognition or behavior.[12] Thus, prevention is the best therapeutic option.

Analysis of Pb is routinely performed by (1) ICP-MS,[2] (2) electrothermal atomic absorption spectrometry, or (3) anodic stripping voltammetry. Because Pb is concentrated in the erythrocytes, blood containing ethylenediaminetetraacetic acid (EDTA) as an anticoagulant is the specimen of choice for Pb analysis. Sodium heparin is also used; however, samples that are not analyzed within 48 hours are frequently clotted and must be rejected. Care must be taken when obtaining capillary blood. For example, samples having (1) surface contamination, (2) insufficient collection volume, or (3) inadequate mixing with EDTA should be rejected. Urinalysis is also used, as urine quantification correlates with exposure.

If ICP-MS is used to measure Pb concentrations, care must be taken to sum the masses of 206, 207, and 208 m/z to account for the natural isotopic variation of Pb in the environment. Failure to sum masses will skew results above or below the actual concentration, as the isotopic abundance of a particular mass in the calibrator might not match the sample. However, this isotopic variation has been exploited to determine the source of Pb exposure. By determining the relative abundances of Pb in blood and of potential sources of exposure (e.g., paint chips, soil), it is possible to identify a matching pattern. The exposure source with the same ratio of major Pb isotopes as the blood should then be avoided or removed from the patient's environment.

Manganese

Mn is ubiquitous in the environment and is used as (1) a binding agent in red brick, (2) an anticorrosive in most steel alloys, (3) a cleaning agent for glassware, and (4) a common pigment in paints and glazes. Humans exhibit toxicity to Mn when exposed to large quantities of dust containing the metal, which occurs in (1) mining, (2) ore crushing, (3) machining of Mn alloys, and (4) construction and destruction of brick.

After chronic exposure, Mn accumulates in the substantia nigra of the brain, causing a Parkinson-like neurodegenerative disorder known as manganism. Manganese toxicity is also a concern in newborns and children receiving long-term parenteral nutrition.

Blood or urine Mn concentrations are good indicators of exposure. Adult reference +intervals for blood Mn are 0.4 to 1.1 ng/mL (7.0 to 20.0 nmol/L) for serum or plasma and 7.7 to 12.1 ng/mL (140 to 220 nmol/L) for whole blood. Typical daily excretion of Mn in urine varies from 0.2 to 0.5 µg/d. However, approximately 5% of healthy individuals excrete up to 2 µg of the metal per day, probably because of greater than average exposure.

Most of the Mn in daily diets is not absorbed. Because Mn-containing dust is common, contamination of urine with the metal occurs easily. Trace contamination of acid preservatives used for stabilizing the urine has also been observed. Manganese is quantified by electrothermal atomization atomic absorption spectrometry and ICP-MS.

Mercury

Metallic mercury is a liquid at room temperature; its elemental symbol, Hg, is derived from the Greek word hydrargyrias, meaning "water silver" (http://emedicine.medscape.com/article/819872-overview/; accessed November 5, 2013). As mentioned earlier, mercury is listed as No. 3 on the 2007 CERCLA Priority List of Hazardous Substances.[19]

Hg is widely found in the environment and occurs both naturally and as the result of industrial processes, with the single largest source of Hg being its natural out-gassing from granite rock. Hg is also found in deposits throughout the world, mostly as cinnabar (mercuric sulfide), which is the source of the red pigment vermilion.

In the past, Hg was extensively used in the manufacture of devices such as (1) thermometers, (2) barometers, (3) manometers, and (4) sphygmomanometers. However, concerns about its toxicity have resulted in the phasing out of Hg-based

instruments, which have been replaced by (1) alcohol-filled, (2) digital, or (3) thermistor-based ones. It is still used as a dental amalgam and in lighting as mercury vapor lamps, although these are being replaced by sodium vapor bulbs. Hg also is used (1) in the pulp and paper industry as a whitener, (2) as a catalyst in the synthesis of plastics, and (3) as a potent fungicide in antifouling and latex paints.

Mercury is essentially nontoxic in its elemental form (Hg^0). In the absence of any chemical or biological system that chemically alters Hg^0, it is possible to consume it orally with no significant side effects. However, once Hg^0 is chemically modified to the ionized, inorganic species, Hg^{2+}, it becomes toxic. Further bioconversion to an alkyl Hg, such as methyl Hg (CH_3Hg^+), yields a very toxic species of Hg that is highly selective for lipid-rich tissue, such as the neuron. The relative order of toxicity is as follows:

$$Hg^0 << Hg^+ << \text{Monomethyl} - Hg\ (CH_3Hg) \text{ or } \text{Dimethyl} - Hg\ [(CH_3)_2 - Hg]$$

Chemically, it is possible to convert Hg from its elemental state to its ionized state; in industry, this is frequently accomplished by exposing Hg^0 to a strong oxidant, such as chlorine. Elemental Hg is also bioconverted to both Hg^{2+} and alkyl Hg by microorganisms that exist both in the normal human gut and in the bottom sediment of lakes and rivers. When Hg^0 enters bottom sediment, it is absorbed by (1) bacteria, (2) fungi, and (3) related microorganisms that metabolically convert it to Hg^{2+}, CH_3Hg^+, $(CH_3)_2Hg$, and similar species. Consequently, the methyl mercurials are accumulated in the aquatic food chain and reach their highest concentrations in predatory fish.

As a consequence of accumulation of methylmercury in the aquatic food chain, most human exposure to mercury happens through the eating of contaminated (1) fish, (2) shellfish, and (3) sea mammals. In adults, cases of methylmercury poisoning are characterized by the focal degeneration of neurons in regions of the brain such as the cerebral cortex and the cerebellum. Depending on the degree of in utero exposure, methylmercury may result in effects ranging from fetal death to subtle neurodevelopmental delays. Consequently, because pregnant women, women of childbearing age, and young children are particularly at risk, the FDA recommends that they avoid eating (1) shark, (2) swordfish, (3) mackerel, and (4) tilefish (http://www.fda.gov/; accessed November 5, 2013).

Mercury toxicity is expressed in three ways. First, Hg^{2+} avidly reacts with sulfydryl groups of protein, causing a change in the tertiary structure of the protein with subsequent loss of the biological activity associated with that protein. As Hg^{2+} becomes concentrated in the kidney during regular clearance processes, this is the target organ that experiences the greatest toxicity. Second, with the tertiary change noted previously, some proteins become immunogenic, eliciting a proliferation of β-lymphocytes that generate immunoglobulins to bind the new antigen (collagen tissues are particularly sensitive to this). Third, alkyl Hg species, such as methylmercury, are particularly lipophilic and actively bind to proteins in lipid-rich tissue, such as neurons; myelin is particularly susceptible to disruption by this mechanism.[12] Mercury has also been found to alter porphyrin excretion patterns.

Experience with Hg poisoning has been gained from the investigation of the 1951 to 1963 industrial dumping of Hg-laden waste sludge into Minamata Bay, Japan. Fish in Minamata Bay became heavily laden with Hg through the food chain. The local human population, whose diet was dependent on fish from the bay, exhibited symptoms of methylmercury poisoning, which include (1) ataxia, (2) impaired speech, (3) visual field constriction, (4) hearing loss, and (5) somatosensory change, characterized histologically by cerebral cortex necrosis. Collectively, these symptoms have become known as **Minamata disease**.

In the late 1980s, the public became concerned about exposure to Hg from dental amalgams.[21] However, later studies failed to confirm a causal relationship.[18] Basic to the initial concerns was the fact that restorative dentistry used an Hg-silver amalgam for approximately 90 years as a filling material. In 2010, the FDA issued rules that classify dental amalgam, reclassify dental mercury, and specify special controls for dental amalgam, mercury, and amalgam alloy (21 CFR Part 872 /http://www.accessdata.fda.gov/; accessed November 5, 2013).

Concerns have been raised about the possible relationship between Hg exposure from vaccines and autistic disorders. In the United States, the prevalence of autism has risen from 1 in approximately 2500 in the mid-1980s to 1 in approximately 300 children in the mid-1990s.[20] Some investigators believe that this rise has occurred because of the Hg that is present in vaccines as the preservative thimerosal (sodium ethyl mercury thiosulfate). However, this causality has been questioned by numerous other studies, which have not been able to confirm the relationship.[22] In 2001, the Committee on Immunization Safety Review of the Board on Health Promotion and Disease Prevention of the Institute of Medicine initiated a study to review the connection between Hg-containing vaccines and neurodevelopmental disorders, including autism. The Committee has issued several reports; in its eighth and final report, put forth in 2004, the Committee reported that the hypothesis was biologically plausible, but that evidence was insufficient to accept or reject a causal connection. At that time, the Committee recommended a comprehensive research program. The findings of this report have been challenged, and thimerosal has been removed from most vaccines in the United States.

The reader should note that the issue of linking Hg exposure from vaccines with autistic disorders became highly controversial and resulted in the journal Lancet retracting the article linking autism to MMR (measles, mumps, and rubella) vaccines. However, the senior author involved with this publication has challenged this retraction and has initiated a lawsuit.[8]

Dietary sources also contribute to Hg body burden, as many foods contain Hg. For example, commercially distributed fish considered safe for consumption contain less than 0.3 μg/g, but some game fish contain more than 2 μg/g and, if consumed on a regular basis, contribute to significant body burdens of Hg.

Of note is the fact that Hg compounds have been used for therapeutic reasons. For example, Hg has been used (1) in medications that were touted as cures for syphilis and dysentery, (2) to treat constipation, and (3) as diuretics.

Analysis of blood, urine, and hair for Hg concentrations is used to determine exposure. The quantity of Hg found in blood and urine correlates with the degree of toxicity, and hair analysis has been used historically to document the time of peak exposure. However, it should be noted that hair analysis for metals in general is difficult because of contamination. Reference whole blood Hg concentration is usually lower than 10 μg/L. Individuals who have mild occupational exposure (e.g., dentists) may routinely have whole blood Hg concentrations up to 15 μg/L. Significant exposure is indicated when the whole blood Hg concentration is greater than 50 μg/L (if exposure is to methylmercury) or greater than 200 μg/L (if exposure is to Hg^{2+}). The WHO safety standard for daily exposure of Hg is 45 μg/d; daily urine excretion exceeding 50 μg/d indicates significant exposure. Normally, hair contains less than 1 μg/g of Hg; greater amounts indicate increased exposure. Treatment with BAL or penicillamine will mobilize Hg, allowing for its excretion in the urine. Therapy is usually monitored by following urinary excretion of Hg; therapy may be terminated after the daily urine excretion rate falls below 50 μg/L.

Nickel

Ni is frequently used (1) in the production of metal alloys, (2) in Ni-based rechargeable batteries, and (3) as a catalyst in the hydrogenation of oils. Nickel alloyed with transition metals is considered nontoxic, except that it will induce inflammation at the point of contact. Nickel oxides and sulfides and aqueous solution of Ni in the oxidation state of 1^+, 2^+, or 3^+ are considered group I carcinogens. If Ni is essential for life, it is so only at very low concentrations, below the detection limit of most analytical techniques. Nickel carbonyl [$Ni(CO)_4$], used in petroleum refining, is one of the most toxic chemicals known to humans, as it is absorbed after inhalation, readily crosses all biological membranes, and noncompetitively inhibits ATPase and RNA polymerase. Patients exposed to Ni carbonyl exhibit rapid onset of pulmonary congestion and inability to oxygenate hemoglobin, followed by development of lesions of the (1) lung, (2) liver, (3) kidney, (4) adrenal glands, and (5) spleen.

Patients undergoing dialysis are exposed to Ni and accumulate Ni in blood and other organs. No adverse health effects have been associated with this exposure. Nickel is quantified by AA-ETA or ICP-MS.

Platinum

A variety of Pt-containing antineoplastic agents are used in chemotherapy, typified by cisplatin (cis-diamminedichloroplatinum)[10] and carboplatin (cyclobutanedicarboxylatoplatinum).[11] These compounds have nephrotoxicity that is related to the concentration of Pt circulating in the blood. Patients responding to carboplatin therapy had serum platinum concentration in the range of 0.6 to 1.8 μg/mL. Trough concentrations varied from 0.1 to 0.4 μg/mL. Platinum concentrations maintained at >1.8 μg/mL can induce neutropenia and renal failure if coadministered with nephrotoxic antibiotics. Both AA-ETA and ICP-MS are used to measure Pt.

Selenium

Se is an essential element (see Chapters 18 and 27) that may play a role in mitigating biological damage caused by oxidative damage. It is a cofactor required to maintain activity of glutathione peroxidase, an enzyme that catalyzes the degradation of organic hydroperoxides. Absence of Se correlates with loss of glutathione peroxidase activity and is associated with damage to cell membranes caused by the accumulation of free radicals. In a situation of Se deficiency associated with loss of glutathione peroxidase activity, the serum concentration is less than 40 ng/mL.

In humans, cardiac muscle is the tissue most susceptible to Se deficiency; with cell membrane damage, normal cells are replaced by fibroblasts.[5] This condition, known as cardiomyopathy, is characterized by an enlarged heart consisting of predominantly nonfunctioning fibrotic tissue.

The geographic source of plant and animal foodstuffs determines the amount of dietary intake. In the United States and Canada, wheat and other cereal products are a good source of selenium; average intakes in North America range from 80 to 220 μg Se/d, whereas in the United Kingdom, dietary intake is about 30 to 60 μg/d. Intakes in China are as low as 11 μg/d, and in New Zealand 28 μg/d (see Chapter 27). Symptoms of selenium toxicity vary among individuals and are dependent on a number of factors such as (1) dose, (2) type, and (3) form of selenium ingested, and length of time the product was used. Symptoms of selenium poisoning include (1) hair loss, (2) muscle cramps, (3) nausea, (4) vomiting, (5) diarrhea, (6) joint pain, (7) fatigue, (8) fingernail changes, and (9) blistering skin. The tolerable upper limit has been set at 400 μg/d for adults and less for children.

Selenium deficiency among people who consume food only from a particular region has been related to the low soil content of the metal in that region. For example, the soil of the Keshan region of China is noted for this characteristic. Children living in the Keshan region who receive no Se supplement develop cardiomyopathy. Deficiency is also related to use of total parenteral nutrition, which is administered to patients who have no functional bowel (e.g., those who have undergone surgical removal of the small and large intestines because of cancer) or who have acute inflammatory bowel disease, such as Crohn's disease (see Chapter 38). Selenium supplementation to raise serum concentration to above 90 ng/mL is the usual practice in these patients, and serum monitoring is performed on a semi-annual basis to ensure the adequacy of supplementation.

Selenium toxicity has been observed in animals when daily intake exceeds 400 μg/d. Teratogenic effects are frequently noted in the offspring of animals living in regions where Se soil content is high, such as in south central South Dakota and the northern coastal regions of California. Selenium toxicity in humans is not known to be a significant problem except in acute overdose cases, and Se is not classified as a human teratogen. Selenium is found in many over-the-counter vitamin preparations because its antioxidant activity is thought to be anticarcinogenic.

Selenium is quantified by ICP-MS or by atomic absorption spectrometry after the specimen has been mixed with a matrix modifier.

Silicon

Si is the most abundant element in the earth's environment; it constitutes 26% of the earth's crust. From the toxicological viewpoint, several forms of Si are of interest, including asbestos (amorphous oxides of Si) and methylated polymers of Si (e.g., silicone).

Inhalation of asbestos-containing dust leads to deposition of asbestos fibers in the pulmonary alveoli. These fibers are needle-shaped spicules approximately 150 micrometers in length and up to 15 micrometers in diameter. When these fibers are inhaled, they deposit in the alveoli, where they are surrounded by macrophages and become coated with protein and mucopolysaccharide to form "asbestos bodies." The diagnosis of asbestosis is made by (1) interpretation of a chest X-ray by a qualified radiologist, (2) demonstration of asbestos in sputum, and (3) documentation of asbestos bodies in a lung biopsy by electron microscopy. Direct analysis of lung tissue for Si is not useful because all lung tissue is infiltrated with Si, most of which is not asbestos. Thus, direct analysis for Si cannot distinguish asbestosis from normal background Si.

Silver

Clinical interest in Ag analysis is limited to two applications: (1) monitoring burn patients treated with Ag sulfadiazine, and (2) monitoring patients treated with Ag-containing nasal decongestants. In both cases, Ag is deposited in many organs, including the subepithelium of the skin and mucous membranes, producing a syndrome called **argyria** (graying of the skin). Argyria is associated with (1) growth retardation, (2) hemopoiesis, (3) cardiac enlargement, (4) degeneration of the liver, and (5) destruction of renal tubules. The customary concentration of serum Ag is less than 2 ng/mL. Typical Ag concentrations observed in serum of unaffected patients during treatment range up to 300 ng/mL, and their urine output has been found to be as high as 550 μg/d.

Thallium

Tl is a byproduct of lead smelting. Interest in Tl derives primarily from its former use as a rodenticide, and accidental contact represents the most likely source of exposure. Additionally, environmental concerns are growing because thallium is a waste product of coal combustion and the manufacturing of cement. Thallium is rapidly absorbed via (1) ingestion, (2) inhalation, and (3) skin contact. It is considered to be as toxic as lead and mercury and has similar sites of action. The mechanism of Tl toxicity consists of (1) competition with potassium at cell receptors to affect ion pumps, (2) inhibition of DNA synthesis, (3) binding to sulfhydryl groups on proteins in neural axons, and (4) concentration in renal tubular cells to cause necrosis. Patients exposed to high doses of Tl (>1 g) demonstrate alopecia (hair loss), peripheral neuropathy and seizures, and renal failure. Typical serum concentrations are less than 10 ng/mL, and daily urine excretion is less than 10 μg/d. Exposed patients have been observed to have serum concentrations as high as 50 μg/mL, with urine output in excess of 500 μg/d.

Titanium

Ti is the ninth most abundant element in the earth's crust. No evidence indicates that titanium is an essential element. In part because of the formation propensity of titanium oxide, the element is considered to be nontoxic. Average daily oral intake through food consumption is 0.1 to 1 mg/d, which accounts for more than 99% of exposure. Gastrointestinal absorption of titanium is low (≈3%), and most ingested titanium is rapidly excreted in the urine and stool. The total body burden of titanium is typically in the range of 9 to 15 mg, a significant portion of which is contained in the lung. Titanium dust entering the respiratory tract is nonirritating and is almost completely nonfibrogenic in humans.

Titanium-containing alloys are used in (1) artificial joints, (2) prosthetic devices, and (3) implants. Titanium dioxide allows osseointegration between an artificial medical implant and bone. Despite their wide use, exposure to these materials has not been linked to toxicity. However, as implant wear occurs, a significant increase in detectable serum titanium becomes evident. Although titanium concentrations are not a measure of toxicity, they are useful in determining whether implant breakdown is occurring. Serum titanium <1.0 ng/mL suggests that a prosthetic device is in good condition. Serum concentrations >3 ng/mL in a patient with a titanium-based implant suggest prosthesis wear. An increased serum titanium concentration in the absence of corroborating clinical information does not independently predict prosthesis wear or failure.

Vanadium

V is naturally found in minerals and rocks and is considered an essential element for mammals (see Chapter 27), although conclusive evidence for humans is lacking. V is recovered from minerals or is derived as a byproduct of (1) iron, (2) titanium, and (3) uranium refining. Vanadium compounds are used in (1) dyes, (2) photography, and (3) ceramics, and (4) in the production of special glasses. V is also a component of many fiber mesh prosthetic devices.

The main source of V intake for the general population is food, with an estimated daily intake of 20 μg, of which most is not absorbed and excreted in the feces. Absorption through the inhalation route results in more effective uptake. The clearance half-life is not well documented, but it appears to be on the order of several days. V has been recognized as an occupational hazard for many years. Elevated atmospheric V concentration results from burning fossil fuels with a high V content. Inhalation and ingestion are the primary exposure routes. V exposure results in a metallic taste and so-called "green tongue." Sensitization has been known to result in asthma or eczema.

Because the kidney is primarily responsible for V elimination, increased serum concentrations are observed in dialysis patients and those with compromised renal function. Serum V values <1.0 ng/mL are typical; values >5.0 ng/mL indicate probable exposure. Elevated serum V concentrations have been observed in patients with joint replacement; concentrations are likely to be increased above the reference interval in

patients with metallic joint prosthesis. A modest increase (1 to 2 ng/mL) in serum V concentration is likely to be associated with a prosthetic device in good condition. Serum concentrations >5 ng/mL in a patient with a vanadium-based implant suggest significant prosthesis wear. Increased serum trace element concentrations in the absence of corroborating clinical information do not independently predict prosthesis wear.

Review Questions

1. A modest increase in this metal occurs in the blood of an individual who has a prosthetic device in good condition, and greater increases occur when a prosthetic device is becoming worn out; however, blood analysis of this metal is not considered to be a good indicator of prosthetic damage. Increased exposure to this same metal can result in a "green tongue."
   a. Cadmium
   b. Copper
   c. Vanadium
   d. Aluminum
2. An individual has eaten a large meal of seafood including shellfish and haddock before submitting a urine specimen for metal analysis. He had also been recently treated for trypanosomiasis. What metal would be present in a high concentration in his urine specimen?
   a. Arsenic
   b. Copper
   c. Mercury
   d. Cadmium
3. Lead inhibits _____, an enzyme that catalyzes synthesis of heme from porphyrin.
   a. ATPase
   b. RNA polymerase
   c. glutathione peroxidase
   d. aminolevulinic acid dehydratase
4. Occupational overexposure via inhalation of this metal can produce squamous cell carcinoma in lungs, and blood analysis of this metal can provide useful information regarding orthopedic implant wear.
   a. Cadmium
   b. Copper
   c. Vanadium
   d. Aluminum
5. A serum level >60 µg/L of which of the following metals interrupts normal calcium exchange in bone and leads to osteomalacia?
   a. Aluminum
   b. Arsenic
   c. Copper
   d. Antimony
6. Which of the following metals is considered to be an essential trace element in humans?
   a. Vanadium
   b. Manganese
   c. Arsenic
   d. Aluminum
7. Amorphous oxides of silicon are also known as:
   a. silicone.
   b. thimerosal.
   c. asbestos.
   d. keratin.
8. A chemical element found in image contrast agents used during magnetic resonance imaging and angiography procedures that is thought to be involved in nephrogenic systemic fibrosis is:
   a. mercury.
   b. gadolinium.
   c. cobalt.
   d. lead.
9. Certain metals that express toxicity have in common an ability to react with sulf ydryl groups of protein to denature these proteins. T ese metals include:
   a. arsenic.
   b. lead.
   c. mercury.
   d. All of the above metals react with sulf ydryl groups.
10. In the periodic table, elements with a particular electron configuration that allows them to bind covalently with sulfur are located in which group(s) and row(s)?
    a. Groups 6 through 12, row 4
    b. Groups 1 and 2, rows 3 and 4
    c. Group 1, row 5
    d. Groups 13 through 16, rows 4 through 6

CHAPTER

33 Diabetes

David B. Sacks, M.B., Ch.B., F.R.C.Path.

Objectives

1. Define the following:
   - Advanced glycation end product
   - Albuminuria
   - C-peptide
   - Diabetes mellitus
   - Epinephrine
   - Fatty acid
   - Fructosamine
   - Gestational diabetes mellitus
   - Glucagon
   - Glucose tolerance
   - Glycated hemoglobin
   - Hemoglobin A_{1c}
   - Hyperglycemia
   - Insulin
   - Insulin-like growth factor 1
   - Insulin resistance syndrome
   - Ketoacidosis
   - Ketone bodies
   - Proinsulin
   - Type 1 and 2 diabetes
2. Compare and contrast type 1 and type 2 diabetes mellitus including the following:
   - Causes
   - Symptoms
   - Insulin concentration in blood
   - Appearance of symptoms versus clinical diagnosis
   - Development of chronic complications
   - Genetic factors
3. Compare impaired glucose tolerance with impaired fasting glucose including the fasting blood glucose concentration in each and the usefulness of these classifications as risk factors for diabetes and cardiovascular disease.
4. List the three important functions of insulin.
5. Summarize how the following hormones specifically affect blood glucose concentration: insulin, glucagon, epinephrine, cortisol, somatostatin, and growth hormone.
6. Briefly describe the function of the facilitative glucose transporters, including the importance of GLUT4 in glucose uptake by skeletal muscle.
7. List five antibodies that are involved in the pathogenesis of type 1 diabetes mellitus.
8. Describe insulin resistance and the role it plays in the pathogenesis of type 2 diabetes mellitus; explain how loss of β-cell function results in development of type 2 diabetes mellitus.
9. State how diet and exercise are related to development of type 2 diabetes mellitus.
10. State the basic criteria for the diagnosis of diabetes mellitus including fasting plasma glucose concentration, casual* plasma glucose concentration, oral glucose tolerance test results, and inclusion of glycated hemoglobin results.
11. Outline the procedure for administration and collection of an oral glucose tolerance test; analyze and interpret the results of this test in the diagnosis of type 2 diabetes mellitus, impaired glucose tolerance, and gestational diabetes mellitus.
12. Summarize the role of the clinical laboratory in the diagnosis and short- and long-term management of diabetes mellitus.
13. Describe the assay of whole blood glucose used in a blood glucose meter; calculate the difference between whole blood and plasma glucose concentrations.
14. List five variables that affect the accuracy and reproducibility of blood glucose meters; state how dehydration affects the reliability of a blood glucose meter.
15. Describe a typical implanted sensor for monitoring blood glucose including assay method, calibration, and usefulness in a person with type 1 diabetes.
16. Discuss the metabolic relationships between glucose, ketones, fatty acids, and metabolic acids including how they are altered, the effects of increased counter-regulatory hormones, and the clinical significance of ketonemia and ketonuria in uncontrolled diabetes mellitus.
17. Describe the glycation of hemoglobin A_{1c}; state the percentage of hemoglobin A_1 constituted by A_{1c}.
18. Explain how measurement of glycated hemoglobin is useful in diagnosis of diabetes and in monitoring control of blood glucose concentration; state the cutoff value of hemoglobin A_{1c} used to diagnose diabetes.
19. Specify the effects that young and old erythrocytes have on hemoglobin A_{1c} values.

*Casual is defined as any time of day without regard to time since last meal.

Objectives—cont'd

20. List and discuss three techniques used to determine glycated hemoglobin values including principles of analysis, possible interference by hemoglobin variants, and specimen requirements.
21. Describe the effects of hyperglycemia on advanced glycation end products and in turn how advanced glycation end products contribute to certain complications of diabetes.
22. State how urinary albumin excretion is useful in determining diabetic nephropathy; list the specimen collection requirements for this urine test.
23. Describe three semi-quantitative analyses of urinary albumin.
24. State the healthy reference intervals used for fasting plasma glucose, oral glucose tolerance, and glycated hemoglobin analyses.
25. Analyze and solve case studies related to the different types of diabetes and impaired glucose tolerance using descriptions of symptoms and results of laboratory analyses.

Key Words and Definitions

Advanced glycation end products (AGEs) Proteins that have been irreversibly modified by nonenzymatic attachment of glucose; may contribute to the chronic complications of diabetes.

C-peptide A 31-amino-acid protein that connects insulin's A-chain to its B-chain in the proinsulin molecule.

Diabetes mellitus A group of metabolic disorders of carbohydrate metabolism in which glucose is underutilized, producing hyperglycemia.

Diabetic nephropathy The nephropathy that commonly accompanies later stages of diabetes mellitus.

Diabetic retinopathy The retinal changes associated with diabetes mellitus.

Diabetogenes Genes that contribute to the development of diabetes; a genetic basis is identified in less than 5% of individuals with type 2 diabetes.

Facilitative glucose transporters A group of membrane proteins that facilitate the transport of glucose over a plasma membrane.

Fasting Abstinence from all food and drink except water for a prescribed period.

Gestational diabetes mellitus (GDM) Carbohydrate intolerance with onset during pregnancy.

Glucagon A polypeptide hormone secreted by the alpha cells of the islets of Langerhans in response to hypoglycemia or the presence of acetylcholine, certain amino acids, or growth hormone.

Glucose A six-carbon simple sugar that is the premier fuel for most organisms and an important precursor of other body constituents.

Glycated hemoglobin Hemoglobin that has a sugar residue attached; HbA_{1c} is the major fraction of glycated hemoglobin; also known as glycohemoglobin.

Glycogen A polysaccharide with a formula of $(C_6H_{10}O_5)$ used by muscle and liver for carbohydrate storage.

Glycogen storage disease A group of rare inborn errors of metabolism caused by defects in specific enzymes or transporters involved in the metabolism of glycogen (also known as Von Gierke disease).

Hyperglycemia Increased glucose concentrations in the blood.

Hypoglycemia Decreased glucose concentrations in the blood.

Impaired glucose tolerance (IGT) A term denoting values of fasting plasma glucose or results of an oral glucose tolerance test that are abnormal but not high enough to be diagnostic of diabetes mellitus.

Insulin A protein hormone produced by β-cells of the pancreas that decreases blood glucose concentrations.

Insulin-like growth factors (IGF) Serum peptides with insulin-like actions, formerly called somatomedins.

Insulin resistance Impairment of normal biologic responses to insulin.

Ketones Compounds that arise from free fatty acid breakdown; insulin deficiency leads to increased serum ketones, which are the major contributors to the metabolic acidosis that occurs in individuals with diabetic ketoacidosis.

Oral Glucose tolerance test (OGTT) A test whereby glucose is ingested into a fasting stomach and measurements of plasma glucose are taken over time; if glucose levels do not return to normal within 2 to 2.5 hours the patient may have impaired glucose tolerance or diabetes mellitus.

Proinsulin A precursor of insulin, with a molecular weight of 8,000 to 10,000; it has minimal hormonal activity and is converted to insulin by removal of the connecting C peptide, leaving the two (A and B)-chain, active insulin molecule.

Self-monitoring of blood glucose (SMBG) A procedure for collecting concentrations of blood glucose at several time points to enable maintenance of a constant glucose concentration.

Type 1 diabetes mellitus (T1DM) One of the two major types of diabetes mellitus. It is an autoimmune disease that results in the destruction beta cells of the pancreas, leading to loss of the ability to secrete insulin. Also called insulin-dependent diabetes, type 1A diabetes.

Type 2 diabetes mellitus (T2DM) One of the two major types of diabetes mellitus, characterized by peak age of onset between 50 and 60 years.

Diabetes mellitus is a group of metabolic disorders of carbohydrate metabolism in which **glucose** is underused, producing **hyperglycemia**. Some patients may experience acute life-threatening hyperglycemic episodes, such as ketoacidosis or hyperosmolar coma. As the disease progresses, patients are at increased risk for the development of specific complications, including **diabetic retinopathy** leading to blindness, **diabetic nephropathy** leading to renal failure, and nerve damage, collectively known as microvascular complications, as well as atherosclerosis, which is considered a macrovascular complication. The last may result in stroke, gangrene, or coronary artery disease.

Diabetes is a common disease, although the exact prevalence is unknown. Current estimates range from ≈285 to 366 million people with diabetes, and by 2030, this number is predicted to reach 552 million, 80% of whom will live in developing countries. In the United States, the number of people with diabetes has increased dramatically. The prevalence in 1999-2002 was 9.3%, 30% of whom were undiagnosed. Recent analysis, using both fasting glucose and hemoglobin A_{1c} (but not **oral glucose tolerance testing [OGTT]**) indicates a 2010 prevalence of diabetes in the United States in persons 20 years of age and older of 11.3% (equivalent to ≈26 million people). Of these, ≈27% are undiagnosed. Similarly, the prevalence of diabetes in Asian populations has increased rapidly in recent decades, reaching more than 110 million in 2007. These statistics led to a description of diabetes as "one of the main threats to human health in the twenty-first century." The prevalence of diabetes increases with age, and approximately half of all cases occur in people older than 55 years. In the United States, more than 25% of the population older than 65 years has diabetes. A racial predilection has been noted, and by the age of 65, 33%, 25%, and 17% of Hispanics, blacks, and whites, respectively, in the United States have diabetes. In 2007, diabetes was estimated to be responsible for $174 billion in healthcare expenditures in the United States. Direct costs were $116 billion, with 56% of that total incurred by those 65 years of age and older. An estimated 3.8 million people worldwide died from diabetes-related causes in 2007. Diabetes is the fourth most common cause of death in the developed world.

Classification

Diabetes was initially diagnosed by OGTT. In 1979 a workgroup of the National Diabetes Data Group proposed modified criteria for diagnosis. This is classification scheme recognized two major forms of diabetes: type I (**insulin**-dependent) diabetes mellitus (IDDM) and type II (non–insulin-dependent) diabetes mellitus (NIDDM). The terms juvenile-onset and adult-onset diabetes were abolished. To base the classification on cause rather than on treatment, the American Diabetes Association (ADA) revised the classification, in 1997, eliminating the terms insulin-dependent diabetes mellitus and non–insulin-dependent diabetes mellitus, which now are termed **Type 1 diabetes mellitus (T1DM)** and **Type 2 diabetes mellitus (T2DM)** respectively (Box 33-1). The previous categories of abnormality of glucose tolerance and potential abnormality of glucose tolerance have been abolished.

BOX 33-1 Classification of Diabetes Mellitus

I Type 1 diabetes
II Type 2 diabetes
III Other specifc types of diabetes
IV Gestational diabetes mellitus (GDM)

From the American Diabetes Association, Diabetes Care 2013;36(Suppl 1):S11-66.

Type 1 Diabetes Mellitus

Approximately 5% to 10% of all cases of diabetes are included in this category. Patients usually have abrupt onset of symptoms such as (1) polyuria, (2) polydipsia, and (3) rapid weight loss. They have insulinopenia (a deficiency of insulin) caused by loss of pancreatic islet β-cells and are dependent on insulin to sustain life and prevent ketosis. Most patients have antibodies that identify an autoimmune process (see later discussion) and some have no evidence of autoimmunity and are classified as type 1 idiopathic. The peak incidence occurs in childhood and adolescence. Approximately 75% acquire this disease before the age of 18, but onset in the remainder may occur at any age. Age at presentation is not a criterion for classification.

Type 2 Diabetes Mellitus

This group accounts for approximately 90% of all cases of diabetes. Patients have minimal symptoms, are not prone to ketosis, and are not dependent on insulin to prevent ketonuria. Insulin concentrations may be (1) normal, (2) decreased, or (3) increased, and most individuals with this form of diabetes have impaired insulin action. Obesity is commonly associated, and weight loss alone usually improves hyperglycemia in these persons. However, many individuals with type 2 diabetes may require (1) dietary manipulation, (2) oral hypoglycemic agents, or (3) insulin to control hyperglycemia. Most patients acquire the disease after age 40, but it may occur in younger people. Type 2 diabetes in children and adolescents is an emerging, significant problem. Among children in Japan, type 2 diabetes is now more common than type 1.

Other Specific Types of Diabetes Mellitus

This subclass includes uncommon patients in whom hyperglycemia is due to a specific underlying disorder, such as (1) genetic defects of β-cell function; (2) genetic defects in insulin action; (3) disease of the exocrine pancreas; (4) endocrinopathies (e.g., Cushing syndrome, acromegaly, glucagonoma); (5) administration of hormones or drugs known to induce β-cell dysfunction (e.g., dilantin, pentamidine) or to impair insulin action (e.g., glucocorticoids, thiazides, β-adrenergics); (6) infection; (7) uncommon forms of immune-mediated diabetes; or (8) other genetic conditions (e.g., Down syndrome, Klinefelter syndrome, porphyria; see Reference 2 for a detailed list). This is was formerly termed secondary diabetes.

Gestational Diabetes Mellitus

This is defined as carbohydrate intolerance of variable severity with onset or *first* recognition during pregnancy. (Note that women with diabetes who become pregnant are not included

in this category.) Estimates of the frequency of abnormal glucose tolerance during pregnancy vary from 1% to 14%, depending on the population studied and the diagnostic tests employed. In the United States, **gestational diabetes mellitus** (GDM) occurs in 6% to 8% of pregnancies (≈200,000 cases annually). Women with GDM are at significantly increased risk for the subsequent development of type 2 diabetes. The risk is particularly high in women (1) who have marked hyperglycemia during or soon after pregnancy, (2) who are obese, and (3) whose GDM was diagnosed before 24 weeks' gestation. At 6 to 12 weeks postpartum, all patients who had GDM should be evaluated for diabetes according to nonpregnant OGTT criteria. If diabetes is not present, patients should be re-evaluated for diabetes at least every 3 years.

Impaired Glucose Tolerance

Impaired glucose tolerance (IGT) is diagnosed in people who have fasting blood glucose concentrations less than those required for a diagnosis of diabetes but have a plasma glucose response during the OGTT between normal and diabetic states. The 2-hour postload plasma glucose following an OGTT is 140 to 199 (7.8-11.1 mmol/L) for this classification. An OGTT is required to assign a patient to this class. Development of overt diabetes occurs at a rate of 1% to 5% per year, but a large proportion of cases spontaneously revert to normal glucose tolerance. Microvascular disease is rare in this group, and patients usually do not experience the renal or retinal complications of diabetes. Patients have an increased prevalence of atherosclerosis and mortality from cardiovascular disease.

Impaired Fasting Glucose

This category is analogous to IGT, but it is diagnosed by a *fasting* glucose concentration between the reference interval for a healthy individual and that diagnostic of diabetes. For example, a fasting plasma glucose (FPG) between 100 and 125 mg/dL (5.6-6.9 mmol/L). It is a metabolic stage between healthy glucose homeostasis and diabetes. As with IGT, persons with impaired fasting glucose (IFG) are at increased risk for the development of diabetes and cardiovascular disease. IFG and IGT are not clinical entities but rather are risk factors for diabetes and cardiovascular disease.

Hormones that Regulate Blood Glucose Concentration

During a brief fast, a precipitous decline in the concentration of blood glucose is prevented by breakdown of **glycogen** stored in the liver and synthesis of glucose in the liver. Some glucose is derived from gluconeogenesis in the kidneys. These organs contain glucose-6-phosphatase, which is necessary to convert glucose-6-phosphate (derived from gluconeogenesis or glycogenolysis) to glucose. Skeletal muscle lacks this enzyme; muscle glycogen therefore cannot contribute directly to blood glucose. With more prolonged fasting (>42 hours), gluconeogenesis accounts for essentially all glucose production. In contrast, after a meal, the absorbed glucose is converted to glycogen (for storage in the liver and skeletal muscle) or fat (for storage in adipose tissue). Despite large fluctuations in the supply and demand of carbohydrates, the concentration of glucose in the blood is typically maintained within a fairly narrow interval by hormones that modulate the movement of glucose into and out of the circulation. These include (1) insulin, which decreases blood glucose, and the counter-regulatory hormones (2) glucagon, (3) epinephrine, (4) cortisol, and (5) growth hormone, which increase blood glucose concentrations (Figure 33-1). Normal glucose disposal depends on (1) the ability of the pancreas to secrete

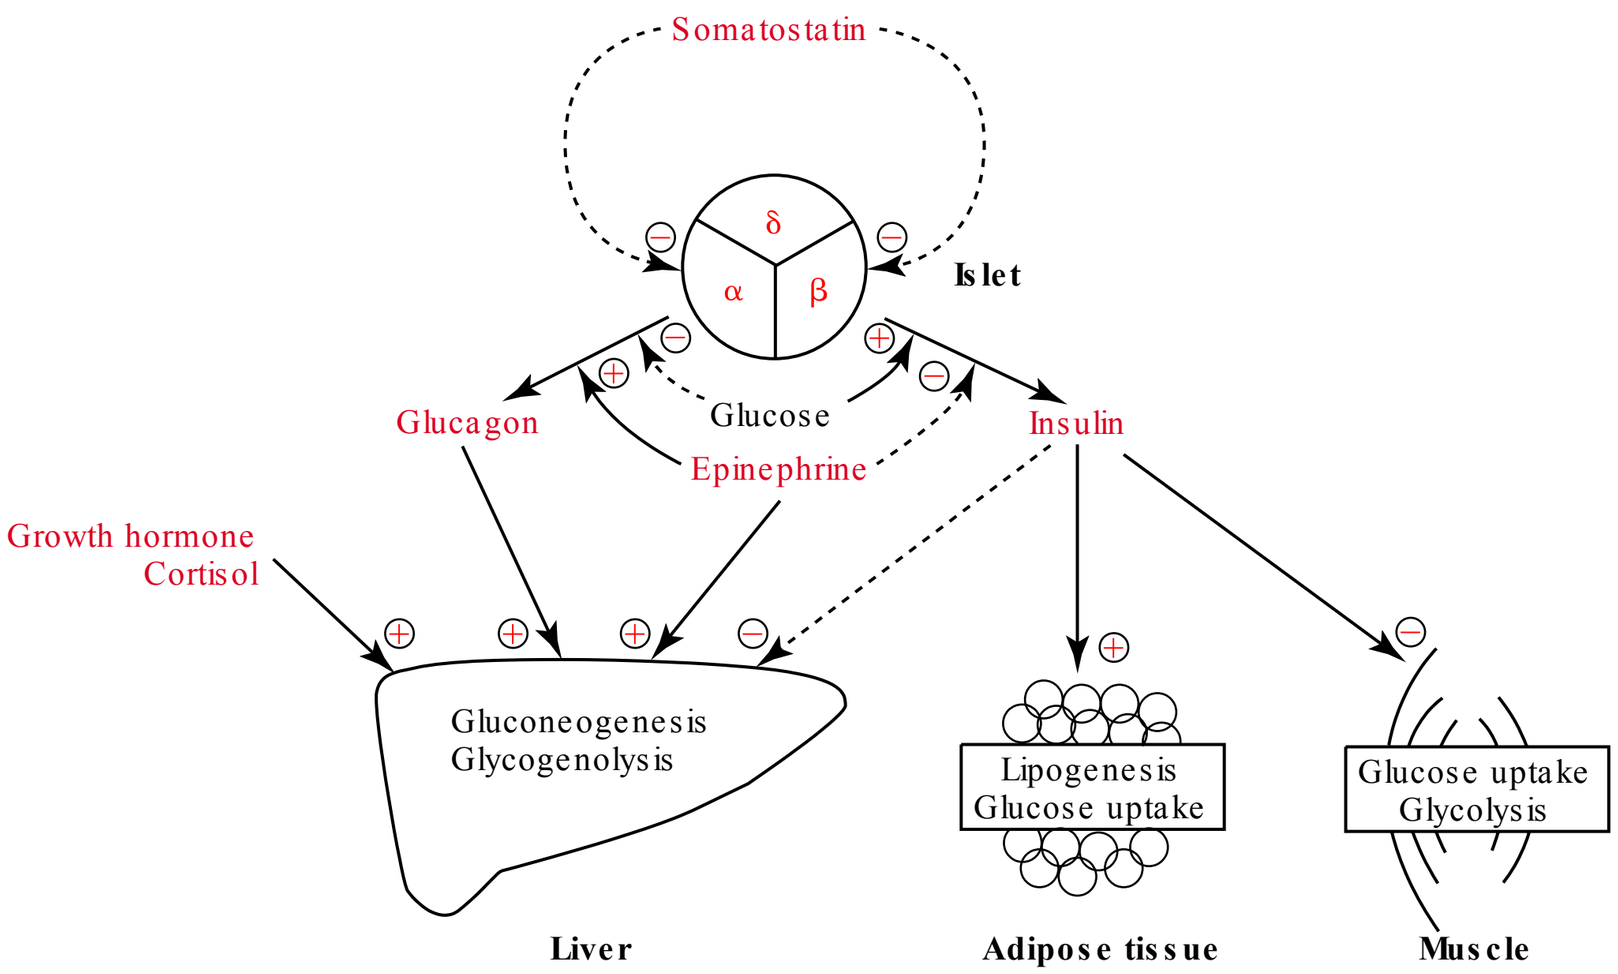

Figure 33-1 Hormonal regulation of blood glucose. Key: +, stimulation; −, inhibition. Cortisol, growth hormone, and epinephrine antagonize the effects of insulin.

insulin, (2) the ability of insulin to promote uptake of glucose into peripheral tissue, and (3) the ability of insulin to suppress hepatic glucose production. The major insulin target organs are (1) liver, (2) skeletal muscle, and (3) adipose tissue. These organs exhibit some differences in their responses to insulin. For example, the hormone stimulates glucose uptake through a specific glucose transporter—GLUT4—into muscle and fat cells but not into liver cells.

Insulin

Insulin is a protein hormone produced by the β-cells of the islets of Langerhans in the pancreas. Insulin was the first protein hormone to be sequenced, the first substance to be measured by radioimmunoassay (RIA), and the first compound produced by recombinant DNA technology for clinical use. It is an anabolic hormone that stimulates the uptake of glucose into fat and muscle, promotes the conversion of glucose to glycogen or fat for storage, inhibits glucose production by the liver, stimulates protein synthesis, and inhibits protein breakdown. The release and mechanisms of action of insulin are discussed in greater detail on pages 1417 to 1422 in an expanded version of this chapter in the 5th edition of Tietz Textbook of Clinical Chemistry and Molecular Diagnostics.[12]

Human insulin (molecular mass 5808 Da) consists of 51 amino acids in two chains (A and B) joined by two disulfide bridges, with a third disulfide bridge within the A chain. Insulin from most animals is immunologically and biologically similar to human insulin, and in the past, patients were treated with insulin purified from beef or pig pancreas. Virtually all patients are now treated with recombinant human insulin.

Preproinsulin, a protein of about 100 amino acids, is not detectable in the circulation under normal conditions because it is rapidly converted by cleaving enzymes to proinsulin. **Proinsulin** is stored in secretory granules in the Golgi complex of the β-cells, where proteolytic cleavage to insulin and connecting peptide (**C-peptide**) occurs. This is post-translational processing is catalyzed by two Ca^{2+}-regulated endopeptidases: prohormone convertases 1 and 2 (PC1 and PC2). These split proinsulin intermediates, split-32,33-proinsulin and split-65,66-proinsulin, are further hydrolyzed to insulin and C-peptide. At the cell membrane, insulin and C-peptide are released into the portal circulation in equimolar amounts. In addition, small amounts of proinsulin and intermediate cleavage forms enter the circulation.

Proinsulin which has relatively low biological activity (approximately 10% of insulin potency), is the major storage form of insulin. Normally, only small amounts (about 3% of the amount of insulin, on a molar basis) of proinsulin enter the circulation. However, the hepatic clearance rate for proinsulin is only 25% of insulin clearance, the half-life of proinsulin is twofold to threefold longer, and concentrations in the fasting state are ≈10% to 15% of insulin concentrations.

C-peptide is devoid of biological activity but appears necessary to ensure the correct structure of insulin. Fasting C-peptide concentrations are fivefold to 10-fold higher than those of insulin owing to the longer half-life of C-peptide (≈35 minutes). The liver does not extract C-peptide, which is removed from the circulation by the kidneys and is degraded, with a fraction excreted unchanged in the urine.

Glucose Transport

One of the fundamental effects of insulin is to increase glucose uptake into cells. The molecular mechanism of this action of insulin is extremely complex. The transport of glucose into cells is modulated by two families of proteins. The sodium-dependent glucose transporter promotes the uptake of glucose and galactose from the lumen of the small bowel and their reabsorption from urine in the kidney. The second family of glucose carriers, termed **facilitative glucose transporters** (GLUTs), is located on the surface of all cells (Table 33-1). These transporters are designated GLUT1 to GLUT14, according to the order in which they were identified. Eleven have been shown to mediate glucose transport. On the basis of sequence similarities, they have been divided into three subfamilies, namely, class I (GLUT 1 to 4), class II (GLUT 5, 7, 9, and 11), and class III (GLUT 6, 8, 10, 12, and 14). GLUT1 is widely expressed and provides many cells with their basal glucose requirement. GLUT1 in the blood-brain barrier and GLUT3 in neuronal cells

TABLE 33-1 Facilitative Human Glucose Transporters

Name	Class	Tissue	Function
GLUT1	I	Wide distribution, especially brain, kidney, colon, and fetal tissues	Basal glucose transport
GLUT2	I	Liver, β-cells of pancreas, small intestine, and kidney	Non–rate-limiting glucose transport
GLUT3	I	Wide distribution, especially neurons, placenta, and testis	Glucose transport in neurons
GLUT4	I	Skeletal muscle, cardiac muscle, adipose tissue	Insulin-stimulated glucose transport
GLUT5	II	Small intestine, kidney, skeletal muscle, brain, and adipose tissue	Transports fructose (not glucose)
GLUT6	III	Brain, spleen, leukocytes	
GLUT7	II	Intestine, testis, prostate	
GLUT8	III	Testis, heart, brain	
GLUT9	II	Kidney, liver	
GLUT10	III	Liver, pancreas	
GLUT11	II	Pancreas, kidney, placenta, skeletal muscle	
GLUT12	III	Heart, prostate	
HMIT		Brain	Transports myo-inositol (not glucose)
GLUT14	III	Testis	

provide the constant high concentrations of glucose required by the brain. GLUT2 is expressed in hepatocytes, β-cells of the pancreas, and basolateral membranes of intestinal and renal epithelial cells. It is a low-af nity, high-capacity transport system that allows non–rate-limiting movement of glucose into and from these cells. GLUT4 catalyzes the rate-limiting step for glucose uptake and metabolism in skeletal muscle, the major organ of glucose consumption.

When circulating insulin concentrations are low, most of the GLUT4 is localized in intracellular compartments and is inactive. After a meal, the pancreas releases insulin, which stimulates the translocation of GLUT4 to the plasma membrane, thereby promoting glucose uptake into skeletal muscle and fat. Insulin-stimulated glucose transport into skeletal muscle is impaired in individuals with type 2 diabetes, but the mechanism of the defect has not been established. GLUT5 is responsible for fructose uptake in the intestine. Less is known about the other GLUTs. Glucose transport has been reported for GLUT 6, 8, 11, and 12.

Insulin-Like Growth Factors

Insulin-like growth factors (IGF) 1 and 2 (IGF-1 and IGF-2) are polypeptides structurally related to insulin (see Chapter 40). T ese hormones (previously referred to as nonsuppressible insulin-like activity or somatomedin) exhibit metabolic and growth-promoting effects similar to those of insulin. Accumulating evidence implicates the IGF axis in the development of several common cancers. IGF-1 (previously known as somatomedin C) is an important mediator of growth hormone action and is one of the major regulators of cell growth and differentiation. T e physiological role of IGF-2 is not known. Synthesis of IGF-1 depends on growth hormone and occurs predominantly in the liver. In addition, many other cells produce IGF-1 that does not enter the circulation but acts locally. Circulating IGF concentrations are approximately 1000-fold higher than insulin concentrations, and the hormone is kept inactive by binding to a family of at least six specific binding proteins. T ese proteins regulate IGF by protecting the ligands in the circulation and delivering them to their target tissue. In contrast to insulin, which is unbound in the circulation, less than 10% of total serum IGF-1 is free. T e biological actions of IGF are exerted through specific IGF receptors or the insulin receptor. T e IGF-1 receptor is closely related to the insulin receptor in structure and biochemical properties. In contrast, the IGF-2 receptor is quite different; it lacks tyrosine kinase activity, and its physiological relevance is not understood. T e IGF-1 receptor has a high af nity for both IGF-1 and IGF-2 but a low af nity for insulin. T e IGF-2 receptor has (1) high, (2) low, and (3) no af nity for IGF-2, IGF-1, and insulin, respectively. T e insulin receptor binds insulin with high af nity and IGF-1 and IGF-2 with low af nity.

T e significance of IGFs in normal carbohydrate metabolism is not known. Exogenous administration produces **hypoglycemia**, whereas a deficiency of IGF-1 results in dwarfism (pygmies and Laron dwarfs). IGFs, particularly IGF-2, may be produced in excess by extrapancreatic neoplasms, and patients may have fasting hypoglycemia. High concentrations of both IGF-2 protein in the blood and IGF-2 messenger RNA (mRNA) in tumor extracts led to the proposal that IGF-2 is the humoral mediator of non–islet cell tumor–induced hypoglycemia. Hypoglycemia resolves after removal of the tumors. Clinically, measurements of plasma IGF-1 concentrations are used primarily to evaluate growth hormone deficiency and to detect and monitor treatment of growth hormone excess (acromegaly).

Counter-Regulatory Hormones

Several hormones have actions opposite to those of insulin. T ese counter-regulatory hormones are catabolic and increase hepatic glucose production initially by enhancing the breakdown of glycogen to glucose (glycogenolysis), and later by stimulating the synthesis of glucose (gluconeogenesis). T e initial response (within minutes) to low blood glucose is an increase in glucose production, stimulated by glucagon and epinephrine. Over time (3 to 4 hours), growth hormone and cortisol increase glucose mobilization and decrease glucose use (see Figure 33-1). Evidence suggests that glucose production by the liver is an inverse function of ambient glucose concentration, independent of hormonal factors (glucose autoregulation). T e role of other hormones or neurotransmitters is not clear but appears relatively unimportant. Multiple counter-regulatory hormones exhibit both redundancy and hierarchy. Glucagon is the most important, and epinephrine becomes critical when glucagon is deficient. T e other factors have lesser roles. Note: T ese hormones, briefly described here, are discussed further in Chapters 25, 26, 40, and 42.

Glucagon

Glucagon is a 29-amino-acid polypeptide secreted by α-cells of the pancreas. T e major target organ for glucagon is the liver, where it binds to specific receptors and increases both intracellular adenosine-5′-monophosphate and calcium. Glucagon stimulates the production of glucose in the liver by glycogenolysis and gluconeogenesis and enhances ketogenesis in the liver. A minor target organ for glucagon is adipose tissue, where the hormone increases lipolysis. Glucagon secretion is regulated primarily by plasma glucose concentrations, with low and high concentrations of plasma glucose being stimulatory and inhibitory, respectively. Long-standing diabetes impairs the glucagon response to hypoglycemia, resulting in an increased incidence of hypoglycemic episodes. Stress, exercise, and amino acids induce glucagon release. Insulin inhibits glucagon release from the pancreas and decreases glucagon gene expression, thereby attenuating its biosynthesis. Increased glucagon concentrations, secondary to insulin deficiency, are believed to contribute to the hyperglycemia and ketosis of diabetes.

Proglucagon is also produced in the distal gut by L-cells, which process it into glucagon, glucagon-like peptide-1 (GLP-1), and GLP-2. Food ingestion stimulates release of GLP-1, which acts on β-cells of the pancreas to stimulate insulin gene transcription and potentiate glucose-induced insulin secretion. GLP-1 and glucose-dependent insulinotropic polypeptide (GIP) are incretin hormones that are responsible for 70% of

postprandial insulin secretion. GLP-1 reduces hyperglycemia by regulating insulin and glucagon secretion. It also inhibits acid secretion and emptying in the stomach and decreases food intake by increasing satiety. For these reasons, GLP-1 analogues are now used in the treatment of type 2 diabetes,

Epinephrine

Epinephrine (see Chapter 26), a catecholamine secreted by the adrenal medulla, stimulates glucose production (via gluconeogenesis and glycogenolysis) and decreases glucose use, thereby increasing blood glucose concentrations. It also stimulates glucagon secretion and inhibits insulin secretion by the pancreas (see Figure 33-1). Epinephrine appears to have a key role in glucose counter-regulation when glucagon secretion is impaired (e.g., in type 1 diabetes). Physical or emotional stress increases epinephrine production, releasing glucose for energy. Tumors of the adrenal medulla, known as pheochromocytomas, secrete excess epinephrine or norepinephrine and produce moderate hyperglycemia as long as glycogen stores are available in the liver.

Growth Hormone

Growth hormone (see Chapter 40) is a polypeptide secreted by the anterior pituitary gland. It stimulates gluconeogenesis, enhances lipolysis, and antagonizes insulin-stimulated glucose uptake.

Cortisol

Cortisol (see Chapter 41), secreted by the adrenal cortex in response to adrenocorticotropic hormone (ACTH), stimulates gluconeogenesis and increases the breakdown of protein and fat. Patients with Cushing syndrome have increased cortisol owing to tumor or hyperplasia of the adrenal cortex and may become hyperglycemic. In contrast, people with Addison's disease have adrenocortical insufficiency caused by destruction or atrophy of the adrenal cortex and may exhibit hypoglycemia.

Other Hormones Influencing Glucose Metabolism

Thyroxine

Thyroxine (see Chapter 42), secreted by the thyroid gland, is not directly involved in glucose homeostasis, but it stimulates glycogenolysis and increases the rates of gastric emptying and intestinal glucose absorption. These factors may produce glucose intolerance in thyrotoxic individuals, but patients usually have a fasting plasma glucose concentration in the reference interval.

Somatostatin

Somatostatin, also called growth hormone–inhibiting hormone, is a 14-amino-acid peptide found in the (1) gastrointestinal tract, (2) hypothalamus, and (3) δ-cells of the pancreatic islets. Although somatostatin does not appear to have a direct effect on carbohydrate metabolism, it inhibits the release of growth hormone from the pituitary. In addition, somatostatin inhibits secretion of glucagon and insulin by the pancreas, thus modulating the reciprocal relationship between these two hormones.

Measurement of Insulin, Proinsulin, C-Peptide, and Glucagon

Although interest in the possible clinical value of measuring the concentrations of insulin and its precursors continues, the assays are useful primarily for research purposes. No role is known for routine testing for insulin, proinsulin, or C-peptide in most patients with diabetes. Measurement of C-peptide is sometimes necessary in the United States for patients to obtain insurance coverage for continuous subcutaneous insulin infusion pumps. It must be emphasized that the diagnostic criteria for diabetes do not include measurements of hormones.

Various methods are used to measure (1) insulin, (2) proinsulin, (3) C-peptide, and (4) glucagon. A brief overview is provided here. For additional details, readers are referred to the expanded version of this chapter in the 5th edition of Tietz Textbook of Clinical Chemistry and Molecular Diagnostics.[12]

Insulin

The primary clinical application of insulin measurement is for the evaluation of patients with fasting hypoglycemia (see Chapter 22). Measurement of circulating insulin, however, could be helpful in evaluating **insulin resistance** and insulin secretion. Insulin determination has also been proposed to be of value in selecting the optimal initial therapy for patients with type 2 diabetes. In theory, the lower the pretreatment insulin concentration, the more appropriate might be insulin or an insulin secretagogue (a substance that causes another substance to be secreted) as the treatment of choice. Although intellectually appealing, no evidence suggests that knowledge of the insulin concentration leads to more efficacious treatment. Moreover, lack of harmonization of insulin assays hampers use of the assays.

In the past, measurement of insulin was advocated in the evaluation and management of patients with polycystic ovary syndrome. Women with this condition have insulin resistance and abnormal carbohydrate metabolism that may respond to oral hypoglycemic agents. However, it is not clear whether assessing insulin resistance by measuring insulin concentrations affords any advantage over clinical signs of insulin resistance (body mass index, acanthosis nigricans), and the American College of Obstetrics and Gynecology does not recommend routine measurements of insulin.

A few investigators have recommended measuring insulin along with glucose during an OGTT as an aid to early diagnosis of diabetes, but this approach also is not recommended.

Although insulin has been assayed for more than 50 years, there is still no (1) highly accurate, (2) precise, and (3) reliable procedure available to measure insulin. Many insulin assays, however, are commercially available. The most widely used techniques are immunoassays and, isotope dilution mass spectrometry (IDMS) assay.The term immunoreactive insulin is used in reference to assays that may recognize, in addition to insulin, substrates that share antigenic epitopes with insulin. Examples include (1) proinsulin, (2) proinsulin conversion intermediates, and (3) insulin derivatives, produced by glycation or dimerization. Antisera raised against insulin show some

cross-reactivity with proinsulin but not with C-peptide. Specificity is not a problem in healthy individuals because the low proinsulin concentrations do not appreciably affect the absolute values of insulin. In certain situations (e.g., patients with diabetes or islet cell tumors), proinsulin is present at higher concentrations, and direct assay of plasma may falsely overestimate the true insulin concentration. Because proinsulin has very low activity, incorrect conclusions regarding the availability of biologically active insulin may be reached in patients with diabetes. The magnitude of the error depends on the concentration of proinsulin and the extent of cross-reactivity of the antiserum with proinsulin. The various immunoassays also show different cross-reactivities with pharmacological insulins.

An IDMS assay has been developed to measure the concentrations of (1) insulin, (2) proinsulin, and (3) C-peptide. Comparison of patient samples revealed that most, but not all, results were higher by immunoassay than by mass spectrometry. Thus immunoassays may overestimate insulin, particularly at low concentrations. The high protein concentration in the serum requires extraction of proteins (e.g., by immunoaffinity) and purification by high-performance liquid chromatography (HPLC) before quantification by mass spectrometry. This method is not suitable for routine laboratory analysis, but it is the best higher-order measurement procedure available and is used as a candidate reference procedure.

In 2004 the ADA convened an international workgroup to standardize insulin assays. Evaluation of 10 commercial insulin methods from nine manufacturers revealed within-assay CVs ranging from 3.7% to 39% and among-assay CVs of 12% to 66%. A common insulin reference preparation failed to improve harmonization of results. The report concluded that not all commercial insulin assays have acceptable performance characteristics.

Reference intervals vary among assays. After an overnight fast, insulin concentrations in healthy, normal, non-obese people vary from 12 to 150 pmol/L (2 to 25 μIU/mL). More specific assays that have minimal cross-reactivity with proinsulin reveal a fasting plasma insulin concentration less than 60 pmol/L (10 μIU/mL). Concentrations up to 1200 pmol/L (200 μIU/mL) have been reached during a glucose tolerance test.[12] **Fasting** insulin values are higher in obesity and lower in trained athletes.

Proinsulin

High proinsulin concentrations are usually noted in patients with benign or malignant β-cell tumors of the pancreas. Most patients with β-cell tumors have increased (1) insulin, (2) C-peptide, and (3) proinsulin concentrations, but occasionally only proinsulin is increased. Despite its low biological activity, proinsulin production may be adequate to produce hypoglycemia. In addition, a rare form of familial hyperproinsulinemia, produced by impaired conversion to insulin, has been described.[12] Measurement of proinsulin can be useful to determine the amount of proinsulin-like material that cross-reacts in an insulin assay. Patients with type 2 diabetes have increased proportions of proinsulin and proinsulin conversion intermediates, high concentrations of which are associated with cardiovascular risk factors. Even relatively mild hyperglycemia produces hyperproinsulinemia, with values greater than 40% of insulin concentration in type 2 diabetes. Increased proinsulin concentrations may also be detected in patients with chronic renal failure, cirrhosis, or hyperthyroidism.

Accurate measurement of proinsulin has been difficult because (1) normal blood concentrations are low; (2) antibody production is difficult; (3) most antisera cross-react with insulin and C-peptide, which are present in much higher concentrations; (4) the assays measure intermediate cleavage forms of proinsulin; and (5) reference preparations of pure proinsulin are not readily available. Biosynthetic proinsulins have more recently allowed the production of monoclonal antibodies to proinsulin and have been used in the manufacture of proinsulin calibrators and reference preparations.

Reference intervals for proinsulin are highly dependent on the method of analysis, the degree of cross-reactivity of the antisera, and the purity of proinsulin calibrators. Each laboratory should establish its own reference intervals. Reference intervals in healthy, fasting individuals reported in the literature vary from 1.1 to 6.9 pmol/L to 2.1 to 12.6 pmol/L.

C-Peptide

Measurement of C-peptide has several advantages over insulin measurement. Because hepatic metabolism is negligible, C-peptide concentrations are better indicators of β-cell function than are insulin concentrations. Furthermore, C-peptide assays do not measure exogenous insulin and are not affected by insulin antibodies, which interfere with insulin immunoassays.

The primary reason for measuring C-peptide is to evaluate fasting hypoglycemia. Some patients with insulin-producing β-cell tumors, particularly if hyperinsulinism is intermittent, may exhibit increased C-peptide concentrations with normal insulin concentrations. When hypoglycemia is due to surreptitious insulin injection, insulin concentrations will be high but C-peptide values will be low; this occurs because C-peptide is not found in commercial insulin preparations and exogenous insulin suppresses β-cell function.

Basal or stimulated (by glucagon or glucose) C-peptide concentrations provide estimates of a patient's insulin secretory capacity and rate. Although valuable in clinical research, C-peptide measurement has a negligible role in the routine management of patients with diabetes. A relatively new indication for C-peptide analysis is the requirement that Medicare patients in the United States must have low C-peptide concentrations to be eligible for coverage of insulin pumps.

Measurement of C-peptide also is used to monitor patients' response to pancreatic surgery. C-peptide should be undetectable after a radical pancreatectomy and should increase after a successful pancreas or islet cell transplant. In addition, a stable C-peptide concentration is used as an end point in immunomodulatory trials for the prevention of type 1 diabetes.

Measurements of urine C-peptide are useful when continuous assessment of β-cell function is desired, or when

frequent blood sampling is not practical. The 24-hour urine C-peptide content (in the absence of renal failure, which produces increased concentrations) correlates well with fasting serum C-peptide concentration or with the sum of C-peptide concentrations in sequential specimens after a glucose load. However, the fraction of secreted C-peptide that is excreted in the urine exhibits high intersubject and intrasubject variability, limiting the value of urine C-peptide as a measure of insulin secretion.

Assays are not affected by anti-insulin antibodies, but methodological problems produce large between-method variation. These difficulties include variable specificity among different antisera, variable cross-reactivity with proinsulin, and various types of C-peptide preparations used as a calibrator. Fasting serum concentrations of C-peptide in healthy people vary from 0.78 to 1.89 ng/mL (0.25 to 0.6 nmol/L). After stimulation with glucose or glucagon, values vary from 2.73 to 5.64 ng/mL (0.9 to 1.87 nmol/L), or three to five times the prestimulation value. Urinary C-peptide is usually in the interval of 74 ± 26 μg/L (25 ± 8.8 μmol/L).

Glucagon

Very high concentrations of glucagon are seen in patients with α-cell tumors of the pancreas called glucagonomas. Patients with this tumor frequently have (1) weight loss, (2) necrolytic migratory erythema, (3) diabetes, (4) stomatitis, and (5) diarrhea. Skin lesions often occur first and are frequently overlooked. Most tumors have metastasized when finally diagnosed. Low glucagon concentrations are associated with chronic pancreatitis and long-term sulfonylurea therapy.

Immunoassays are commercially available for measuring glucagon. The WHO glucagon international standard (69/194) has been used to calibrate some of these assays.

Fasting plasma concentrations of glucagon vary from 70 to 180 ng/L (20 to 52 pmol/L). Values up to 500 times the upper reference limit may be found in patients with autonomously secreting α-cell neoplasms.

Pathogenesis of Type 1 Diabetes Mellitus

Type 1 diabetes results from cell-mediated autoimmune destruction of the insulin-secreting cells of pancreatic β-cells.[3] In the vast majority of patients, destruction is mediated by T cells. This is termed type 1A or immune-mediated diabetes (see Box 3-1). The α-, δ-, and other islet cells are preserved. The islet cells have a chronic mononuclear cell infiltrate, called insulitis. The autoimmune process leading to type 1 diabetes begins months or years before the clinical presentation, and an 80% to 90% reduction in the volume of β-cells is required to induce symptomatic type 1 diabetes. The rate of islet cell destruction is variable and is usually more rapid in children than in adults.

The other subtype of type 1 diabetes is called idiopathic, or type 1B diabetes. Individuals who have idiopathic type 1 diabetes also experience beta cell destruction, but it is due to a chromosomal abnormality or an unknown cause rather than any autoimmune process.

Antibodies

The most practical markers of β-cell autoimmunity are circulating antibodies, which have been detected in the serum years before the onset of hyperglycemia. The best characterized antibodies are as follows:

Islet cell cytoplasmic antibodies (ICAs) react with a sialoglycoconjugate antigen present in the cytoplasm of all endocrine cells of the pancreatic islets. These antibodies are detected in the serum of 0.5% of normal individuals and in 75% to 85% of patients with newly diagnosed type 1 diabetes.

Insulin autoantibodies (IAAs) are present in more than 90% of children who develop type 1 diabetes before age 5, but in less than 40% of individuals who develop diabetes after age 12. Their frequency in healthy people is similar to that of ICA.

Antibodies to the 65 kDa isoform of glutamic acid decarboxylase (GAD_{65}) have been found up to 10 years before the onset of clinical type 1 diabetes and are present in ≈60% of patients with newly diagnosed diabetes.

Insulinoma-associated antigens (IA-2A and IA-2βA), directed against two tyrosine phosphatases, have been detected in more than 50% of newly diagnosed type 1 diabetes patients.

Zinc transporter ZnT8 was identified recently as a major autoantigen in type 1 diabetes. Initial analysis identified ZnT8 in 60% to 80% of patients with new-onset type 1 diabetes compared with less than 2% of controls.

The American Diabetes Association's "Standards of Medical Care in Diabetes—2013" indicates that antibody tests may be used, in the context of clinical research studies,[1] in relatives of individuals with type 1 diabetes to assess their risk of developing diabetes.

Genetics

Susceptibility to type 1 diabetes is inherited, but the mode of inheritance is complex and has not been defined. It is a multigenic trait, and the major locus is the major histocompatibility complex on chromosome 6. At least 11 other loci on 9 chromosomes also contribute, with the regulatory region of the insulin gene INS on chromosome 11p15 serving as an important locus. The human leukocyte antigen (HLA)-DQ and -DR genetic factors are by far the most important determinants for risk of type 1 diabetes. The concordance rate between identical twins is approximately 30%, and approximately 95% of whites with type 1 diabetes express HLA-DR3 or HLA-DR4 histocompatibility antigens. However, up to 40% of the nondiabetic population also expresses these alleles. In contrast, the HLA-DQB1*0602 allele significantly decreases the risk of type 1 diabetes. HLA typing can indicate absolute risk of diabetes. The risk of a sibling developing diabetes is 1%, 5%, and 10% to 20% if the number of haplotypes shared is none, one, and two, respectively. Nevertheless, only 10% of patients with type 1 diabetes have an affected first-degree relative. Genome-wide

association studies have also identified non-HLA genetic factors that increase risk, including the insulin gene variable number tandem repeat (INS VNTR, CTLA4, and PTPN22). The multiplicity of independent chromosomal regions associated with a predisposition to type 1 diabetes suggests that other susceptibility genes will be identified. Routine measurement of genetic markers is not of value at this time for the diagnosis or management of patients with type 1 diabetes.

Environment

Environmental factors are reported to contribute to the onset of diabetes. Viruses, such as (1) rubella, (2) mumps, and (3) coxsackie virus B, have been implicated. It seems likely that autoimmunity to β-cells is initiated by a viral protein (that shares amino acid sequence with a β-cell protein) or some other environmental insult. Genetic susceptibility and other host factors (e.g., HLA type) determine the progression of the β-cell destruction.

Pathogenesis of Type 2 Diabetes Mellitus

At least two major identifiable pathological defects have been reported in patients with type 2 diabetes. One is a decreased ability of insulin to act on peripheral tissue. This is called **insulin resistance** and is thought by many to be the primary underlying pathological process. The other is β-cell dysfunction, which is an inability of the pancreas to produce sufficient insulin to compensate for the insulin resistance. Thus a relative deficiency of insulin occurs early in the disease, and absolute insulin deficiency occurs late in the disease. The debate over whether type 2 diabetes is due primarily to a defect in β-cell secretion or to peripheral resistance to insulin, or to both, has been raging for decades. However, data are available to support the concept that insulin resistance is the primary defect, preceding the derangement in insulin secretion and clinical diabetes by as much as 20 years. Despite the lack of consensus, it is clear that type 2 diabetes is an extremely heterogeneous disease, and no single cause is adequate to explain the progression from normal glucose tolerance to diabetes. The fundamental molecular defects in insulin resistance and insulin secretion result from a combination of environmental and genetic factors.

Insulin Resistance

Insulin resistance is defined as "a decreased biological response to normal concentrations of circulating insulin"; it is found in obese individuals without diabetes and in patients with type 2 diabetes. The underlying pathophysiological defects have not been identified, but insulin resistance is usually attributed to a defect in insulin action. Measurement of insulin resistance in a routine clinical setting is difficult, and surrogate measures, namely, fasting insulin concentration and the euglycemic insulin clamp, are used to provide an indirect assessment of insulin function. The euglycemic clamp is performed in hospital under close supervision. The patient receives a constant intravenous infusion of insulin in one arm with concurrent intravenous infusion of variable amounts of glucose in the other arm to maintain blood glucose at a normal fasting concentration. A broad clinical spectrum of insulin resistance varies from euglycemia (with marked increase in endogenous insulin) to hyperglycemia (despite large doses of exogenous insulin). Several rare clinical syndromes are also associated with insulin resistance. The prototype is the type A insulin resistance syndrome, which is characterized by hyperinsulinemia, acanthosis nigricans, and ovarian hyperandrogenism.

The insulin resistance syndrome (also known as syndrome X, or the metabolic syndrome) is a constellation of associated clinical and laboratory findings, consisting of (1) insulin resistance, (2) hyperinsulinemia, (3) obesity, (4) dyslipidemia (high triglyceride and low high-density lipoprotein [HDL] cholesterol), and (5) hypertension.[11] Individuals with this syndrome are at increased risk for cardiovascular disease. The metabolic syndrome is diagnosed if an individual meets three or more of the following criteria:

- Abdominal obesity: waist circumference greater than 35 inches (women) or 40 inches (men)
- Triglycerides greater than 150 mg/dL (1.70 mmol/L)
- HDL cholesterol less than 50 mg/dL/(1.30 mmol/L) (women) or less than 40 mg/dL/1.1 mmol/L (men)
- Blood pressure greater than or equal to 130/85 mm Hg
- Fasting plasma glucose greater than or equal to 110 mg/dL (6.1 mmol/L)

The diagnostic criteria proposed by the WHO differ from those listed here. The concept of the "metabolic syndrome" has been questioned by several experts, including the person who first described it, and by major clinical diabetes organizations.

Loss of β-cell Function

Increased β-cell demand induced by insulin resistance is ultimately associated with progressive loss of β-cell function that is necessary for the development of fasting hyperglycemia. The major defect is a loss of glucose-induced insulin release, which is termed selective glucose unresponsiveness. Hyperglycemia appears to render the β-cells increasingly unresponsive to glucose (called glucotoxicity), and the degree of dysfunction correlates with both glucose concentration and duration of hyperglycemia. Restoration of euglycemia rapidly resolves the defect. Increased free fatty acids in serum have also been implicated in β-cell failure. Other insulin secretory abnormalities in type 2 diabetes include disruption of the normal pulsatile release of insulin and an increased ratio of plasma proinsulin to insulin. Evidence obtained from knockout mice reveals that insulin resistance in the β-cells may contribute to alterations in insulin secretion, as occur in type 2 diabetes.

Environment

Environmental factors, such as diet and exercise, are important determinants of the pathogenesis of type 2 diabetes. Convincing evidence links obesity to the development of type 2 diabetes, but the association is complex. Although 60% to 80% of patients with type 2 diabetes are obese, diabetes develops in less than 15% of obese individuals. In contrast, virtually all obese individuals, even those with normal carbohydrate tolerance, have hyperinsulinemia and are insulin resistant. Other

factors that are important include (1) family history of type 2 diabetes (genetic predisposition), (2) the duration of obesity, and (3) the distribution of fat. Nevertheless, the rising prevalence of diabetes is believed to be a consequence of the increase in obesity (defined as a body mass index ≥30 kg/m^2), which was reported to be 35.7% in U.S. adults in 2009 to 2010.

An inverse relationship has been noted between the degree of physical activity and the prevalence of type 2 diabetes. For every 500-kcal increase in daily energy expenditure, a 6% decrease in age-adjusted risk of type 2 diabetes occurs. This effect is independent of both body weight and a parental history of diabetes. The mechanism of the protective effect of exercise is thought to be increased sensitivity to insulin in skeletal muscle and adipose tissue.

Diabetogenes

Genetic factors contribute to the development of type 2 diabetes. For example, the concordance rate for type 2 diabetes in identical twins approaches 100%. Type 2 diabetes is 10 times more likely to occur in an obese person with a parent who has diabetes than in an equally obese person without a diabetic family history. However, the mode of inheritance is unknown, and type 2 diabetes has been described as a "geneticist's nightmare." It is genetically more complex than mendelian disorders and is not inherited according to simple mendelian rules. Multiple genetic factors interact with exogenous influences (such as environmental factors) to produce the phenotype.

Numerous factors complicate the search for **diabetogenes** in type 2 diabetes. A variety of approaches have produced several genes that are associated with type 2 diabetes. Recent genome-wide association studies (GWAS) have substantially contributed to our understanding of the genetic architecture of type 2 diabetes, with >30 genetic loci identified. Most of these genetic loci are associated with the insulin secretion pathway, rather than with insulin resistance. Despite considerable effort to identify the genetic basis of type 2 diabetes, genetic defects identified to date account for only ≈5% of patients with type 2 diabetes. Therefore, the gene or genes causing common forms of type 2 diabetes remain unknown. Moreover, all of the risk alleles in these loci have small effects (odds ratios, 1.1 to 1.3). Incorporation of 18 different risk loci to construct a genotype score did not significantly improve clinical prediction based on current phenotype risk factors.

Diagnosis of Diabetes

For many years, the diagnosis of diabetes was dependent solely on the demonstration of hyperglycemia (Box 33-2).[2] Several influential clinical organizations now include hemoglobin A_{1c} (HbA_{1c}), which reflects long-term blood glucose concentrations, as a diagnostic criterion for diabetes (for additional information, see the "**Glycated Hemoglobins**" section, later in this chapter). For type 1 diabetes, the diagnosis is usually easy because hyperglycemia (1) appears abruptly, (2) is severe, and (3) is accompanied by serious metabolic derangements. Diagnosis of type 2 diabetes may be difficult because hyperglycemia often is not severe enough for the patient to notice symptoms of diabetes. Nevertheless, the risk of complications makes it important to identify people with the disease.

BOX 33-2 Criteria for the Diagnosis of Diabetes Mellitus

Any of the following is diagnostic:

Hemoglobin A_{1c} (HbA_{1c})* ≥6.5%

OR

Fasting plasma glucose (FPG) ≥ 126 mg/dL (7.0 mmol/L) †

OR

2-hour plasma glucose ≥200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test (OGTT)

*The test should be performed in a laboratory that is NGSP-certified and standardized to the DCCT assay. Point-of-care assays should not be used for diagnosis.

†In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeating the same test on a different day. Mixing different methods to diagnose diabetes should be avoided.

From the American Diabetes Association. Diagnosis and classification of diabetes mellitus. Diabetes Care 2013;36(Suppl 1):S67-74.

Fasting Plasma Glucose Concentrations

FPG concentrations of 126 mg/dL (7.0 mmol/L) or greater on more than one occasion are diagnostic of diabetes mellitus (see Box 33-2). The diagnosis of most cases of diabetes is often established with this criterion. However, some investigators believe that fasting hyperglycemia may be a relatively late development in the course of type 2 diabetes, delaying the diagnosis and leading to underestimation of the prevalence of diabetes in the population. Complications of diabetes, such as (1) retinopathy, (2) proteinuria, and (3) neuromuscular disease, are present in approximately 30% of patients at clinical diagnosis of type 2 diabetes, and onset of type 2 diabetes probably occurs at least 4 to 7 years before clinical diagnosis. Screening of high-risk individuals for diabetes is now recommended. Fasting glucose (or HbA_{1c}) should be measured in all asymptomatic persons at age 45 (or younger in patients at increased risk), with follow-up testing every 3 years. However, no published evidence indicates that treatment based on screening is efficacious.

Oral Glucose Tolerance Test

Serial measurement of plasma glucose before and after a specific amount of glucose given orally should provide a standard method by which to evaluate individuals and establish values for healthy and diseased individuals. Although more sensitive than FPG determinations, glucose tolerance testing is affected by multiple factors that result in poor reproducibility (Box 33-3). Moreover, approximately 20% of OGTTs fall into the nondiagnostic category (e.g., only one blood sample exhibits increased glucose concentration). Unless results are grossly abnormal initially, the OGTT should be performed on two separate occasions to establish the diagnosis of diabetes.

The following conditions should be met before an OGTT is performed: (1) discontinue, when possible, medications known to affect glucose tolerance; (2) perform test in the morning after 3 days of unrestricted diet (containing at least 150 g of carbohydrate per day) and activity; and (3) perform

BOX 33-3 Factors Other Than Diabetes That Influence the Oral Glucose Tolerance Test

Patient Preparation
Duration of fast
Prior carbohydrate intake
Medications (e.g., thiazides, oral contraceptives, corticosteroids)
Trauma
Intercurrent illness
Age
Activity
Weight

Administration of Glucose
Form of glucose (anhydrous or monohydrate)
Quantity of glucose ingested
Volume in which administered
Rate of ingestion

During the Test
Posture
Anxiety
Caffeine
Smoking
Activity
Time of day
Sample preservation

TABLE 33-2 Screening and Diagnosis of Gestational Diabetes Mellitus

Screening

1. Perform at between 24 and 28 weeks' gestation on all average and very high-risk pregnant women not identified as having glucose intolerance.
2. Give 50 g oral glucose load without regard to time of day or time of last meal.
3. Measure venous plasma glucose at 1 hour.
4. If glucose is ≥140 mg/dL (7.8 mmol/L),* perform glucose tolerance test.

Diagnosis

1. Perform in the morning after an overnight fast of at least 8 hours.
2. Measure fasting venous plasma glucose.
3. Give 75 or 100 g of glucose orally.
4. Measure plasma glucose hourly for 3 hours (or for 2 hours if 75 g of glucose is given).
5. At least two values must meet or exceed the following:

	100 g Load	75 g Load
Fasting	95 mg/dL (5.3 mmol/L)	95 mg/dL (5.3 mmol/L)
1 hour	180 mg/dL (10 mmol/L)	180 mg/dL (10 mmol/L)
2 hour	155 mg/dL (8.6 mmol/L)	155 mg/dL (8.6 mmol/L)
3 hour	140 mg/dL (7.8mol/L)	—

6. If results are normal in a clinically suspect situation, repeat during the third trimester.

*Some experts recommend a cutoff of 130 mg/dL (7.2 mmol/L).

the test after a 10- to 16-hour fast only in ambulatory outpatients (bed rest impairs glucose tolerance), who should remain seated during the test without smoking cigarettes. Glucose tolerance testing should not be performed on hospitalized, acutely ill, or inactive patients. The test should begin between 7 am and 9 am. Concentrations of venous plasma glucose should be measured fasting, and then 2 hours after the oral glucose load. For nonpregnant adults, the recommended load is 75 g, which may not be a maximum stimulus; for children, 1.75 g/kg, up to 75 g maximum, is given. The glucose should be dissolved in 300 mL of water and ingested over 5 minutes. A commercial, more palatable form of glucose may be ingested, but whether the anhydrous or monohydrate form of glucose should be used is still in question.

Diagnosis of Gestational Diabetes

Normal pregnancy is associated with increased insulin resistance, especially in the late second and third trimesters. Euglycemia (glucose concentrations within healthy reference interval) is maintained by increased insulin secretion, with GDM developing in those women who fail to augment insulin sufficiently. Risk factors for GDM include (1) a family history of diabetes in a first-degree relative, (2) obesity, (3) advanced maternal age, (4) glycosuria, and (5) selected adverse outcomes in a previous pregnancy (e.g., stillbirth, macrosomia). ADA recommendations for laboratory diagnosis of GDM have been modified extensively since the publication in 2008 of the Hyperglycemia in Pregnancy and Adverse Outcome (HAPO) study (http://www.ncbi.nlm.nih.gov/; accessed November 11, 2013).[8] The is large prospective, multinational study of ≈25,000 pregnant women revealed strong, graded, linear associations between maternal glycemia and adverse outcomes. All pregnant women not previously known to have diabetes should be evaluated for GDM by a 75-g OGTT at 24 to 28 weeks' gestation. Diagnostic cutpoints for fasting, 1-hour and 2-hour plasma glucose concentrations have been established.

These new criteria, which increase the incidence of GDM by □2.5-fold, have not been accepted by all clinical organizations. For example, the American College of Obstetrics and Gynecology in the United States continues to advocate prior diagnostic criteria (Table 33-2). These state that all pregnant women should be evaluated by a two-step method:

1. Screen by history, clinical risk factors, or a 50-gram oral glucose load (the patient does not need to be fasting). A plasma glucose value greater than or equal to 140 mg/dL (7.7 mmol/L) at 1 hour after glucose ingestion indicates the necessity for definitive testing. Approximately 15% of pregnant women meet this criterion and require a full OGTT. This subgroup includes ≈80% of all women with GDM. Some experts recommend a cutoff of 130 mg/dL (7.1 mmol/L), which increases sensitivity for GDM to 90% but includes ≈25% of all pregnant women.
2. The diagnosis of GDM can be made on the basis of the result of the 100-gram, 3-hour OGTT. This should be performed on a different day from the 50-gram OGTT.

Although usually asymptomatic and not life-threatening to the mother, GDM is associated with increased neonatal mortality and morbidity, including (1) hypocalcemia, (2) hypoglycemia, and (3) macrosomia. Maternal hyperglycemia causes the fetus to secrete more insulin, resulting in stimulation

of fetal growth and macrosomia. Recognition is important because therapy can reduce perinatal morbidity and mortality. Maternal complications include a high rate of cesarean delivery and hypertension. In addition, mothers with GDM are at significantly increased risk of subsequent type 2 diabetes.

Distinct from GDM is pregnancy in a patient with preexisting diabetes (≈19,000 per annum in the United States). T is is associated with an increased incidence of congenital malformation, but meticulous glycemic control during the first 8 weeks of pregnancy can significantly decrease the risk of congenital malformation. Tight control results in an increased incidence of maternal hypoglycemia, which is teratogenic in animals but does not cause malformation in humans.

Chronic Complications of Diabetes Mellitus

Patients with type 1 or type 2 diabetes are at high risk for the development of chronic complications. Diabetes-specific microvascular pathology in the (1) retina, (2) renal glomeruli, and (3) peripheral nerves produces (1) retinopathy, (2) nephropathy, and (3) neuropathy, respectively. As a result, diabetes is the most frequent cause of new cases of blindness in the industrialized world in persons between 25 and 74 years of age and is the leading cause of end-stage renal disease. Diabetes is also associated with a marked increase in atherosclerotic macrovascular disease involving (1) cardiac, (2) cerebral, and (3) peripheral large vessels. T erefore, patients with diabetes have a high rate of (1) myocardial infarction (the major cause of mortality in diabetes), (2) stroke, and (3) limb amputation.

Type 1 Diabetes

Although it was theorized for many years that better glycemic control would decrease rates of long-term complications of diabetes, it was not until the publication of the Diabetes Control and Complications Trial (DCCT) in 1993 that this hypothesis was verified (http://www.diabetes.niddk.nih.gov/; accessed November 11, 2013). T e DCCT was a multicenter, randomized trial that compared the effects of intensive and conventional therapy on the development and progression of complications in 1441 patients with type 1 diabetes, all of whom required insulin. During the study period, which averaged 6.5 years, intensively managed patients maintained significantly lower mean blood glucose concentrations. Compared with conventional therapy, intensive therapy reduced the risks of (1) retinopathy, (2) nephropathy, and (3) neuropathy by 40% to 75%. Intensive therapy delayed the onset and slowed the progression of these complications, regardless of age, sex, or duration of diabetes. Absolute risks of retinopathy and nephropathy were proportional to the mean HbA_{1c} values (discussed later in the chapter). Although intensive therapy also reduced the development of hypercholesterolemia, macrovascular complications were not significantly decreased in the initial assessment. However, analysis after 17 years of follow-up documented a 42% lower incidence of cardiovascular disease in the intensively treated group. T is landmark study has had a considerable impact on therapeutic goals and comprehension of the pathogenesis of complications of diabetes.

At the conclusion of the DCCT, 95% of participants enrolled in the long-term follow-up study, termed the Epidemiology of Diabetes Interventions and Complications (EDIC)/ http://www.ncbi.nlm.nih.gov/; accessed November 11, 2013). Five years after the end of the DCCT, no difference in metabolic control (as assessed by HbA_{1c} measurements) was noted between the former conventional and intensively treated groups. Nevertheless, further progression of retinopathy and neuropathy was significantly lower in the former intensive group, demonstrating that the beneficial effects of intensive treatment persisted for at least several years beyond the period of strictest intervention.[5]

Type 2 Diabetes

T e role of hyperglycemia in the development of complications in individuals with type 2 diabetes was established in the United Kingdom Prospective Diabetes Study (UKPDS/ http://www.dtu.ox.ac.uk/; accessed November 11, 2013). T e UKPDS was a major randomized, multicenter clinical study that included 5102 patients with newly diagnosed type 2 diabetes who were followed for an average of 10 years. Analogous to the findings of the DCCT, the UKPDS demonstrated in patients with type 2 diabetes that intensive treatment diminishes by approximately 10% to 40% the development of microvascular complications. Intensive treatment also decreased the rate of occurrence of macrovascular complications. Although the reduction was not statistically significant initially, follow-up 10 years after the study ended showed a significant reduction in myocardial infarction among patients who had received intensive therapy. Analogous to the EDIC findings, long-term benefits for microvascular complications were observed with follow-up of patients in the UKPDS despite loss of glycemic separation between intensive and standard cohorts after the study ended. An important caveat of both the DCCT and the UKPDS was that intensive therapy produced a threefold increase in the incidence of severe hypoglycemia.

Role of the Clinical Laboratory in Diabetes Mellitus

T e clinical laboratory has a vital role in both the diagnosis and management of diabetes.[13] Some of the important variables assayed are outlined in Table 33-3. In 2002 the National Academy of Clinical Biochemistry (NACB) published evidence-based guidelines for laboratory analysis in diabetes. T ese guidelines were reviewed by the Professional Practice Committee of the ADA and were consistent in those areas where the ADA also published recommendations. Specific recommendations for laboratory testing based on published data or derived from expert consensus are presented. An updated version of these guidelines was published in 2011 (http://www.aacc.org/; accessed November 11, 2013). T e revised guidelines were also published as a Position Statement by the ADA.

TABLE 33-3 Role of the Laboratory in Diabetes Mellitus

Diagnosis		
Preclinical (screening)	Immunological markers	
		ICA
		IAA
		GAD antibodies
		Protein tyrosine phosphatase antibodies (IA-2)
		Zinc transporter ZnT8 antibodies
	Genetic markers (e.g., human leukocyte antigen [HLA])	
	Insulin secretion	
		Fasting
		Pulses
		In response to a glucose challenge
	Blood glucose	
	Hemoglobin A1c (HbA_{1c})	
Clinical	Blood glucose	
	Oral glucose tolerance test (OGTT)	
	HbA_{1c}	
	Ketones (urine and blood)	
	Other (e.g., insulin, C-peptide, stimulation tests)	
Management		
Acute	Glucose	
		Blood
		Urine
	Ketones	
		Blood
		Urine
	Acid-base status (pH, bicarbonate)	
	Lactate	
	Other abnormalities related to cellular dehydration or therapy (e.g., potassium, sodium, phosphate, osmolality)	
Chronic	Glucose	
		Blood (fasting-random)
		Urine
	Glycated proteins	
		Glycated hemoglobin (GHb) (HbA_{1c})
		Fructosamine
		Glycated serum albumin
	Urinary protein	
		Urinary albumin excretion (UAE) (high albuminuria)
		Proteinuria
	Evaluation of complications (e.g., creatinine, cholesterol, triglycerides)	
	Evaluation of pancreas transplant (C-peptide, insulin)	
	Eligibility for insulin pump (C-peptide)	

Diagnosis

Preclinical (Screening)

Evidence from animal studies suggests that immune intervention therapy provided before the appearance of clinical symptoms is capable of delaying or preventing type 1 diabetes. Results from human studies, however, have been disappointing. Nevertheless, several large clinical trials are under way to assess a variety of therapeutic strategies designed to delay or prevent the onset of type 1 diabetes. Until effective intervention therapy becomes available and cost-effective screening strategies are developed for young children, screening for antibodies outside of clinical studies is not recommended. Also, screening by determining HLA type is not currently warranted, except in research studies. A decrease in glucose-stimulated insulin secretion is the first functional abnormality in both type 1 and type 2 diabetes. Nevertheless, tests of insulin secretion are not currently recommended for routine clinical use.

Screening asymptomatic individuals for type 2 diabetes has been the subject of much controversy. The ADA, which previously did not support screening, now advocates screening in all asymptomatic individuals over the age of 45 years. If the HbA_{1c} is less than 5.7% or the FPG is less than 100 mg/dL (5.5 mmol/L), testing should be repeated at 3-year intervals.

Clinical

The laboratory diagnosis of diabetes is made exclusively by the demonstration of hyperglycemia, as evidenced by measurements of venous plasma glucose or HbA_{1c}. Although other tests (e.g., C-peptide, insulin analysis) have been proposed to assist in the diagnosis and classification of the disease, they do not at present have a role outside of research studies.

Management

Acute

In disorders such as (1) diabetic ketoacidosis, (2) hyperosmolar nonketotic coma, and (3) hypoglycemia, the clinical laboratory has an essential role in both diagnosis and monitoring of therapy. Several analytes are frequently measured to guide clinicians in treatment regimens to restore euglycemia and correct other metabolic disturbances. The metabolic abnormalities of these conditions are beyond the scope of this book, and interested readers are referred to a standard textbook of medicine. The NACB guidelines (http://www.aacc.org/accessed November 11, 2013) also provide information on the tests that are used.

Chronic

The DCCT and UKPDS studies documented a correlation between blood glucose concentrations and the development of long-term complications of diabetes.[15] Measurement of glucose and glycated proteins provides an index of short- and long-term glycemic control. Detection of and monitoring for complications are achieved by assaying (1) creatinine, (2) urine albumin, and (3) serum lipids. In practice, the success of newer therapies, such as islet cell or pancreas transplantation, is monitored by measuring serum C-peptide or insulin concentrations.

Self-Monitoring of Blood Glucose

Patients with diabetes, especially those who need insulin, require careful monitoring to maintain control of blood glucose. This has become particularly important with the results

of the DCCT and the recommendation that patients use intensive therapy to achieve nearly normal glycemia. These regimens include (1) multiple daily insulin injections, (2) insulin pumps, and (3) continuous subcutaneous insulin injections. However, testing urine for glucose is not adequate for monitoring patients on insulin therapy. Although some evidence suggests that it may be effective for monitoring type 2 diabetes, the ADA states that limitations of urine testing make blood glucose measurements the preferred method for assessing glycemic control.

Portable meters for measurement of blood glucose concentrations are used in three major settings: (1) in acute and chronic care facilities (at the patient's bedside and in clinics or hospitals); (2) in physicians' offices; and (3) by patients at home, work, and school. The last, **self-monitoring of blood glucose (SMBG),** used by approximately 1 million people with diabetes, is performed in the United States at least once a day by 40% and 26% of individuals with type 1 and 2 diabetes, respectively.

Using SMBG, patients measure their own blood glucose concentrations and modify their insulin doses on the basis of the result. It is impractical for patients themselves to perform glucose determinations by the methods described earlier, but a large number of simple test strips that are available permit rapid measurements on a drop of whole blood. These use the same enzyme-catalyzed reactions as described earlier for glucose analysis—predominantly glucose oxidase or glucose dehydrogenase. The reagents are combined in dry form on a small surface area of a test strip. More than 80 different blood glucose meters are commercially available. To perform the measurement, a sample of blood, usually from a fingerstick, but anticoagulated whole blood collected in ethylenediaminetetraacetic acid (EDTA) or heparin, is placed on the test pad, which is attached to a plastic support. The test strip is then inserted into the meter. (In some devices, the strip is inserted into the meter before the sample is applied.) After a fixed time, the result appears on a digital display screen. These meters use reflectance photometry or electrochemistry to measure the rate of the reaction or the final concentration of the products. Large variability has been noted among meters as to the test time (5 to 45 seconds) and the claimed reading range of 30 to 500 mg/dL (1.65-27.5 mmol/L) to 0 to 600 mg/dL (0-33.0 mmol/L). Calibration is automatic on some devices, whereas others use lot-specific code chips or strips. All manufacturers supply control solutions. Strict adherence to the instructions is necessary for accurate results to be obtained. Some meters have a porous membrane that separates erythrocytes, and analysis is performed on the resultant plasma. Of note, whole blood glucose concentrations are approximately 10% to 15% lower than plasma or serum concentrations, but meters can be calibrated and adjusted to report plasma glucose values, even when the sample is whole blood. For example a study group of the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) recommended a factor of 1.11× to convert concentrations of glucose measured per volume of whole blood to the concentration of glucose in plasma.[12]

Analytical Goals for Glucose Meters

Multiple analytical goals have been proposed for the performance of glucose meters. The recommendations promulgated by the Clinical and Laboratory Standards Institute (CLSI) and the International Organization for Standardization (ISO) are that 95% of results should fall within 20% of laboratory-measured glucose concentrations when >75 mg/dL (4.2 mmol/L), and within 15 mg/dL (0.83 mmol/L) of laboratory glucose when the glucose concentration is ≤75 mg/dL (4.2 mmol/L). Many experts consider these acceptance criteria to be too wide. In 2013, a new guideline from CLSI on Point-of-Care Blood Glucose Testing in Acute and Chronic Care Facilities (POCY12-A3/WWW.CLSI.org/; accessed November 11, 2013) concluded that "meter performance is acceptable for use in hospitals when 95% of the individual results from the POC glucose meter system agree within ±12 mg/dL (0.67 mmol/L) of the laboratory analyzer values at glucose concentrations below 100 mg/dL (5.55 mmol/L) and within ±12.5% of the laboratory analyzer values at glucose concentrations at or above 100 mg/dL (5.55 mmol/L). In addition, the sum of the number of individual results with (1) errors that exceed 15 mg/dL (0.83 mmol/L) at glucose concentrations below 75 mg/dL (4.2 mmol/L) and (2) errors that exceed 20% at glucose concentrations at or above 75 mg/dL (4.2 mmol/L) should not exceed 2% of all results." It also indicated that samples used to validate meter performance should be taken from the patient care area where the meter is intended to be used. Shortly after publication of the CLSI guideline, this higher standard was shown to be achievable, with at least one glucose meter validated with the challenging samples that come from patients in ICUs where patients receive multiple drugs and have extremes of hematocrit and sodium that may adversely affect meter performance.[12]

A different method uses an error grid to try to define clinically important errors by identifying fairly broad target ranges. An approach using simulation modeling concluded that meters that achieve both a CV and a bias less than 5% rarely lead to major errors in insulin dose. It should be noted, however, that lack of consensus on quality goals for glucose meters reflects the absence of agreed-upon objective criteria. When biological variation criteria are used, a goal for total error (including both bias and imprecision) of ≤6.9% has been proposed.

Glucose meters are also used to calculate insulin dose in patients without diabetes on tight glucose control protocols in intensive care units (ICUs). Evidence in 2001 showed that intensive insulin therapy significantly reduced mortality and morbidity of critically ill patients in the surgical ICU. Although some subsequent studies were unable to replicate these findings, aggressive glucose control with intravenous infusion of insulin still is used extensively in hospital ICUs. Many factors, such as (1) hypoxia, (2) shock, and (3) low hematocrit, are common in these patients and can compromise glucose analysis in capillary blood samples.[6] The use of glucose meters in these settings has been questioned by some experts. Some meters may have adequate analytical performance (as noted earlier), but the use of skin puncture (fingerstick) samples introduces serious error in patients who have conditions such as shock.

Performance of Glucose Meters

The most common errors in SMBG, such as (1) proper application, (2) timing, and (3) removal of excess blood, have been reduced by advances in technology but still can occur. Additional innovations that reduce operator error include (1) systems that abort testing if the sample volume is inadequate, (2) built-in programs that simplify quality control, and (3) increased memory that allows the instrument to store up to several hundred glucose readings that can be downloaded into a computer.

Several factors affect the accuracy and reproducibility of SMBG. These include (1) user variability—up to 50% of values may vary by more than 20% from reference values; (2) hematocrit—the presence of anemia (false increase) or polycythemia (false depression) may result in up to 30% variability; and (3) defective reagent strips or instrument malfunction (rare). Other variables include changes in (1) altitude, (2) environmental temperature, (3) humidity; (4) hypotension; (5) hypoxia; and (6) high triglyceride concentrations. In addition, these assays are unreliable at very high and very low glucose concentrations, for example, <60 mg/dL (3.3 mmol/L) and >500 mg/dL (27.5 mmol/L). Because dehydration, a common feature of diabetic ketoacidosis, greatly increases blood viscosity, inaccurately low blood glucose results may be obtained. Several drugs interfere, but not with all meters. Another important factor is the lack of correlation among meters, even from a single manufacturer, caused by different assay methods and architecture. Moreover, results from two meters of the same brand have been observed to differ substantially. Patient factors are also important, particularly adequate training when the meter is used for SMBG. Recurrent education at clinic visits and comparison of SMBG with concurrent laboratory glucose analysis improved the accuracy of patients' blood glucose readings. It is important to evaluate the patient's technique at regular intervals.

Meter performance varies widely. Under carefully controlled conditions in which all assays were performed by a single medical technologist, ≈50% of analyses met the ADA criterion of less than 5% deviation from reference values. Performance of older meters was substantially worse. Note that medical technologists perform better than patients. Comparison with laboratory values of almost 22,000 measurements of capillary glucose by patients using meters revealed no significant improvement in meter performance between 1989 and 1999. The imprecision of most meters precludes their use in the diagnosis of diabetes.

Alternatives to Meters for Monitoring of Blood Glucose

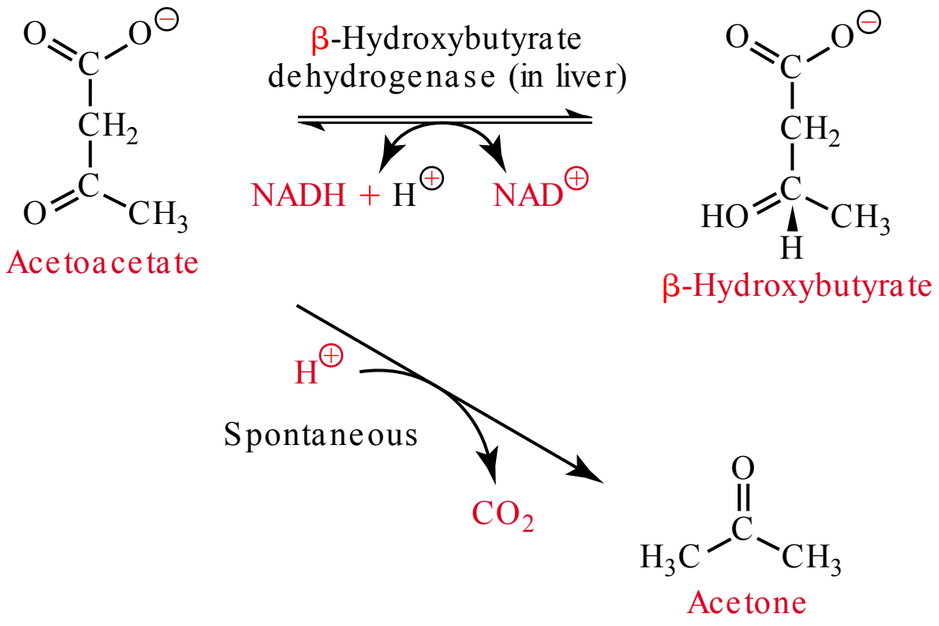
A major limitation to performing SMBG is that it is painful and inconvenient. Since the 1960s, attempts have been made to develop a painless method for monitoring blood glucose concentrations. Three general approaches have been used, namely, (1) implanted sensors, (2) minimally invasive monitoring, and (3) noninvasive monitoring.

Implanted Sensors

Several implanted biosensors have been developed and evaluated in both animals and humans. Detection systems are based on (1) enzymes, (2) electrodes, or (3) fluorescence. The most widely studied method is an electrochemical sensor that is usually implanted subcutaneously. All monitoring devices use glucose oxidase to measure glucose every 1 to 5 minutes. The values are sent to a monitor. Results are recorded and may be downloaded later in the physician's office and usually are available to the patient in real time. These devices are subject to some limitations. Implantation of a needle type of sensor into the subcutaneous tissue induces inflammatory responses in the host that alter the sensitivity of the device, limiting to 3 to 7 days the time the devices can be worn. The sensors require calibration by the user initially and at least twice a day with a glucose meter and are subject to the imprecision of the meter. In addition, changes in glucose concentration in the interstitial fluid occur 4 to 20 minutes later than changes in the blood. Nevertheless, real-time continuous glucose monitoring improves long-term glycemic control in a subset of patients with type 1 diabetes.[14]

Minimally Invasive Glucose Monitoring

The concept underlying these methods is that the concentration of glucose in the interstitial fluid correlates with the blood glucose concentration. The principle of the GlucoWatch Biographer involved the application of a low-level electrical current to the skin. This is induced movement by electro-osmosis of glucose across the skin, where it is measured by a glucose oxidase detector. Glucose concentrations in transdermal fluid and plasma are highly correlated. The clearest application of the GlucoWatch, which is designed to measure glucose three times per hour for up to 12 hours, appears to be in the detection of unsuspected hypoglycemia. Initial clinical studies reveal reasonable correlation of the GlucoWatch with SMBG. Of note, this device has been withdrawn from the market.



Nonivasive Glucose Monitoring

Noninvasive in vivo monitoring of glucose has been an area of active investigation for many years. Near-infrared spectroscopic devices measure absorption or reflection of light from subcutaneous tissue. Although glucose has a specific absorption at 1035 nm, many substances interfere. A computer, individually calibrated, screens out interfering information to obtain the glucose result. Alternative approaches include Raman scattering spectroscopy and photoacoustic spectroscopy. Notwithstanding the investment of considerable resources, no noninvasive sensing technology has been approved by the FDA for glucose measurement in patients.

Ketone Bodies

The development of ketosis requires changes in both adipose tissue and the liver. The primary substrates for ketone body formation are free fatty acids from adipose stores. Normally, long-chain fatty acids are (1) taken up by the liver, (2) re-esterified to triglycerides, (3) stored in the liver or incorporated in very

low-density lipoproteins and (4) returned to the plasma. In contrast to other tissues, the brain cannot use free fatty acids for energy. When glucose is unavailable, ketone bodies supply the vast majority of the brain's energy. After a 3-day fast, ketone bodies provide 30% to 40% of the body's energy requirements. In uncontrolled diabetes, the low insulin concentrations result in increased lipolysis and decreased re-esterification, thereby increasing plasma free fatty acids. In addition, the increased glucagon/insulin ratio enhances fatty acid oxidation in the liver. Increased counter-regulatory hormones also augment lipolysis and ketogenesis in fat and liver, respectively. Thus increased hepatic ketone production and decreased peripheral tissue metabolism lead to acetoacetate accumulation in the blood. A small fraction undergoes spontaneous decarboxylation to form acetone, but most of it is converted to β-hydroxybutyrate.

The relative proportions in which the three ketone bodies are present in blood vary, depending on the redox state of the cell. In healthy people, β-hydroxybutyrate and acetoacetate—which are present at approximately equimolar concentrations—constitute virtually all the serum **ketones**. Acetone is a minor component. In severe diabetes, the ratio of β-hydroxybutyrate to acetoacetate may increase to 6:1 owing to the presence of a high concentration of nicotinamide adenine dinucleotide (NADH), which favors β-hydroxybutyrate production.

Clinical Significance of Ketones

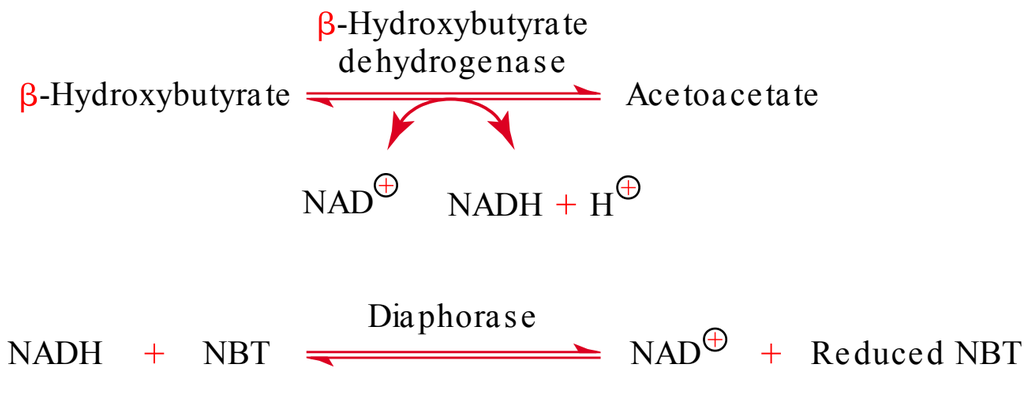
Excessive formation of ketone bodies results in increased blood concentrations of ketones (ketonemia) and increased excretion of ketones in the urine (ketonuria). This process is observed in conditions associated with decreased availability of carbohydrates (such as starvation or frequent vomiting) or decreased use of carbohydrates such as (1) diabetes mellitus, (2) **glycogen storage disease** (von Gierke disease), and (3) alkalosis. The popular high-fat, low-carbohydrate diets are ketogenic and increase ketone bodies in the circulation. Diabetes and alcohol consumption are the most common causes of ketoacidosis. Urine ketone test results are positive in ≈30% of first-morning-void specimens from pregnant women. Semiquantitative determination of ketone bodies in blood is more accurate than determination of these compounds in urine in the treatment of diabetic ketoacidosis. Although not always excreted in proportion to blood ketone concentrations, urine ketones are widely used for monitoring control in patients with type 1 diabetes because of convenience. Patients with type 1 diabetes should test for ketones during acute illness or stress, with consistent increases in blood glucose (greater than 300 mg/dL/16.5 mmol/L), during pregnancy, or when symptoms of ketoacidosis are present.[7] Measurement of ketones in urine and blood is widely performed in patients with diabetes for both diagnosis and monitoring of diabetic ketoacidosis.

None of the commonly used methods for the detection and determination of ketone bodies in serum or urine reacts with all three ketone bodies. Gerhardt's ferric chloride test reacts with acetoacetate only. Tests using nitroprusside are at least 10 times more sensitive to acetoacetate than to acetone and give no reaction at all with β-hydroxybutyrate. Thus, most of the tests used for this purpose essentially detect or measure acetoacetate only.

Measurement of Ketones in Body Fluids

In general, the tests described above are not used as routine tests. The semi-quantitative (1) Acetest, (2) Ketostix, and (3) DiaScreen 1K are frequently used but are insensitive to β-hydroxybutyrate. It is important to bear in mind, therefore, that a negative nitroprusside test result does not rule out ketoacidosis.

Acetest



Acetest tablets contain a mixture of glycine, sodium nitroprusside, disodium phosphate, and lactose. Acetoacetate or acetone (to a lesser extent) in the presence of glycine forms a lavender-purple complex with nitroprusside. β-Hydroxybutyrate does not react with nitroprusside. Disodium phosphate provides an optimum pH for the reaction, and lactose enhances the color.

Ketostix

Ketostix is a modification of the nitroprusside test, in which a reagent strip is used instead of a tablet. The Ketostix test gives a positive reaction within 15 seconds with a specimen containing at least 50 mg of acetoacetate per liter. The color chart from the manufacturer gives readings for ketone concentrations of 50, 150, 400, 800, and 1600 mg/L. Acetone also reacts, but the test is less sensitive to it.

Determination of β-Hydroxybutyrate

In this test, β-hydroxybutyrate in the presence of nicotinamide adenine dinucleotide (NAD^+) is converted by β-hydroxybutyrate dehydrogenase to acetoacetate, producing reduced nicotinamide adenine dinucleotide (NADH). Diaphorase catalyzes the reduction of nitroblue tetrazolium (NBT) by NADH to produce a purple compound, and its absorbance is read in a special meter that provides a digital readout.

β-Hydroxybutyrate concentrations range from 0.02 to 0.27 mmol/L (0.21 to 2.81 mg/dL) in healthy people after an overnight fast. Ketone bodies in the blood can reach 2 mmol/L (20 mg/dL) with prolonged exercise.[9] Patients with diabetic ketoacidosis usually have β-hydroxybutyrate concentrations greater than 2 mmol/L (20 mg/dL).

Determination of Ketone Bodies in Urine

Acetest and Ketostix are also suitable for detecting ketone bodies in urine. The sensitivity and specificity of these tests are the same as outlined for serum.

Glycated Proteins

Measurement of glycated proteins, primarily GHb, is effective in monitoring long-term glucose control in people with diabetes. It provides a retrospective index of integrated plasma glucose concentrations over an extended time and is not subject to the wide fluctuations observed when blood glucose concentrations are assayed. GHb concentrations therefore are a valuable and widely used adjunct to blood glucose determinations for monitoring long-term glycemic control. In addition, HbA_{1c} has recently been recommended for the diagnosis of diabetes and is a measure of risk for the development of microvascular complications of diabetes.

Glycated Hemoglobins

Glycation is the nonenzymatic addition of a sugar residue to amino groups of proteins. Human adult hemoglobin (Hb) usually consists of HbA (≈97% of the total), HbA_2 (2.5%), and HbF (0.5%). HbA is made up of four polypeptide chains, two α-chains and two β-chains. Chromatographic analysis of HbA identifies several minor hemoglobins, namely, HbA_{1a}, HbA_{1b}, and HbA_{1c},which are collectively referred to as HbA_1, *f*ast hemoglobins (because they migrate more rapidly than HbA in an electrical field), glycohemoglobins, or glycated hemoglobins. The Joint Commission on Biochemical Nomenclature of the International Union of Pure and Applied Chemistry recommends the term neoglycoprotein for such derivatives and the term glycation to describe this process. Therefore, although glycosylated and glucosylated have been widely used in the literature, the term glycated now is preferred. HbA_{1c} is formed by the condensation of glucose with the N-terminal valine residue of each β-chain of HbA to form an unstable Schiff base (aldimine, pre-HbA_{1c}; see Figure 33-2). The Schiff base may dissociate or may undergo an Amadori rearrangement to form a stable ketoamine, HbA_{1c}. Also HbA_{1a1} and HbA_{1a2}, which make up HbA_{1a}, have fructose-1,6-diphosphate and glucose-6-phosphate, respectively, attached to the amino terminal of the β-chain. HbA_{1b} contains pyruvic acid linked to the amino terminal valine of the β-chain, probably by a ketamine bond. HbA1c is the major *f*raction, constituting approximately 80% of HbA_1.

Glycation may also occur at sites other than the end of the β-chain, such as lysine residues, or the α-chain. The sum of all GHbs, referred to as total glycated hemoglobin, cannot be separated from nonglycated hemoglobin by methods based on charge but are measured by boronate affinity chromatography.

Formation of GHb is essentially irreversible, and the concentration in the blood depends on both the life span of the red blood cell (RBC; average 120 days) and the blood glucose concentration. Because the rate of formation of GHb is directly proportional to the concentration of glucose in the blood, the GHb concentration represents integrated values *f*or glucose over the preceding 8 to 12 weeks. This provides an additional criterion for assessing glucose control because GHb values are free of day-to-day and hour-to-hour glucose fluctuations and are unaffected by exercise or food ingestion immediately before collection of the blood sample. The contribution of the plasma glucose concentration to GHb depends on the time interval, with more recent values (such as during the preceding month) providing a larger contribution than earlier values (such as 3 months earlier). The plasma glucose in the preceding 1 month determines 50% of the HbA_{1c}, whereas days 60 to 120 determine only 25%. After a sudden alteration in blood glucose concentrations, the rate of change in HbA_{1c} is rapid during the initial 2 months, followed by a more gradual change approaching steady state 3 months later.

Interpretation of GHb depends on RBCs having a normal life span. Patients with hemolytic disease or other conditions with shortened RBC survival exhibit a substantial reduction in HbA_{1c}.[4] HbA_{1c} can still be used to monitor these patients, but values must be compared with previous values from the same patient—not with published reference intervals. Similarly, individuals with recent significant blood loss have falsely low values owing to a higher fraction of young erythrocytes. High HbA_{1c} concentrations have been reported in iron deficiency anemia, probably because of the high proportion of old erythrocytes. The effects of hemoglobin variants such as (1) HbF, (2) HbS, and (3) HbC depend on the specific method of analysis used. Depending on the particular hemoglobinopathy and assay, results may be spuriously increased or decreased. Most manufacturers of HbA_{1c} assays have modified their assays to

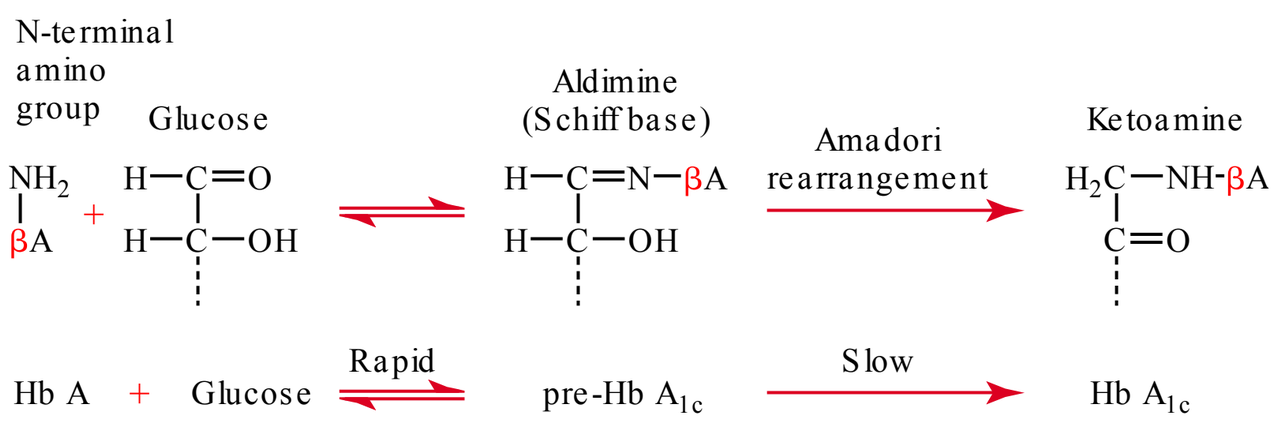


Figure 33-2 Formation of hemoglobin A_{1c}.

eliminate interference from many of the common hemoglobin variants. Therefore, HbA_{1c} can be accurately measured by selecting an appropriate instrument, and is useful provided the RBC life span is not altered by the hemoglobinopathy (see www.NGSP.org/accessed November 11, 2013 for additional information). Another source of error in selected methods is carbamylated hemoglobin, formed by attachment of urea. It is present in large amounts in renal failure, which is more common in people with diabetes. Most interferents produce small effects, and HbA_{1c} is measured accurately in the vast majority of patients with diabetes.

Hemoglobin A_{1c} in Diagnosis of Diabetes

A major change in the diagnosis of diabetes was recommended in 2009. An International Expert Committee advised that HbA_{1c} could be used for the diagnosis of diabetes (see Box 33-2). An HbA_{1c} value ≥6.5% was selected as the decision point, based on the prevalence of retinopathy. This recommendation has been endorsed by both the ADA and the WHO. HbA_{1c} values from 5.7% to 6.4% indicate individuals at high risk of developing diabetes. HbA_{1c} was also recommended as an alternative to glucose for screening for diabetes. This last recommendation has been accepted by the ADA.

Hemoglobin A_{1c} in Monitoring of Diabetes

HbA_{1c} is firmly established as an index of long-term blood glucose concentrations and a measure of the risk for developing microvascular complications in patients with diabetes. Absolute risks of retinopathy and nephropathy are directly proportional to the mean HbA_{1c} concentration. In persons without diabetes, HbA_{1c} is directly related to risk of cardiovascular disease.

Methods for Determination of Glycated Hemoglobins

More than 130 different methods may be used to determine GHb. These methods separate glycated from nonglycated hemoglobin using techniques based on (1) charge differences (ion exchange chromatography, HPLC, electrophoresis, and isoelectric focusing), (2) structural differences (affinity chromatography and immunoassay), or (3) chemical analysis (photometry and spectrophotometry). The result is expressed as a percentage of total hemoglobin. Most laboratories in the United States use immunoassay or HPLC and report % HbA_{1c}. The selection of method by a laboratory is influenced by several factors, including (1) sample volume, (2) patient population, and (3) cost. It is advisable to consult clinicians in this process. The ADA recommends that laboratories use only HbA_{1c} assays that are certified by the National Glycohemoglobin Standardization Program (NGSP) as traceable to the DCCT reference. The list of these assays on the NGSP website (www.NGSP.org/accessed November 12 2013) is updated at least annually.

High-Performance Liquid Chromatography

HbA_{1c} and other hemoglobin fractions are separated by HPLC, with cation exchange chromatography. Several fully automated systems are commercially available. Assays require only 5 µL of whole blood, and fingerstick samples are collected in a capillary tube for analysis. Anticoagulated blood is diluted with a hemolysis reagent containing borate. Samples are incubated at 37 °C for 30 minutes to remove the Schiff base and are inserted into the autosampler. (Some instruments have a shorter preincubation step, and others separate labile GHb chromatographically, eliminating the step to remove the Schiff base.) A step gradient using three phosphate buffers of increasing ionic strength is passed through the column. Detection is performed at both 415 and 690 nm, and results are quantified by integrating the areas under the peaks. Analysis time is as short as 3 minutes. HbA_{1c} by HPLC was used for analysis of all patient samples in the DCCT.

Immunoassay

Assays for HbA_{1c} have been developed using antibodies raised against the Amadori product (acid or base catalyzed isomerization or rearrangement reaction of the N-glycoside of the glycosylamine) of glucose (ketoamine linkage) plus the first few (four to eight) amino acids at the N-terminal end of the β-chain of hemoglobin. A widely used assay measures HbA_{1c} in whole blood by inhibition of latex agglutination. The agglutinator, a synthetic polymer containing multiple copies of the immunoreactive portion of HbA_{1c}, binds the anti-HbA_{1c} monoclonal antibody that is attached to latex beads. This agglutination produces light scattering, measured as an increase in absorbance. HbA_{1c} in the patient's sample competes for the antibody on the latex, inhibiting agglutination, thereby decreasing light scattering. Immunoassays are generally calibrated to give values that match HPLC values. The antibodies do not recognize labile intermediates or other GHbs (such as HbA_{1a} or HbA_{1b}) because both the ketoamine with glucose and specific amino acid sequences are required for binding. Similarly, several hemoglobin variants, such as HbF, HbA_2, HbS, and carbamylated hemoglobin, are not detected. The procedure has been adapted for capillary blood samples using a bench-top analyzer with reagent cartridges designed for use in physicians' office laboratories.

Affinity Chromatography

Affinity gel columns are used to separate GHb, which binds to m-aminophenylboronic acid on the column, from the nonglycated fraction. The boronic acid reacts with the cis-diol groups of glucose bound to hemoglobin to form a reversible five-member ring complex, thus selectively holding the GHb on the column. Nonglycated hemoglobin does not bind. Sorbitol is added to elute the GHb. Absorbance of bound and nonbound fractions, measured at 415 nm, is used to calculate the percentage of GHb.

The major advantages of affinity chromatography are no interference from nonglycated hemoglobins and negligible interference from the labile intermediate form of HbA_{1c}. It is unaffected by variations in temperature and has reasonably good precision. Hemoglobin variants such as HbS, HbC, HbD, or HbE produce little effect.

Af nity methods measure total GHb. T is includes components other than HbA_{1c} because the assay detects ketoamine structures on lysine and valine residues on both α- and β-chains of hemoglobin.

Although the method detects all GHbs, most commercial systems are calibrated to report a standardized HbA_{1c} value. T e value is derived from an equation obtained from linear regression between total GHb and HbA_{1c} analysis by HPLC. A linear relationship has been demonstrated, and standardized HbA_{1c} values are thus comparable with values obtained by methods specific for HbA_{1c}. Columns and reagents are commercially available.

Removal of Labile Glycated Hemoglobin from Red Blood Cells

T e concentration of the labile form of HbA_{1c} (Schiff base) fluctuates rapidly in response to acute changes in plasma glucose concentrations, and it should be removed before analysis by charge-based assays. T is may be accomplished by any of several methods including incubation of RBCs in saline or in buffer at pH 5 to 6. Most reagent sets for column assays contain reagents to remove this labile component.

Assay Standardization

Clinical laboratories measure GHb with diverse assays that use multiple methods and quantify different components. T e DCCT results accentuated the need for accurate GHb measurement and provided a strong impetus for harmonization. At the end of the DCCT, it was noted that absence of both a reference method and a single GHb standard had generated confusion. Interlaboratory comparisons were not possible, and a single quality control sample analyzed by a single method exhibited interlaboratory CVs of 16.5%. Committees were established under the auspices of the American Association for Clinical Chemistry (AACC) in 1993 and the IFCC in 1995 to standardize GHb assays.

T e NGSP was established in 1996 to implement the protocol developed by the AACC to calibrate GHb results to DCCT-equivalent values. Employing a network of reference laboratories, the NGSP interacts with manufacturers of GHb methods to help them calibrate their methods and trace values to the DCCT. Manufacturers apply for certification by performing precision testing and reporting results in DCCT-equivalent HbA_{1c} values. T is calibration effort has markedly improved harmonization of results and reduced imprecision. Results obtained using NGSP-certified assays can be compared with results of the DCCT and the UKPDS, allowing alignment with clinical outcomes data. T e ADA recommends that clinical laboratories use only assays certified by the NGSP and participate in proficiency testing offered by the College of American Pathologists (CAP). T e CAP-GH2 survey uses pooled whole blood specimens at three HbA_{1c} concentrations. Target values are assigned by the NGSP network. T us individual laboratories can directly compare their HbA_{1c} results with those of the DCCT and the UKPDS. Note: Beginning January 2014, 37 of 40 results (38 of 40 for Level I laboratories) will need to be within ±6% (relative) of the NGSP Secondary Reference Laboratory (SRL) in order to pass certification (current limits are ±7%).

A different approach was adopted by the IFCC. T e IFCC Working Group isolated standards of pure HbA_{1c} and HbA_0 as primary reference materials and developed two reference methods, namely, HPLC electrospray ionization mass spectrometry (ESI-MS) and HPLC-capillary electrophoresis. T ese specifically measure the glycated N-terminal valine of the β-chain of hemoglobin. Analysis is performed by digesting the hemoglobin molecule with endoproteinase Glu-C, which cleaves the β-chain between Glu-6 and Glu-7, releasing the N-terminal hexapeptide. Glycated and nonglycated hexapeptides are separated and quantified by HPLC-ESI-MS or by HPLC-capillary electrophoresis. HbA_{1c} is measured as the ratio between glycated and nonglycated N-terminal hexapeptides. T e IFCC method is (1) time-consuming, (2) technically complex, and (3) not designed to be used for routine analysis of patient samples. T e IFCC Working Group has established a network of laboratories to implement and maintain the reference system. Comparisons between IFCC and NGSP reference methods (and reference systems from Japan and Sweden) indicate a close and stable relationship and allow manufacturers to calibrate their instruments to a higher-level reference method. However, HbA_{1c} results obtained using IFCC reference methods are 1.5% to 2% absolute HbA_{1c} units lower than those of the NGSP (and lower than other reference systems).

Units for Reporting of HbA_{1c}

HbA_{1c} is reported in the NGSP system as a percentage of total hemoglobin. T ese values, which are equivalent to those reported in the DCCT and the UKPDS, represent the most widely used reporting system in patient care and in the published literature. T e IFCC method reports HbA_{1c} in System International (SI) units, namely, mmol HbA_{1c} /mol total Hb. Comparison between the IFCC and NGSP networks produced a master equation that permits conversion between the two reference systems. For example, an HbA_{1c} result of 7% (in NGSP/DCCT/UKPDS units) is equivalent to 53 mmol/mol (in IFCC units). A calculator to convert between units is available at http://www.ngsp.org/convert1.asp/; accessed November 11, 2013. Some countries have elected to report HbA_{1c} exclusively in SI units.

In some countries, an estimated average glucose (eAG) is reported together with HbA_{1c}. A conversion table is available at http://www.ngsp.org/A1ceAG.asp/; accessed November 11, 2013. A large, prospective clinical study revealed a significant correlation between HbA_{1c} and mean plasma glucose concentrations. T e concept of reporting eAG with HbA_{1c} is not accepted by all and is controversial.[10]

Specimen Collection and Storage

Patients need not be fasting to submit a specimen for HbA_{1c} analysis. Venous blood should be collected in tubes containing EDTA, oxalate, or fluoride. Sample stability depends on the assay method used. Whole blood may be stored at 4 °C for up to 1 week. Above 4 °C, HbA_{1a+b} increases in a time- and

temperature-dependent manner, but HbA_{1c} is only slightly affected. Samples are not stable at −20 °C. For most methods, whole blood samples stored at −70 °C or colder are stable for at least 18 months.

Reference Intervals

Values for GHbs are expressed as a proportion of total blood hemoglobin. HbA_{1c} should be reported. The reference interval (using an NGSP-certified method) is 4% to 5.6% (20 to 38 mmol/mol).

Results are not affected by acute illness. Intraindividual variability is minimal (CV ≈1%). **HbA_{1c}** increases slightly with age and differs among racial groups and is higher in African Americans and Hispanics than Caucasians. It is not known whether this has clinical significance. In patients with poorly controlled diabetes, values rarely exceed 15%. **HbA_{1c}** greater than 15% or below 4% should prompt additional studies to determine the possible presence of variant hemoglobin. Note that ADA target values derived from DCCT and UKPDS, not the reference values, are used to evaluate metabolic control in patients with diabetes.

There is no specific value of HbA_{1c} below which the risk of diabetic complications is eliminated completely. The ADA states that for most patients the goal of treatment should be to maintain HbA_{1c} at less than 7%. (Some organizations recommend an HbA_{1c} target of less than 6.5%.) These goals are applicable only if the assay method is certified as traceable to the DCCT reference. Each laboratory should establish its own reference interval. Assay precision is important because each 1% change in HbA_{1c} represents an approximate 30-mg/dL (1.7 mmol/L) change in average blood glucose.

No consensus has been reached on optimum frequency of testing. The ADA recommends that HbA1c should be routinely monitored at least every 6 months in patients meeting treatment goals (and who have stable glycemic control). These recommendations are for patients with type 1 or type 2 diabetes.

Fructosamine

In selected patients with diabetes (e.g., GDM), assays may be needed that are more sensitive than HbA_{1c} to shorter-term alterations in average blood glucose concentrations. Nonenzymatic attachment of glucose to amino groups of proteins other than hemoglobin (e.g., serum proteins, membrane proteins, lens crystallins) to form ketoamines also occurs. Because serum proteins turn over more rapidly than erythrocytes (the circulating half-life for albumin is about 20 days), the concentration of glycated serum albumin reflects glucose control over a period of 2 to 3 weeks. Therefore, deterioration of control and improvement with therapy are evident earlier than with HbA_{1c}.

Fructosamine is the generic name for plasma protein ketoamines. The name refers to the structure of the ketoamine rearrangement product formed by the interaction of glucose with the ε-amino group on lysine residues of albumin. Analogous to HbA_{1c}, fructosamine may be used as an index of the average concentration of blood glucose over an extended time.

Because all glycated serum proteins are fructosamines and albumin is the most abundant serum protein, measurement of fructosamine is thought to be largely a measure of glycated albumin, but this has been questioned by some investigators. Although the fructosamine assay has been automated and is less expensive and faster than HbA_{1c} assay, there is a lack of consensus on its clinical utility. The clinical value of fructosamine has not been firmly established, and no convincing evidence relates its concentration to the chronic complications of diabetes.

Fructosamine may be useful in circumstances where HbA_{1c} is of little value, such as in patients with hemoglobin variants that are associated with decreased erythrocyte life span. Gross changes in protein concentration and half-life may have large effects on the proportion of protein that is glycated. Thus fructosamine results may be invalid in patients with (1) nephrotic syndrome, (2) cirrhosis of the liver, or (3) dysproteinemias, or (4) after rapid changes in acute-phase reactants. However, in current practice, there is no role for fructosamine in the diagnosis of diabetes.

Determination of Fructosamine

Methods for measuring glycated proteins such as fructosamine include (1) affinity chromatography using immobilized phenylboronic acid (similar to the GHb assay); (2) HPLC of glycated lysine residues after hydrolysis; (3) a photometric procedure in which mild acid hydrolysis releases 5-hydroxymethylfurfural—proteins are precipitated with trichloroacetic acid and the supernatant is reacted with 2-thiobarbituric acid; and (4) other procedures using phenylhydrazine and ε-N-(2-furoylmethyl)-l-lysine (furosine). None of these assays is popular because they are not suitable for routine clinical laboratories. The development of monoclonal antibodies to glycated albumin, although theoretically advantageous, has not yet resulted in the widespread availability of commercial glycated albumin assays. Prolonged storage at ultra-low temperatures (−96 °C) prevents in vitro glycation of serum proteins.

An alternative method used to measure fructosamine is based on the principle that under alkaline conditions, fructosamine undergoes an Amadori rearrangement. The resultant compounds have reducing activity that is different from other reducing substances. In the presence of carbonate buffer, fructosamine rearranges to the eneaminol form, which reduces NBT to a formazan. Absorbance at 530 nm is measured at two time points, and the absorbance change is proportional to the fructosamine concentration. A 10-minute preincubation period is necessary to allow fast-reacting interfering reducing substances to react. The assay is easily automated and has excellent between-batch analytical precision. Hemoglobin (>100 mg/dL) and bilirubin (>4 mg/dL/27.7 μmol/L) may interfere; therefore moderate to grossly hemolyzed and icteric samples should not be used. Ascorbic acid concentrations greater than 5 mg/dL may cause negative interference.

In one method to measure glycated albumin the molecule is first hydrolyzed by proteinases to glycated amino acids, which are oxidized by ketoamine oxidase, producing H_2O_2. The H_2O_2 is then quantified and glycated albumin is expressed as a percentage of total albumin. This assay is not available in the United States at the time of this writing.

Reference Intervals for Fructosamine

Values in a nondiabetic population vary from 205 to 285 µmol/L. The reference interval for results that are adjusted to account for high or low concentrations of (total) albumin is slightly different (e.g., 191 to 265 µmol/L).

Advanced Glycation End Products

The molecular mechanism by which hyperglycemia produces toxic effects is unknown, but glycation of tissue proteins may be important. Nonenzymatic attachment of glucose to long-lived proteins, lipids, or nucleic acids produces stable Amadori early-glycated products. These undergo a series of additional (1) rearrangements, (2) dehydration, and (3) fragmentation reactions, resulting in stable **advanced glycation end products (AGEs).** The amounts of these products do not return to normal when hyperglycemia is corrected, and they accumulate continuously over the life span of the protein. Hyperglycemia accelerates the formation of protein-bound AGE, and patients with diabetes thus have more AGE than healthy subjects. Through effects on the functional properties of protein and the extracellular matrix, AGEs may contribute to the microvascular and macrovascular complications of diabetes. AGEs are also able to activate the receptor for AGE (RAGE) to induce intracellular signaling that leads to enhanced oxidative stress and the production of proinflammatory cytokines. Moreover, inhibitors of AGE formation, such as aminoguanidine, prevent some of the complications of diabetes in animal models. The clinical role of AGE is yet to be elucidated and defined.

Urinary Albumin Excretion

Patients with diabetes are at high risk of suffering renal damage. End-stage renal disease requiring dialysis or transplantation develops in approximately one-third of patients with type 1 diabetes, and diabetes is the most common cause of end-stage renal disease in the United States and Europe. Although nephropathy is less common in patients with type 2 diabetes, approximately 60% of all cases of diabetic nephropathy occur in these patients because of the considerably higher incidence of this form of diabetes. Persistent proteinuria detectable by routine screening tests (equivalent to a urinary albumin excretion [UAE] rate ≥200 µg/min) indicates overt diabetic nephropathy. This condition is usually associated with long-standing disease and is unusual less than 5 years after the onset of type 1 diabetes. Once diabetic nephropathy occurs, renal function deteriorates rapidly and renal insufficiency evolves. Treatment at this stage can retard the rate of progression without stopping or reversing the renal damage. Preceding this stage is a period of increased UAE not detected by routine dipstick methods. This range of 20 to 200 µg/min (or 30 to 300 mg/24 h) of increased UAE is termed high albuminuria, formerly called microalbuminuria. The term microalbuminuria, although widely used, is misleading. It implies a small version of the albumin molecule rather than an excretion rate of albumin greater than normal but less than that detectable by routine methods. Use of the term is discouraged.

The presence of increased UAE denotes an increase in the transcapillary escape rate of albumin and therefore is a marker of microvascular disease. Persistent UAE greater than 20 µg/min represents a 20-fold greater risk for the development of clinically overt renal disease in patients with type 1 and type 2 diabetes. Prospective studies have demonstrated that increased UAE precedes and is highly predictive of (1) diabetic nephropathy, (2) end-stage renal disease, (3) cardiovascular mortality, and (4) total mortality in patients with diabetes. Intensive glucose-lowering therapy can significantly reduce the risk of development of increased UAE and overt nephropathy in individuals with diabetes.[12] In addition, increased UAE identifies a group of people without diabetes who are at increased risk for coronary artery disease. Interventions such as control of blood glucose concentrations and blood pressure, particularly with angiotensin-converting enzyme (ACE) inhibitors, slow the rate of decline in renal function.

Specimen Collection and Storage

Variations in urine flow rate may be corrected by expressing albumin as a ratio to creatinine (i.e., albumin/creatinine). UAE is increased by physiological factors (e.g., exercise, posture, diuresis), and the method of urine collection must be standardized. Samples should not be collected (1) after exertion, (2) in the presence of urinary tract infection, (3) during acute illness, (4) immediately after surgery, or (5) after an acute fluid load. All the following urine samples are currently acceptable: (1) 24-hour collection; (2) overnight (8 to 12 hours, timed) collection; (3) 1- to 2-hour timed collection (in laboratory or clinic); and (4) first-morning sample for simultaneous albumin and creatinine measurement. Timed specimens are most sensitive, but the albumin/creatinine ratio is more practical and convenient for the patient and is the recommended method. A first-morning-void sample is best because it has lower within-person variation than a random urine sample. At least three separate specimens, collected on different days, should be assayed because of high intraindividual variation (CV of 30% to 50%) and diurnal variation (50% to 100% higher during the day). Urine should be stored at 4 °C after collection. Alternatively, 2 mL of 50 g/L sodium azide can be added per 500 mL of urine, but preservatives are not recommended for some assays. Bacterial contamination and glucose have no effect. Specimens are stable for 1 week at 4 °C and for at least 5 months at −80 °C. Albumin concentration decreases by 0.27%/d at −20 °C.

Semi-quantitative Assays

Several semi-quantitative assays are available for screening for increased UAE.[12] These test strips, most of which are optimized to read "positive" at a predetermined albumin concentration, have been recommended for screening programs. In view of the wide variability in UAE, a "normal" value does not rule out renal disease. Because these assays measure albumin concentration, dilute urine may yield a *f*alse-negative test result. Refrigerated urine samples should be allowed to reach at least 10 °C before analysis.

Quantitative Assays

All quantitative sensitive, specific assays for urine albumin use immunochemistry with antibodies to human albumin. Methods available include (1) RIA, (2) ELISA, (3) radial immunodiffusion, and (4) immunoturbidimetry. Each method has advantages and disadvantages, and the choice depends on local experience and technical support. In general, these methods have similar (1) imprecisions, (2) detection limits, and (3) reference intervals. Details of these methods are found in an expanded version of this chapter.[12]

Reference Intervals

Albuminuria

	µg/min	mg/24 h	Albumin/Creatinine Ratio (µg/mg Urine Creatinine)
Normal	<20	<30	<30
High albuminuria (formerly microalbuminuria)	20-200	30-300	30-300
Very high albuminuria*	>200	>300	>300

*Also termed overt nephropathy.

The ADA recommends initial albuminuria measurement in patients with type 1 diabetes who have had diabetes for 5 years or longer, and at the time of diagnosis of type 2 diabetes. Analysis should be performed annually in all patients who have a negative screening result. Screening may be performed with a semi-quantitative assay. If the screening result is positive, albuminuria should be evaluated by a quantitative assay. Diagnosis requires the demonstration of increased UAE in at least two of three tests measured within a 3- to 6-month period.

If the confirmatory test result is positive, treatment with an ACE inhibitor or an angiotensin-receptor blocker should be initiated. ACE inhibitors delay progression to overt nephropathy, and the National Kidney Foundation recommends their use in both normotensive and hypertensive patients with type 1 or type 2 diabetes. Untreated, the UAE would increase by 10% to 30% per year, whereas the albumin/creatinine ratio in patients taking ACE inhibitors should stabilize or decrease by up to 50%.

Review Questions

1. Glycated hemoglobin indicates compliance of a patient with diabetes with his or her insulin-taking regimen by monitoring glucose control. GHb concentration represents the integrated glucose value in the blood over what period?
   a. 8 to 12 days
   b. 8 to 12 weeks
   c. 8 to 12 months
   d. One day
2. Which of the following values obtained during an oral glucose tolerance test (OGTT) is above the appropriate cutpoint for diagnosis of diabetes mellitus?
   a. 2-Hour specimen = 125 mg/dL (6.9 mmol/L)
   b. Fasting glucose = 138 mg/dL (7.7 mmol/L)
   c. Fasting glucose = 110 mg/dL (6.1 mmol/L)
   d. 2-Hour specimen = 80 mg/dL (4.4 mmol/L)
3. Type 2 diabetes:
   a. is associated with resistance to the action of insulin.
   b. is caused by destruction of pancreatic β-cells.
   c. is also known as insulin-dependent diabetes mellitus.
   d. occurs less frequently than type 1 diabetes.
4. All of the following results are confirmatory and diagnostic laboratory values for diabetes mellitus except:
   a. nonfasting blood glucose >200 mg/dL (11.1 mmol/L).
   b. 2-hour oral glucose tolerance values >200 mg/dL. (11.1 mmol/L)
   c. urine glucose >250 mg/dL. (13.9 mmol/L)
   d. fasting plasma glucose >126 mg/dL (7.0 mmol/L)
5. Release of glucose from its storage form is referred to as:
   a. glycogenesis.
   b. glycogenolysis.
   c. glycolysis.
   d. glyconeogenesis.
6. Which of the following hormones produces hyperglycemia?
   a. Epinephrine
   b. Glucagon
   c. Thyroid hormone
   d. All of the above hormones produce hyperglycemia.
7. Whole blood glucose values are approximately what percent different from plasma glucose values?
   a. 20% higher
   b. 15% lower
   c. 50% higher
   d. There is no difference between whole blood glucose and plasma glucose values.
8. The development of ketosis in uncontrolled diabetes is a result of:
   a. increased lipolysis of fatty acids from adipose stores and decreased re-esterification of these fatty acids to triglycerides.
   b. increased nonenzymatic addition of glucose to proteins, lipids, and nucleic acids that form ketoamines.
   c. increased formation of advanced glycation end products that do not return to normal levels when diabetes is controlled.
   d. formation of circulating antibodies that are formed against the excess adipose tissue present in a person with diabetes.
9. Which of the following hormones promotes decreased blood glucose?
   a. Epinephrine
   b. Glucagon
   c. Cortisol
   d. Insulin

10. The purpose of examining urinary albumin excretion in an individual with type 1 or type 2 diabetes is to:
    a. assess the ability of the pancreas to synthesize sufficient insulin.
    b. determine the rate of formation of advanced glycation end products.
    c. assess the possibility of overt diabetic nephropathy.
    d. examine the health of the liver in its ability to synthesize albumin.

CHAPTER

34 Cardiovascular Disease

Fred S. Apple, Ph.D., Jens Peter Goetze, M.D., D.M.Sc., and Allan S. Jaffe, M.D.

Objectives

1. Define the following terms:
   - Acute coronary syndrome (ACS)
   - Acute myocardial infarction (AMI)
   - Angina
   - Atherosclerosis
   - Cardiac biomarker
   - Congestive heart failure (CHF)
   - Coronary artery disease (CAD)
   - Creatine kinase (CK)
   - Electrocardiogram (ECG)
   - Ischemia
   - Myocardium
   - Myocardial infarction
   - Myoglobin
   - Natriuretic peptide (NP)
   - Plaque
   - Troponin
2. Describe the anatomy of the heart, including layers, chambers, and protein makeup of muscle.
3. List the events in the process of atherosclerotic plaque formation.
4. Describe an ideal cardiac biomarker, including necessary characteristics, analytical considerations, and persistence in blood following an acute myocardial infarction (AMI).
5. Compare troponin I and T, including structural differences, physiological function, localization, and usefulness in diagnosing an AMI.
6. List six proposed elements of the guidelines of the National Academy of Clinical Biochemistry for point-of-care testing (POCT) of cardiac biomarkers.
7. For the following cardiac biomarkers, list and describe location with heart tissue, physiological function if known, clinical utility as a cardiac biomarker, specificity, and other conditions that cause increased values, laboratory analysis of choice and specimen requirements:
   - Creatine kinase (CK)
   - CK isoforms
   - Myoglobin
   - Natriuretic peptides (NPs)
   - NT-proBNP
   - Troponins
8. List four preanalytical considerations that must be assessed by a clinical laboratory that uses NP assays; state what units must be used to report these analytes.
9. Evaluate and analyze case studies related to cardiovascular disease and the use of cardiac biomarkers in the diagnosis of cardiovascular disease.

Key Words and Definitions

Acute coronary syndrome (ACS) A sudden cardiac disorder that varies from angina (chest pain on exertion with reversible tissue injury), to unstable angina (with minor myocardial injury), and to myocardial infarction (with extensive tissue necrosis, which is irreversible).

Acute myocardial infarction (AMI) An acute infarction (obstruction of circulation) of the heart muscle occurring during the period when circulation to a region of the heart is obstructed and necrosis is occurring.

Angina A condition marked by severe pain in the chest, often also spreading to the shoulders, arms, and neck, caused by an inadequate blood supply to the heart.

Arrhythmia Any variation from the normal rhythm of the heartbeat; alternative (and broader) term: dysrhythmia, especially to indicate an abnormally slow or fast heartbeat which may have rhythmic beating.

Atherosclerosis Any of a group of diseases characterized by thickening and loss of elasticity of arterial walls.

Atherosclerotic plaque A pearly white area within the wall of an artery that causes the intimal (interior) surface to bulge into the lumen; composed of lipid, cell debris, smooth muscle cells, collagen, and sometimes calcium; also known as an atheroma; vulnerable to rupture that causes the formation of a platelet- and fibrin-rich thrombus leading to myocardial infarction and ischemic stroke.

Cardiac biomarker A biological compound whose measurement is useful in the diagnosis of cardiac disease; used to (1) detect cardiac disorders, (2) detect risk of developing cardiac disorders, (3) monitor the disorder, or (4) predict the response of a disorder to a treatment.

Congestive heart failure (CHF) A clinical syndrome due to heart disease, characterized by breathlessness and abnormal sodium and water retention, often resulting in edema; also called heart failure.

Key Words and Definitions—cont'd

Coronary arteries The two main arteries that provide blood to the heart, surrounding the heart like a crown, coming out of the aorta, arching down over the top of the heart, and dividing into two branches.

Electrocardiogram (ECG) A graphic recording of the electrical activity produced by the heart.

Myocardial ischemia Deficiency of blood supply to the heart muscle due to obstruction or constriction of the coronary arteries

Myocardium The middle and thickest layer of the heart wall, composed of cardiac muscle.

Necrosis The sum of the morphological changes indicative of cell death and caused by the progressive degradative action of enzymes.

Non–ST segment elevation myocardial infarction (NSTEMI) A myocardial infarction in which the ST segment is not elevated in one lead or several leads of the ECG.

Percutaneous coronary intervention (PCI) The management of coronary artery occlusion by any of various catheter-based techniques.

Risk stratification A statistical process used to determine detectable characteristics associated with an increased chance of experiencing unwanted outcomes.

ST segment elevation myocardial infarction (STEMI) Any type of myocardial infarction in which the ST segment is elevated in one lead or several leads of the ECG.

Thrombolysis Lysis of a thrombus or thrombi.

Unstable angina An angina that occurs unpredictably or suddenly increases in severity or frequency.

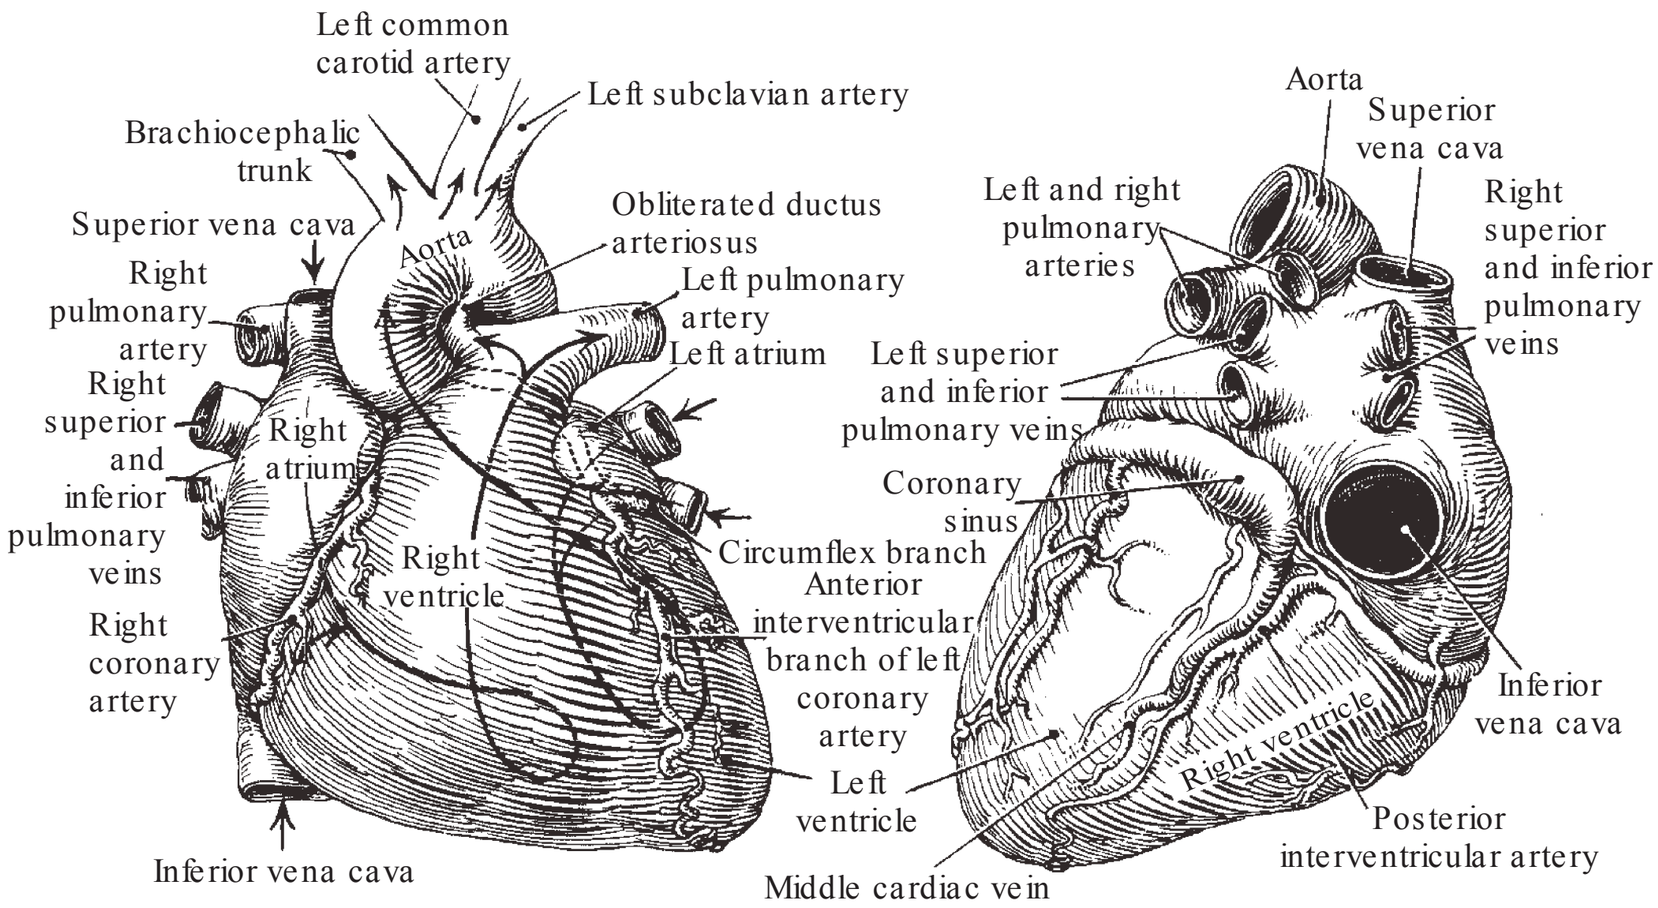
Ventricles (right and left) The two lower chambers of the heart, responsible, respectively, for pumping blood into the lungs via the pulmonary artery and into the systemic circulation via the aorta.

Acute ischemic disease and heart failure are the two most common cardiovascular diseases that rely on a biochemical diagnosis. They, and the **cardiac biomarkers** used in their diagnosis, are the major focus of this chapter.

The most serious form of ischemic heart disease is **acute myocardial infarction (AMI)**. AMI occurs when there is an imbalance between supply and demand for oxygen in the **myocardium** (heart muscle) resulting in injury to and the eventual death of muscle cells (myocytes). When the blood supply to the muscle in a region of the heart is blocked for more than a few minutes, many or most of the muscle cells in the affected region die. This is called **necrosis** (cell death) of the myocardium. Other events of lesser severity may be missed entirely or be called **angina**, which ranges from stable to **unstable angina**. The ischemic events in the heart, ranging from angina (no cell death) to AMI (cell death), are known as **acute coronary syndromes (ACSs)**.

In the United States, approximately 700,000 patients every year suffer a first AMI, and another 500,000 people who had suffered an AMI in the past suffer another one (called recurrent AMI). About 1.7 million patients are hospitalized each year in the United States with ACS. The yearly economic burden of coronary artery disease (CAD) is in excess of $133.2 billion, more than a third of the total of $368.4 billion due to cardiovascular disease overall. Today the management of AMI suggested by most guidelines is aggressive and invasively oriented in the hope of reducing the extent of the myocardial damage and thus improving prognosis.

In acute ischemic heart disease, the clinical laboratory plays an important role in detection of myocardial injury. For example, the measurement of the cardiac troponins (cTns) is an important test for this purpose. These proteins are found exclusively in heart muscle cells and released into the circulation when cells die. Increased concentrations of cTns in the blood are sensitive signs of damage to heart muscle. Conversely, reference concentrations provide powerful evidence for the healthcare provider that a patient's symptoms are not related to cardiac injury.



Heart failure is often termed **congestive heart failure (CHF)**. The National Heart, Lung, Blood Institute estimates that the current prevalence of CHF in America is 4.9 million individuals with an annual incidence of approximately 400,000 new cases each year. It is the leading cause of hospitalization in individuals 65 years and older. Prognosis is dependent on disease severity, but overall it is poor. Five-year mortality is (1) approximately 10% in mild CHF, (2) 20% to 30% in moderate CHF, and (3) up to 80% in end-stage disease. The cost of these poor outcomes is estimated at $18.8 billion per year in the United States.

Clinical chemistry testing has become important in detection of CHF. The key tests are B-type natriuretic peptide (BNP) and the N-terminal [portion of] proBNP (NT-proBNP) molecules, which are breakdown products of proBNP. BNP and NT-proBNP are released by the stressed heart and are found in the circulation. As the name "natriuretic" implies, BNP increases the renal excretion of sodium. Unlike cTns, which are intracellular proteins that escape from heart muscle cells only because the cells are dead or seriously injured, BNP is a hormone that is secreted into the blood. The secretion of BNP is stimulated by the stretch of the heart wall that occurs in heart failure. Measurement of BNP in plasma has proven to be clinically valuable as will be explored in this chapter. (Note that the general use of the term BNP in this chapter refers to either BNP or NT-proBNP unless specifically indicated.)

Anatomy and Physiology of the Heart

The average human adult heart weighs approximately 325 g in men and 275 g in women. It is enclosed in a sac called the pericardium. The cardiac wall is composed of three layers: the

epicardium (the outer most layer), a middle layer, and an inner layer called the endocardium. T e heart has four chambers. T e two upper chambers are termed the right and lef atria, and the two lower chambers are termed the right and lef **ventricles** (Figure 34-1). T e endocardium is the layer most susceptible to **myocardial ischemia**, a condition where the heart tissue is slowly or suddenly starved of oxygen and other nutrients. Note that the **coronary arteries**, which supply the blood to the wall of the heart, are on the epicardium. T e myocardium contains bundles of striated muscle fibers. T e work of the heart is generated by the alternating contraction and relaxation of these fibers. T e fibers contain the contractile proteins actin and myosin. T e fibers also contain the troponins that regulate contraction. Two of the troponins, the cardiac forms of troponins I and T, have become the definitive biomarkers of cardiac injury.

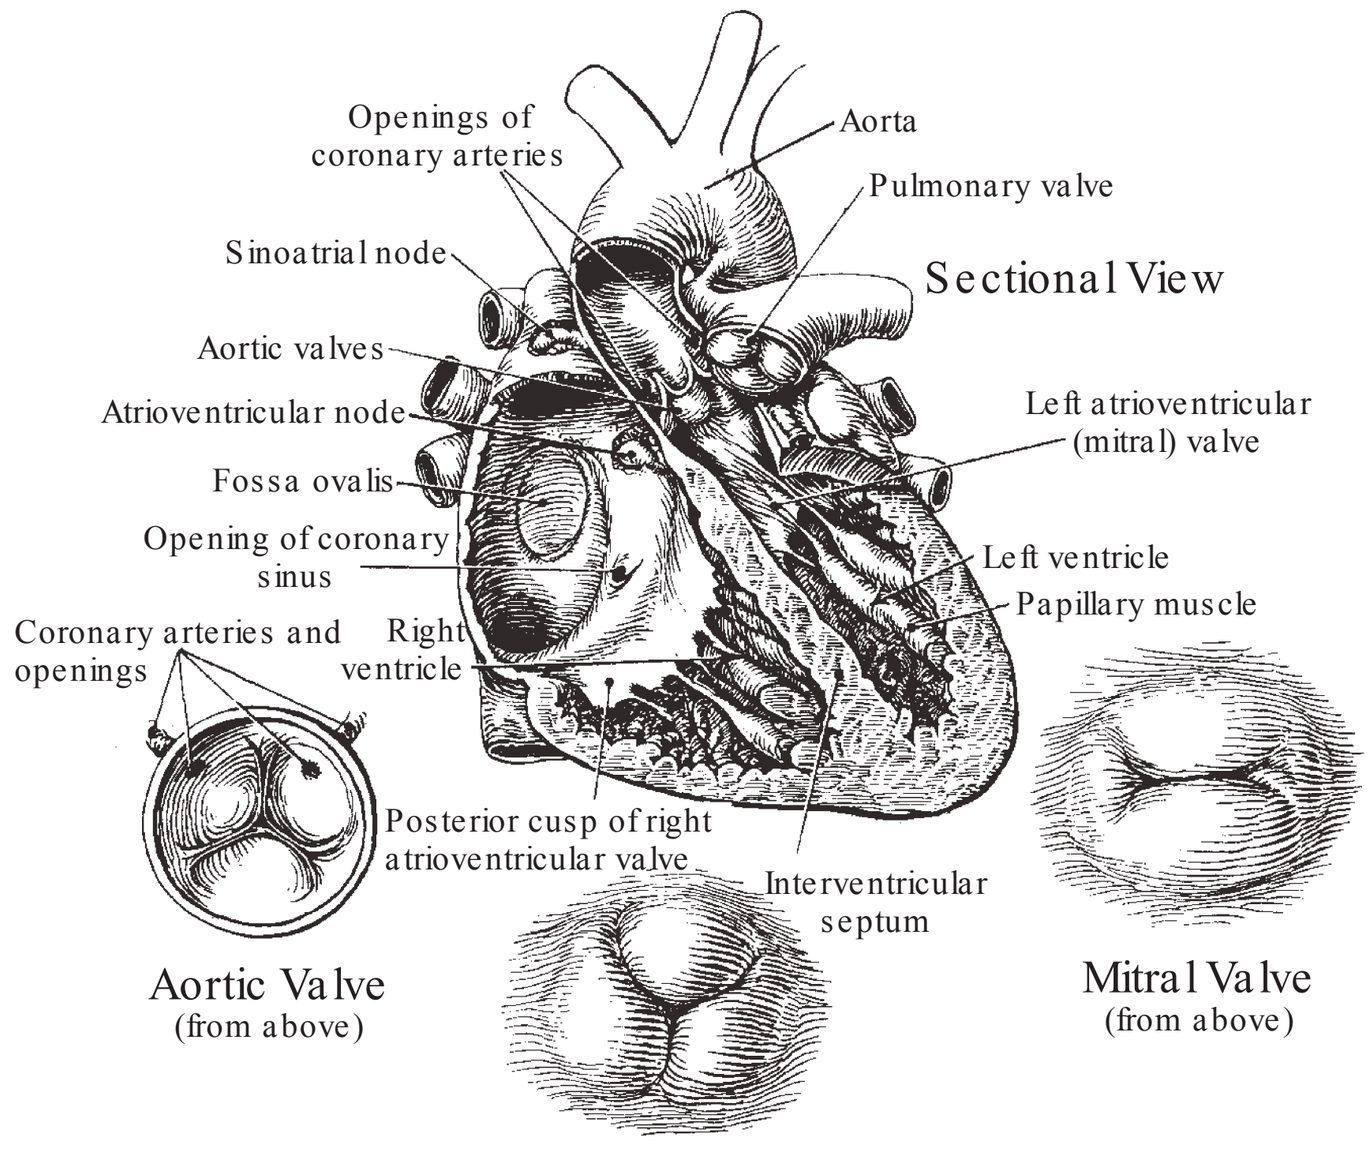


Figure 34-1 Anatomy of the heart. (From Dorland's illustrated medical dictionary, 30th edition. Philadelphia: WB Saunders, 2003: Panel 20.)

A typical cardiac cycle consists of two intervals known as systole and diastole (Figure 34-2). During systole, the blood pressure (BP) in the aorta is typically about 120 mm Hg. During diastole, the BP falls to about 70 mm Hg. At rest, the heart pumps between 60 and 80 times per minute. The cardiac cycle is tightly controlled by the cardiac conducting system, which initiates electrical impulses and carries them, via a specialized conducting system, to the myocardium. The **electrocardiogram (ECG)** records changes in electrical potential and is a graphic tracing of the variations in electrical potential caused by the excitation of the heart muscle. The surface ECG is a recording of the electrical potential as detected at the body surface. Clinically, the ECG is used to identify (1) anatomic, (2) metabolic, (3) ionic, and (4) hemodynamic changes. The clinical sensitivity and specificity of ECG abnormalities for detecting ACSs are influenced by a wide spectrum of physiological and anatomical changes and the clinical situation.

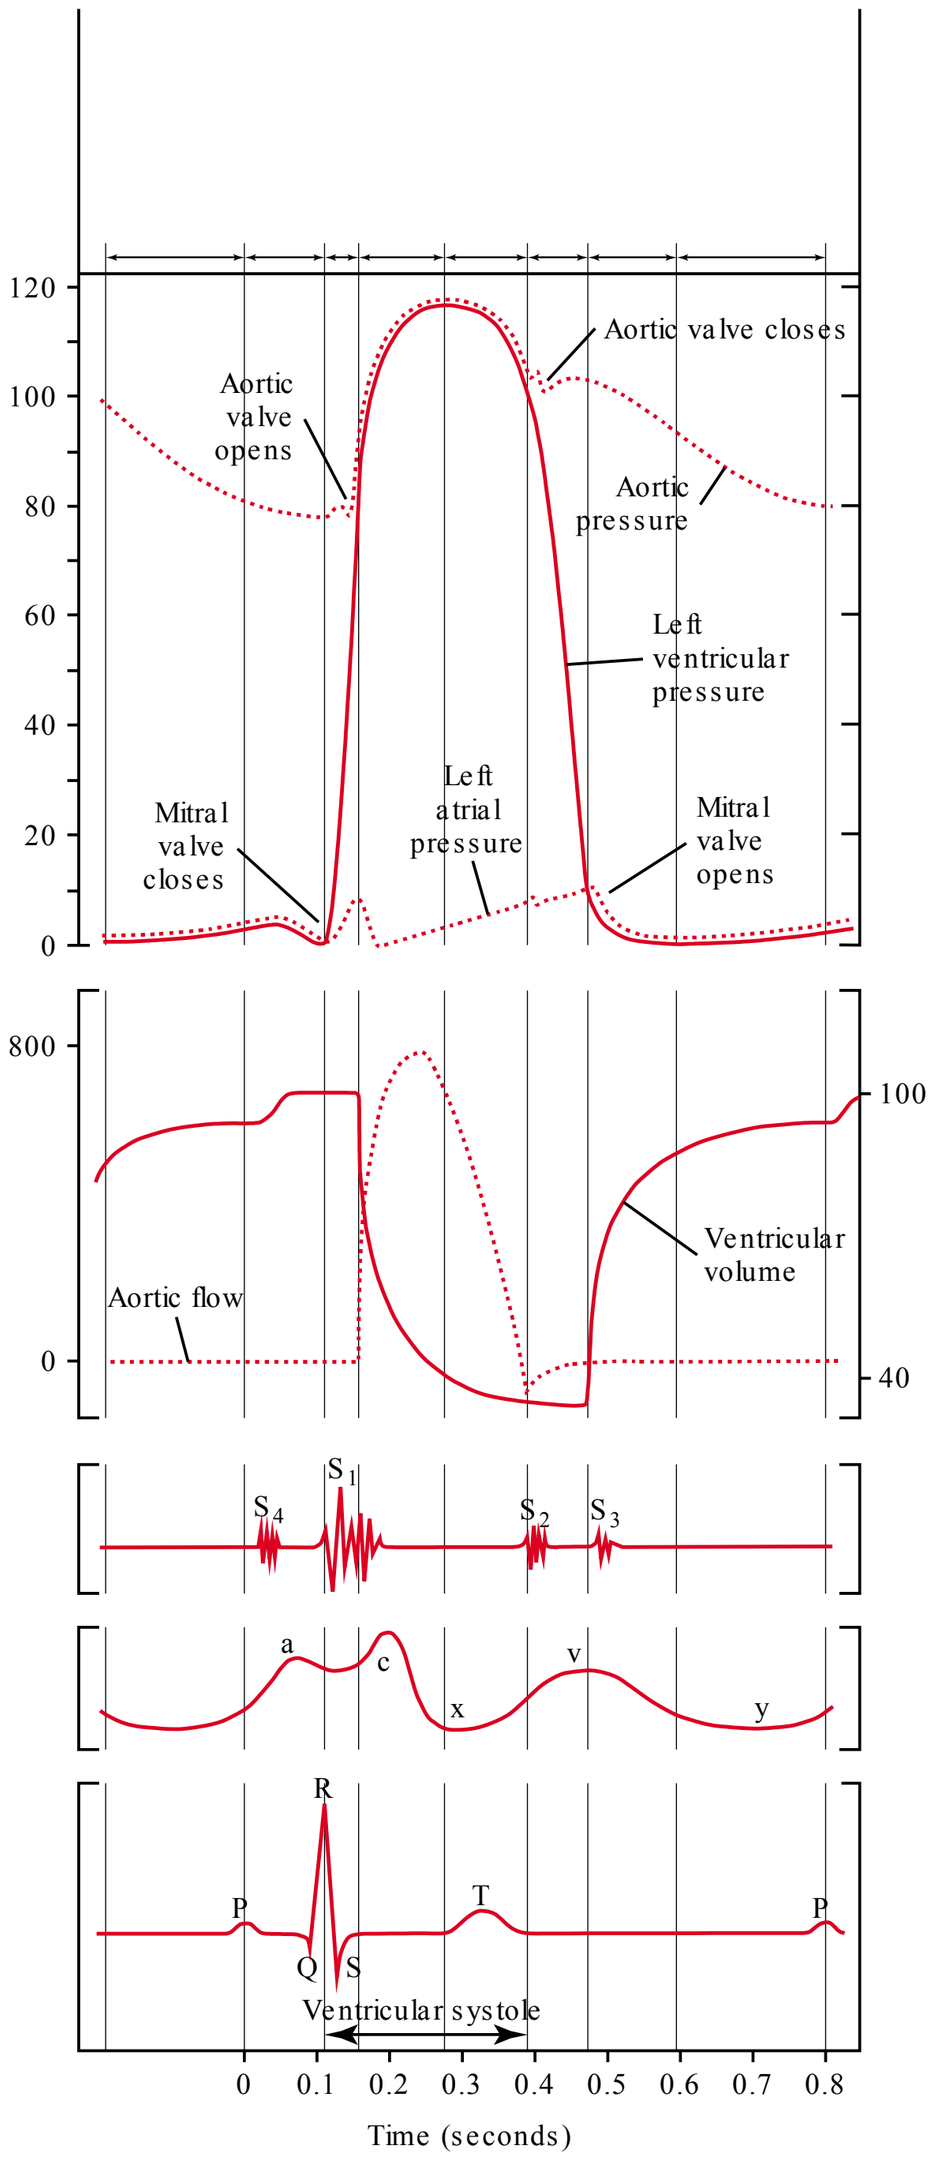

Figure 34-2 The cardiac cycle. (From Dorland's illustrated medical dictionary, 30th edition. Philadelphia: WB Saunders, 2003, with permission from the National Kidney Foundation.)

Under normal circumstances, each cardiac cycle's electrical potential changes, with each being similar to that of every other cycle, and includes three major components (Figure 34-3): the atrial depolarization (the P wave), ventricular depolarization (the QRS complex), and repolarization (the ST segment and T wave). A routine ECG is composed of twelve leads. Six are called limb leads, because they are recorded between arm and leg electrodes, and six are called precordial or chest leads and are recorded across the sternum and left precordium. Each lead records the same electrical impulse but in a different position relative to the heart. Areas of pathology shown on the ECG are localized by analyzing differences between the tracing in question and what is considered normal in the twelve different leads.

Cardiac Disease

In this section, ACS and heart failure are discussed in more detail.

Acute Coronary Syndromes

The term, acute coronary syndrome (ACS), includes patients who have a variety of forms of unstable ischemic heart disease. In the severe form of AMI, the ECG typically shows elevation of a portion called the ST segment. The associated clinical picture is known as **ST segment elevation myocardial infarction (STEMI)**. Partial loss of coronary perfusion, if severe, also leads to necrosis, but the magnitude of cell death is generally less and the ECG does not show elevation of the ST segment. The condition is known as **non–ST segment elevation myocardial infarction (NSTEMI)**, or non-STEMI. Patients with STEMI usually will develop Q waves on their ECGs (see Figure 34-3) hence the term Q-wave MI. If they

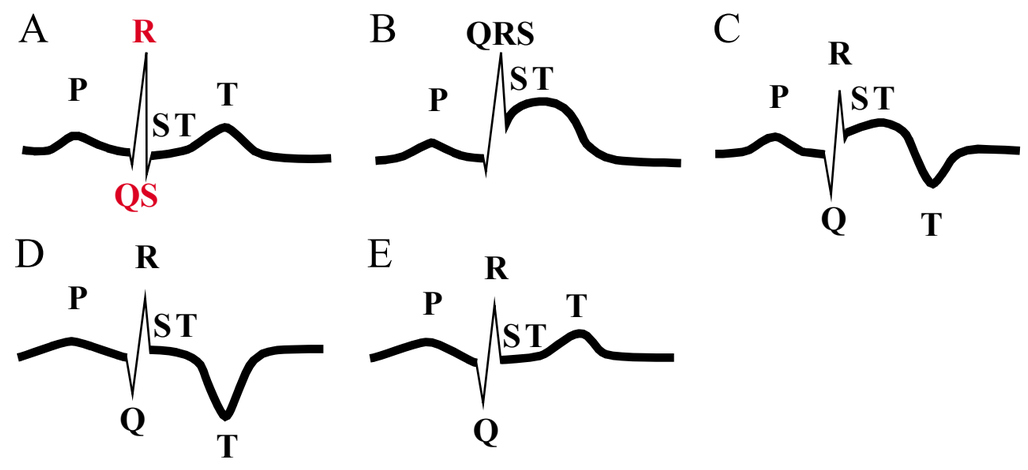

Figure 34-3 Electrocardiograms (ECGs) from a patient with an acute myocardial infarction (AMI). The sequence is (A) normal, (B) hours after infarction, the ST segment becomes elevated, (C) hours to days later, the T wave inverts and the Q wave becomes larger, (D) days to weeks later, the ST segment returns to near normal, and (E) weeks to months later, the T wave becomes upright again, but the large Q wave may remain.

do not have STE but have biochemical evidence of cardiac injury (e.g., an increasing cTnI or cTnT in blood), they are called NSTEMI. T ose who have unstable ischemia and do not show evidence of cardiac necrosis (cell death) as indicated by increased blood concentrations of a cTn are classified as having unstable angina. Most of these syndromes occur in response to an acute event in the coronary artery that obstructs circulation to a region of the heart. If the obstruction blocks much of the passageway for blood in the vessel and persists, then necrosis usually results. Since necrosis is known to take some time to develop, it is apparent that opening the blocked coronary artery in a timely fashion often will prevent some of the death of myocardial tissue.

T e major cause of ACS is **atherosclerosis**. T is is a disease caused by plaque (a deposit of fatty material) being formed on the inner lining of the coronary arteries that feed the surface of the heart, which contributes to significant narrowing of the artery's lumen. Such plaques are vulnerable to rupture that results in the formation of a platelet- and fibrin-rich thrombus leading to myocardial infarction and ischemic stroke.

Atherosclerosis is also considered a chronic inflammatory disease that results after some event damages the internal lining cells (endothelium) of blood vessels, which facilitates the passage of lipid into the subendothelial space. T e process of atherosclerosis progresses slowly with the involvement of (1) lymphocytes, (2) monocytes, (3) macrophages, and (4) smooth muscle cells. T is process also involves adherence of white blood cells to the damaged endothelial surface with subsequent degranulation of the white cells and release of myeloperoxidase (MPO). T ere also is a procoagulant component attributable predominantly to the presence of tissue factor, which is localized immediately under the cap of the plaque. T ere also is intermittent instability because of inflammatory products within the plaque that release chemicals that degrade ground substances. T ese processes, in addition to a reduction in flow, lead to necrosis or at least recurrent myocardial ischemia. It is also thought that the process that eventually leads to acute events involves a systemic tendency to platelet aggregation and inflammation. Finally, necrosis when present also stimulates an acute phase reaction, including an inflammatory component. Given this pathophysiology, many therapies are now oriented toward inhibition of (1) thrombosis, (2) fibrinolysis, (3) platelet aggregation, and (4) inflammation.

In addition, **atherosclerotic plaque** has a tendency to break open (plaque disruption) and form blood clots (thrombi) within the vessel, further blocking or completely stopping blood flow. Myocardial ischemia and subsequent infarction usually begin in the endocardium and spread toward the epicardium. T e extent of myocardial injury reflects: (1) extent of the occlusion, (2) the metabolic needs of the area deprived of perfusion, and (3) the duration of the imbalance between coronary supply, substrate availability, and the metabolic needs of the tissue. Irreversible cardiac injury consistently occurs when the occlusion is complete for at least 15 to 20 minutes. Most of the damage occurs within the first 2 to 3 hours.

Restoration of coronary blood flow within the first 60 to 90 minutes results in the maximal salvage of tissue, but treatment even up to 4 to 6 hours is associated with increased survival. For patients with STEMI, earlier opening the vessel can be achieved with clot dissolving agents (**thrombolysis**) and/or **percutaneous coronary intervention (PCI)**, which is a non-surgical method used to open narrowed arteries that supply the heart muscle with blood. With PCI, a catheter typically is inserted into a femoral artery, and its tip is maneuvered through the aorta and into the coronary artery. T ere the blockage is opened, often by inflating a balloon that is on the catheter, near its tip. T e cardiologist may then insert a stent, a wire mesh tube placed inside the vessel to keep it open. T is approach yields the highest acute opening rate and fewer bleeding problems than do other interventions, such as use of agents to dissolve clots. However, many hospitals cannot or do not offer urgent PCI 24 hours a day, 365 days per year. T us administration of clot-dissolving medications without the use of PCI still plays a major role in treatment. In addition, it is now apparent that urgent invasive revascularization also benefits those with NSTEMI. It is now known that many treatments, such as newer (1) anticoagulant, (2) antiplatelet, and (3) antiinflammatory agents, when used in conjunction with PCI and other approaches to coronary revascularization, save lives in this group.

Precipitating Factors

In medical terminology, a precipitating *f*actor is defined as an element that causes or contributes to the occurrence of a disorder. In many patients with AMI, the following precipitating factors have been observed for patient activities at the onset of AMI: (1) heavy physical exertion, 13%; (2) modest or usual exertion, 18%; (3) surgical procedure, 6%; (4) rest, 51%; and (5) sleep, 8%.

Role of Clinical History in Diagnosis of Acute Coronary Syndrome

T e clinical history remains of substantial value in establishing a diagnosis. A prodromal history of angina is elicited in 40% to 50% of patients with AMI. Approximately one-third have had symptoms from 1 to 4 weeks before hospitalization. In the remaining two-thirds, symptoms predate admission by a week or less, with one-third of these patients having had symptoms for 24 hours or less.

In most patients, the pain of an ACS is severe but rarely intolerable. Such pain is described as (1) constricting, (2) crushing, (3) oppressing, or (4) compressing. In addition, the patient often complains of something sitting on or squeezing the chest. T e pain is usually felt behind the sternum (retrosternal), spreading frequently to both sides of the chest, favoring the left side. Often the pain radiates down the left arm. In some instances, the pain of AMI may begin in the upper abdomen (epigastrium) and simulate a variety of abdominal disorders, which may lead to a misdiagnosis of indigestion. In other patients, the discomfort of AMI radiates to the (1) shoulders, (2) upper extremities, (3) neck, and (4) jaw, again usually favoring the left side. In patients with preexisting angina, the pain of infarction usually resembles that of angina with respect to features and location, but it is generally (1) much more severe, (2) lasts longer (more than 30 minutes), and/or (3) is not relieved by rest and nitroglycerin. Older individuals,

diabetics, and women are more likely to present atypically, without pain or with nonspecific symptoms. Sometimes, the pain of AMI may have disappeared by the time a physician first encounters the patient, or it may persist for a few hours.

Role of Cardiac Biomarkers in Acute Coronary Syndrome

A cardiac biomarker is a biochemical compound whose measurement is useful in detecting cardiac disease, most commonly for detecting AMI or myocardial injury. In the latter setting, they are most useful when patients have nondiagnostic ECGs. For a biomarker to be clinically useful in detecting AMI, it must be released rapidly from the heart into the circulation and provide sensitive and specific diagnostic information. Furthermore, the analytical assays must be rapid and able to measure low concentrations of the biomarker in serum, plasma or whole blood samples. Also, the ideal biomarker of myocardial injury would persist in the circulation for several days to provide a late diagnostic time window for patients who arrive late after the event (for example, those with minimal pain).

Diagnosis of Acute Myocardial Infarction

Historically, the use of cardiac biomarkers in the diagnosis of AMI began in the 1950s. Initially, measurement of serum biomarkers for this purpose included (1) aspartate aminotransferase (AST), (2) lactate dehydrogenase (LD), (3) total creatine kinase (CK) and (4) α-hydroxybutyrate. In 1986 the World Health Organization (WHO) produced criteria for the diagnosis of AMI. These criteria required that at least two of the following be met for diagnosing AMI: (1) a history of chest pain, (2) evolutionary changes on the ECG, and/or (3) elevations of serial cardiac biomarkers to a level two times the normal value. (http://www.who.int/classifications/; accessed April 1, 2013).[26] These criteria are have been superseded by newer guidelines.

A 2000 European Society of Cardiology/American College of Cardiology (ESC/ACC) consensus conference updated in 2007 and 2012 (Global Task Force)[24,25] codified the role of cardiac biomarkers by advocating that the diagnosis should be based on biomarkers of cardiac damage in the appropriate clinical situation (Box 34-1).[24,25] The recommendations of the Biochemistry Panel of the ESC/ACC Committee for the use of biomarkers in the diagnosis of an established AMI are listed in Box 34-2.

BOX 34-1 Criteria for the Definition of Acute Myocardial Infarction

1. Detection of rise and/or fall of cardiac biomarkers (preferably troponin) above the 99th percentile of the upper reference limit, together with evidence of ischemia with at least one of the following:
   a. Ischemic symptoms
   b. Electrocardiogram (ECG) changes of new ischemia (new ST-T changes or new left bundle branch block [LBBB])
   c. Development of pathologic Q waves on the ECG
   d. Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
   e. Identification of an intracoronary thrombus by angiography or autopsy

From Thygesen K, Alpert JS, Jaffe AS, et al. Third universal definition of myocardial infarction. ESC/ACCF/AHA/WHF expert consensus document. Circulation 2012;126:2020-35.

BOX 34-2 European Society of Cardiology/American College of Cardiology Recommendations for Use of Cardiac Biomarkers for Detection of Myocardial Injury and Myocardial Infarction

- Increases in biomarkers of cardiac injury are indicative of injury to the myocardium, but not an ischemic mechanism of injury.
- cTns (I or T) are preferred biomarkers for diagnosis of myocardial injury.
- Increases in cardiac biomarker proteins reflect irreversible injury.
- Improved quality control of troponin assays is essential.
- Myocardial infarction is present when there is cardiac damage, as detected by biomarker proteins (an increase above the 99th percentile of the reference interval) in a clinical setting consistent with myocardial ischemia.
- For patients with an ischemic mechanism of injury, prognosis is related to the extent of troponin increases.
- If an ischemic mechanism is unlikely, other causes for cardiac injury should be pursued.
- Samples must be obtained at least 6 to 9 hours after the symptoms begin.
- After PCI and CABG, the significance of biomarker elevations and patient care should be individualized.

CABG, Coronary artery bypass grafting; cTn, cardiac troponin; PCI, percutaneous coronary intervention.

Congestive Heart Failure

CHF is defined as a condition in which the heart has lost the ability to pump enough blood to the body's tissues. With too little blood being delivered, the organs and other tissues do not receive enough oxygen and nutrients to function properly. Encompassed in the definition of heart failure is a wide spectrum of clinical conditions, ranging from (1) a primary impairment in pump function, such as might occur after a large AMI; (2) increased cardiac stiffness, which causes increases in pressure in the heart, restricts filling, and increases hydrostatic pressures behind the area of reduced compliance; and (3) situations in which peripheral demand is excessive. The latter results in what is known as high output heart failure, which is defined as the inability of the heart to increase its output sufficiently to meet the peripheral demands for blood.

To functionally stage CHF patients, the New York Heart Association (NYHA) classification system is often used (Table 34-1). In this system, Class I patients are generally considered asymptomatic with no restrictions on physical activity. In the highest class (Class IV), patients are often symptomatic at rest with severe limitations on physical activity. The clinical manifestations of heart failure vary considerably and many are nonspecific. The findings depend on many factors, including (1) the clinical characteristics of the patient, (2) the extent and rate at which the heart's performance becomes abnormal, (3) the cause of the heart disease, (4) concomitant co-morbidities, and (5) the part of the heart that is affected by abnormal functioning. The severity of impairment ranges from mild—manifested

TABLE 34-1 New York Heart Association Functional Classification Used to Classify the Extent of Heart Failure*

NYHA Class	Symptoms
I	Cardiac disease, but no symptoms and no limitation in ordinary physical activity (e.g., shortness of breath when walking, climbing stairs, etc.)
II	Mild symptoms (mild shortness of breath and/or angina) and slight limitation during ordinary activity
III	Marked limitation in activity due to symptoms, even during less-than-ordinary activity (e.g., walking short distances [20-100m]). Comfortable only at rest.
IV	Severe limitations; experiences symptoms even while at rest (mostly bedbound patients)

*As of April 1, 2013.
NYHA, New York Heart Association.

clinically only during stress—to advanced, in which cardiac pump function is unable to sustain life without external support.

Because the symptoms and signs of heart failure are nonspecific, an objective test for heart failure would be extremely useful. Ideally, the biomarker would increase progressively with increasing severity of disease and not be increased (or decreased) in conditions that mimic CHF. Furthermore, as for biomarkers of cardiac injury, rapid assays are desirable.

Cardiac Biomarkers

Numerous biomarkers have been monitored to assess myocardial injury and dysfunction (Table 34-2 and Table 34-3). Most are myocardial proteins and differ in their (1) location within the myocyte, (2) release kinetics after damage, and (3) clearance from the circulation. In this section, cTns (used as biomarkers of myocardial injury and in diagnosis of AMI) and natriuretic peptides (used in CHF) are described first and followed by brief discussions of three other biomarkers of myocardial injury (CK and CKMB, high-sensitivity C-reactive protein [hsCRP], and myoglobin) that are available but are not used as widely.[21] The section ends with a discussion of other cardiac biomarkers that may find utility in the next few years for various purposes.

Cardiac Troponins I and T

cTns are specific proteins found in cardiac muscle (Figure 34-4) and are measured in the diagnosis of myocardial infarction. Cardiac troponins I and T are the two main types of troponin and are referred to as cTnT and cTnI, respectively.

Biochemistry

The troponin subunits form a complex that regulates the interaction of actin and myosin and thus regulates cardiac contraction (see Figure 34-4). The three troponins are (1) troponin T (the tropomyosin-binding component), (2) troponin I (the inhibitory component), and (3) troponin C (the calcium-binding component). Troponins are localized primarily in the myofibrils (94% to 97%) with a smaller cytoplasmic fraction (3% to 6%). cTnI and cTnT have different amino acid sequences encoded by different genes, and are different from the predominant troponins found in other muscle such as skeletal muscle. Human cTnI has an additional post translational 31–amino acid residue on the amino terminal end compared with skeletal muscle TnI, giving it cardiac specificity. Only one isoform of cTnI has been identified. cTnI is not expressed in normal, regenerating, or diseased human or animal skeletal muscle. cTnT is also encoded by a different gene than the one that encodes skeletal muscle isoforms. An 11–amino acid amino terminal residue gives this biomarker cardiac specificity. However, during human fetal development, in regenerating rat skeletal muscle, and in diseased human skeletal muscle, small amounts of

cTnT are expressed as one of four identified isoforms in skeletal muscle. In humans, cTnT isoform expression has been reported in skeletal muscle specimens obtained from patients with (1) muscular dystrophy, (2) polymyositis, (3) dermatomyositis, and (4) end-stage renal disease; there is some evidence that diseased skeletal muscle increases circulating cTnT immunoreactivity measured by the current cTnT immunoassay. The other troponin, troponin C, is not useful as a cardiac biomarker as the troponin C expressed in the heart is not specific for the heart.

Following myocardial injury or because of genetic disposition, multiple forms of troponin appear both in tissue and in blood. These include (1) the complexes of cardiac troponins T, I, and C (T-I-C, or ternary complex); (2) complexes of I and C (I-C binary complex); and (3) free I. Multiple modifications of these three forms exist resulting from biochemical processes involving (1) oxidation, (2) reduction, (3) phosphorylation, (4) dephosphorylation, and (5) removal of the amino acids at the ends (C or N) of the molecules. Clinically useful immunoassays ideally recognize epitopes in the stable region of the measured molecule and measure equally the various forms (have an "equimolar response" to the various forms) that circulate in the blood.

Analytical Considerations

Many assays have been developed to measure cTns. However, these assays have been difficult to standardize, resulting in unique reference intervals for each assay.

Types of Assays

In general, immunoassay is the technique of choice for measuring cTns. Cummins and coworkers were the first to develop a cTn immunoassay. They measured cTnI by use of a radioimmunoassay (RIA) and (polyclonal) anti-cTnI antisera.[3] This RIA was followed by an enzyme-linked immunosorbent cTnI assay that eliminated the need for radioactivity and achieved high specificity by use of monoclonal antibodies.[3]

Numerous manufacturers have since developed monoclonal antibody-based diagnostic immunoassays for the measurement of cTnI in serum. Typically, these assays have lower limits of detection in the range of 0.01 to 0.10 μg/ L.[1,2,5] Many of these assays have been approved by the US Food and Drug Administration (FDA) for patient testing within the United States on central laboratory and point-of-care testing (POCT) platforms. In addition to these quantitative assays, several assays have been approved by the FDA for the qualitative determination of cTnI. Further development has led to the design of high-sensitivity cTnI (hs-cTnI) assays and a hs-cTnT assay that have lower limits of detection of 0.1-3.0 ng/L.[2,11,16,18] In practice, two obstacles limit the ease of switching from one cTnI assay to another in clinical practice or research. First, no primary reference cTnI material is currently available for manufacturers to use in standardizing cTnI assays. Second, assay concentrations are not consistent between assays because cTnI circulates in its various forms and the different antibodies used in the available assays recognize different epitopes of cTnI.

In addition to the immunoassays developed for use in clinical laboratories, assays and devices have been developed for POCT. To guide their use, the National Academy of Clinical Biochemistry (NACB) has developed Laboratory Medicine Practice Guidelines for POCT for the use of cardiac biomarkers in ACS. (American Association for Clinical Chemistry. NACB: laboratory medicine practice guidelines [LMPG]. http://www.aacc.org/members/nacb/LMPG/; accessed September 9, 2013).

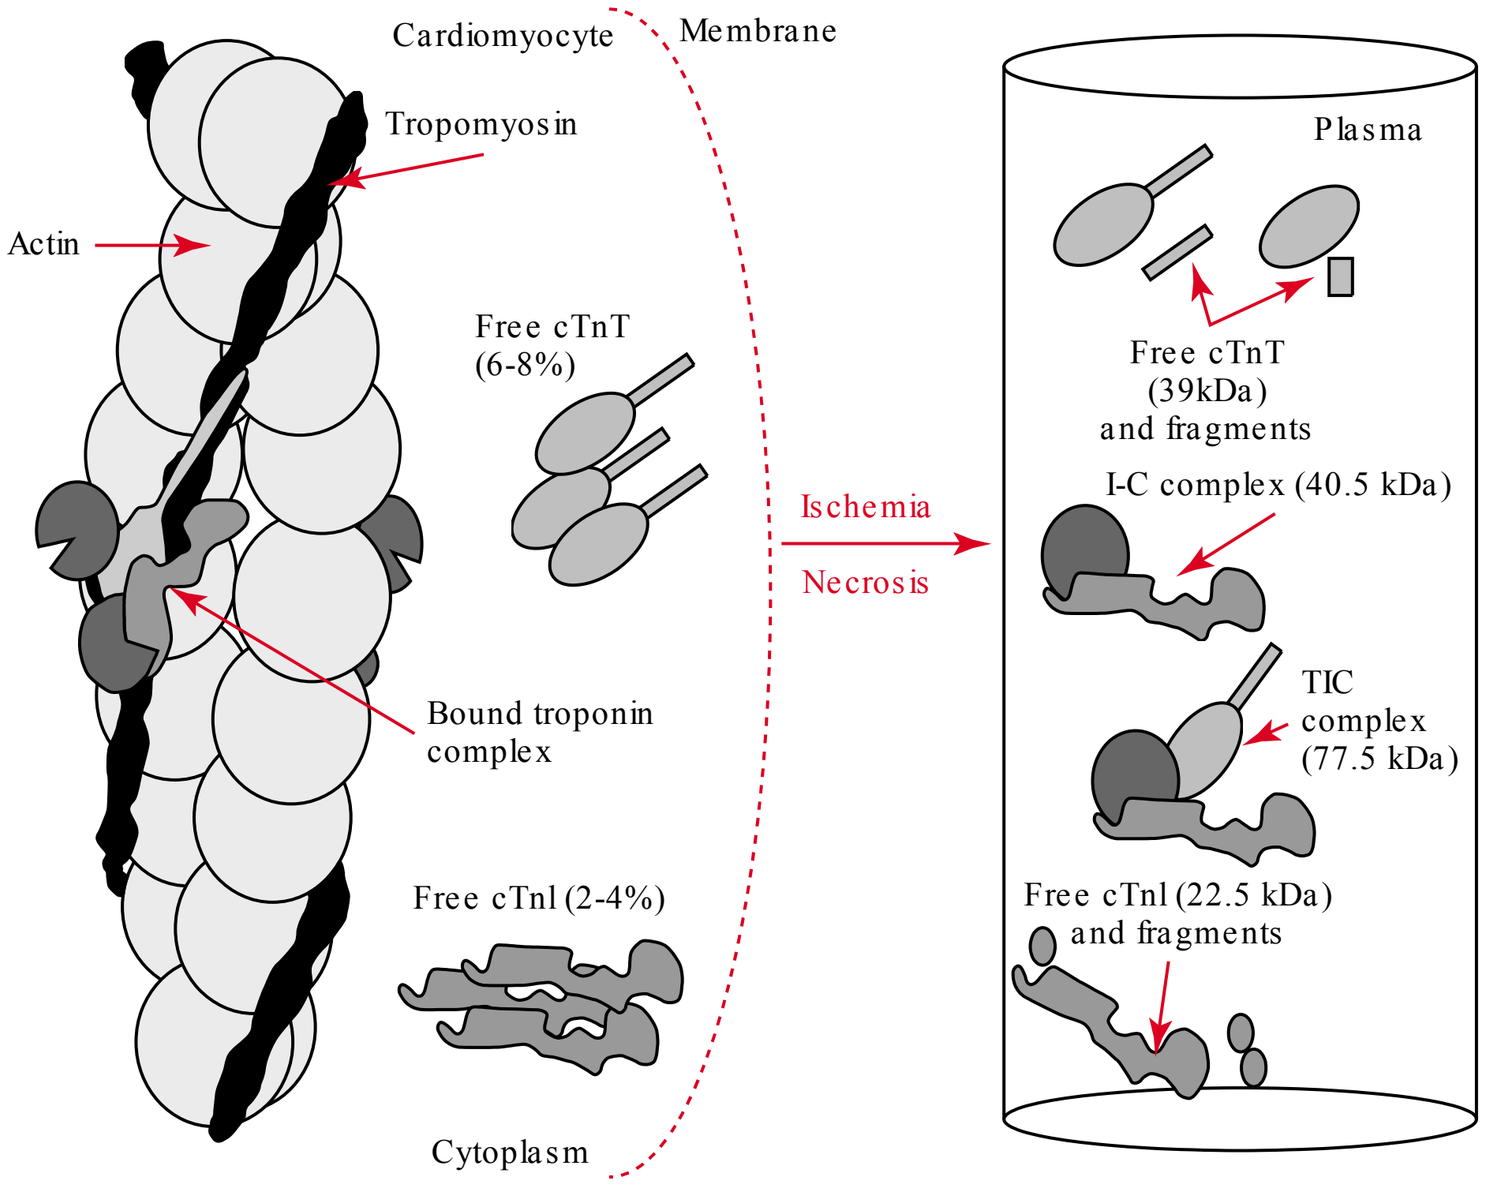

Figure 34-4 Structure of cardiac troponin (cTn) complex and troponin forms released following myofbril necrosis. (From Gaze DC, Collinson PO. Multiple molecular forms of circulating cardiac troponin: analytical and clinical signifcance. Ann Clin Biochem 2008;45:349-59. Figure courtesy of Paul Collinson.)

T ese guidelines address (1) administrative issues, (2) cost-effective utilization, and (3) clinical and technical performance of cardiac biomarkers in the emergency medicine department. Proposed elements of the guidelines include:

1. Members of emergency medicine departments, primary care physicians, cardiologists, hospital administrators, and clinical laboratory staff should work collectively to develop an accelerated protocol for the use of biomarkers in the evaluation of patients with possible ACS.
2. Quality assurance measures should be used with monitoring to reduce medical errors and improve patient treatment.
3. T e laboratory should perform biomarker testing with a maximum turnaround time (TAT) of 1 hour, optimally 30 minutes. T e TAT is defined as the time from blood collection to reporting of results to the provider. Institutions that cannot consistently provide a 1 hour TAT should implement POCT assays. Performance specifications and characteristics for central laboratory and POCT assays should not differ. POCT assays should provide quantitative results.

Specimen Requirements

For both laboratory and POCT, and for practical considerations, anticoagulated whole blood or plasma appears to be the optimal specimen for rapid processing and testing. T is eliminates the extra time needed for clotting and additional sample handling. However, differences have been described between plasma, whole blood, and serum specimens for cTnI concentration measurement by an individual assay. Both ethylenediaminetetraacetic acid (EDTA) and heparin are known to interfere with cTnI and cTnT antibody-binding af nity, as well as produce matrix effects. In addition, it is recommended that different sample types should not be used during an individual's workup when serial, timed samples are being drawn to rule in or out a myocardial infarction. It should be noted that at present, results obtained from POCT assays are substantially less sensitive than laboratory-based assays and that should be acknowledged by both laboratorians and clinicians when such assays are used. T e higher limits of quantification mean that small increases of cTn at early time points after AMI will not be detected with these assays. T is fact works against the goal of early detection of AMI.

Standardization/Harmonization

Standardization of cTn assays remains elusive. T e cTnI Standardization Subcommittee of the American Association for Clinical Chemistry (AACC) in collaboration with the National Institute of Standards and Technology (NIST) have produced a cTnI standard reference material (SRM #2921) that is a TnC-cTnI-cTnT complex purified from human heart under nondenaturing conditions. Since this material was found to be commutable with only 50% of current cTnI assays, it is of limited value for assay harmonization of current assays and is not useful as a common calibrator. It does, however, allow for traceability to a common reference material. Currently an International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) Working Group is working toward developing a secondary serum-based reference material.

In 2001, the IFCC Committee on Standardization of Markers of Cardiac Damage (C-SMCD) updated quality specifications for cTn assays that were intended for use by the manufacturers of commercial assays and by clinical laboratories utilizing cTn assays.[20] T e overall goal was to attempt to establish uniform criteria so that all assays could be

BOX 34-3 Quality Specifications—Cardiac Troponin Assays

Analytical Factors

1. Antibody specificity—recognize epitopes as part of molecule and equimolar for all forms
2. Influence of anticoagulants
3. Calibration against natural form of molecule
4. Defined type of material useful for dilutions
5. Demonstrated recovery and linearity of method
6. Described detection limit and imprecision (10% CV)
7. Addressing interferants (e.g., RF, heterophile antibodies)

Preanalytical Factors

1. Storage time and temperature conditions
2. Centrifugation effects—gel separators
3. Serum-plasma—WB correlations

CV, Coefficient of variation; RF, rheumatoid factor; WB, whole blood.

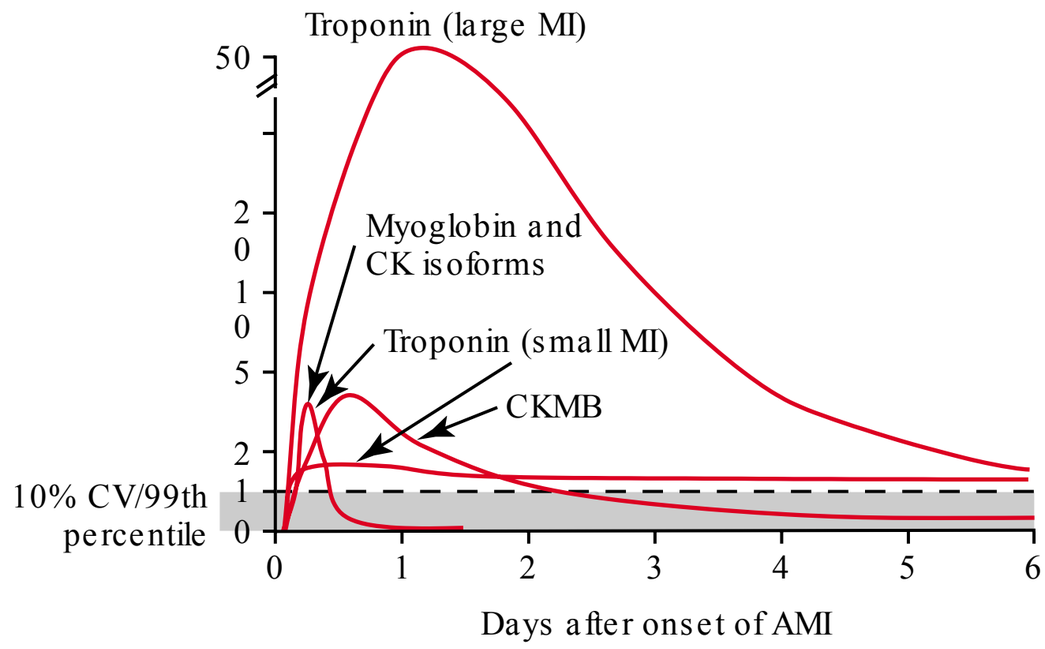

Figure 34-5 Kinetics of myoglobin, troponin, and CK-MB. With contemporary assays, cardiac troponin (cTn) rises more rapidly than do other markers. With small myocardial infarctions, two types of time courses are possible, as indicated by the two sets of arrows.

evaluated objectively for their analytical qualities and clinical performance. A description of the (1) analytical principles, (2) method design, and (3) assay components developed by this group is found in Box 34-3.

Reference Intervals

There are many ways to obtain reference intervals for biomarkers of AMI, including those described in Chapter 5 and those published in the literature and in manufacturer's package inserts. However, different methods for the same analyte may yield different values, depending on calibration and other technical considerations.[20] Consequently, different reference intervals and results are often obtained in different laboratories. Variability among methods is particularly characteristic of methods that use antibodies to detect the analyte of interest. Values from apparently "healthy" and diseased people may overlap significantly. Therefore reference intervals, although useful as a guide for clinicians, should not be used as absolute indicators of health and disease (see Chapter 5). The reference intervals presented in this chapter and in Chapter 50 are for general informational purposes only. Guidelines for defining and determining reference intervals have been discussed in Chapter 5 and published in the 2010 Clinical Laboratory Standards Institute (CLSI) EP28-A3C guideline (Defining, Establishing, and Verifying Reference Intervals in the Clinical Laboratory; Approved Guideline—Third Edition, which is available at http://www.clsi.org/ (accessed September 9, 2013). As stated in several chapters in this textbook, each individual laboratory should generate its own set of reference intervals.

Guidelines

In addition to the "how to" guidelines mentioned earlier, guidelines have also been generated to define AMI. For example, consensus guidelines have been developed by the (1) Global Task Force for the Third Universal Definition of Myocardial Infarction,[24,25] (2) NACB/IFCC,[4,19] (3) ESC/ACC,[8] (4) American Heart Association (AHA)/ACC[23] and (5) Acute Decompensated Heart Failure National Registry (ADHERE) Scientific Advisory Committee.[13] Additional guidelines have been published in 2012[12] and 2013.[10]

To quote the NACB/IFCC recommendations "The 99th percentile of a reference decision-limit (medical decision cut-off) for cTn assays should be determined in each local laboratory by internal studies using the specific assay that is used in clinical practice or validating a reference interval that is based on findings in the literature".[7] Desirable imprecision (expressed as % coefficient of variation [CV]) of each cTn assay (and CK-MB mass assay) has been defined as less than 10% CV at the 99th percentile reference limit. Unfortunately, some laboratories do not have (1) the resources to perform adequately powered 99th percentile reference studies, nor (2) the ability to carry out CLSI protocols to establish total imprecision criteria. Therefore, these clinical laboratories must rely on the peer-reviewed published literature to assist in establishing both local reference limits and imprecision characteristics. Caution must be taken when comparing the findings reported in the manufacturers' package inserts, which have been cleared by the FDA with the findings reported in journals because of differences in (1) total sample size, (2) distributions by sex and ethnicity, (3) age ranges, and (4) statistical methods used to calculate the 99th percentile.

Clinical Utility

As discussed earlier, cardiac biomarkers have been used since the 1950s in the diagnosis of AMI. Because of their high clinical sensitivity and specificity, the assays for the measurement of troponins have become the cornerstone of the diagnosis of myocardial infarction (Figure 34-5 and Figure 34-6). Therefore, in practice, an increased value of cardiac cTn is required in the appropriate clinical setting with values that manifest a rising pattern for the diagnosis of AMI. It should be noted, however, that other conditions (Box 34-4) also cause the death of cardiomyocytes and lead to increases of cTn in the blood, thus indicating myocyte damage.

Guidelines have been developed for their use in a clinical setting. Individuals with spontaneous AMI typically

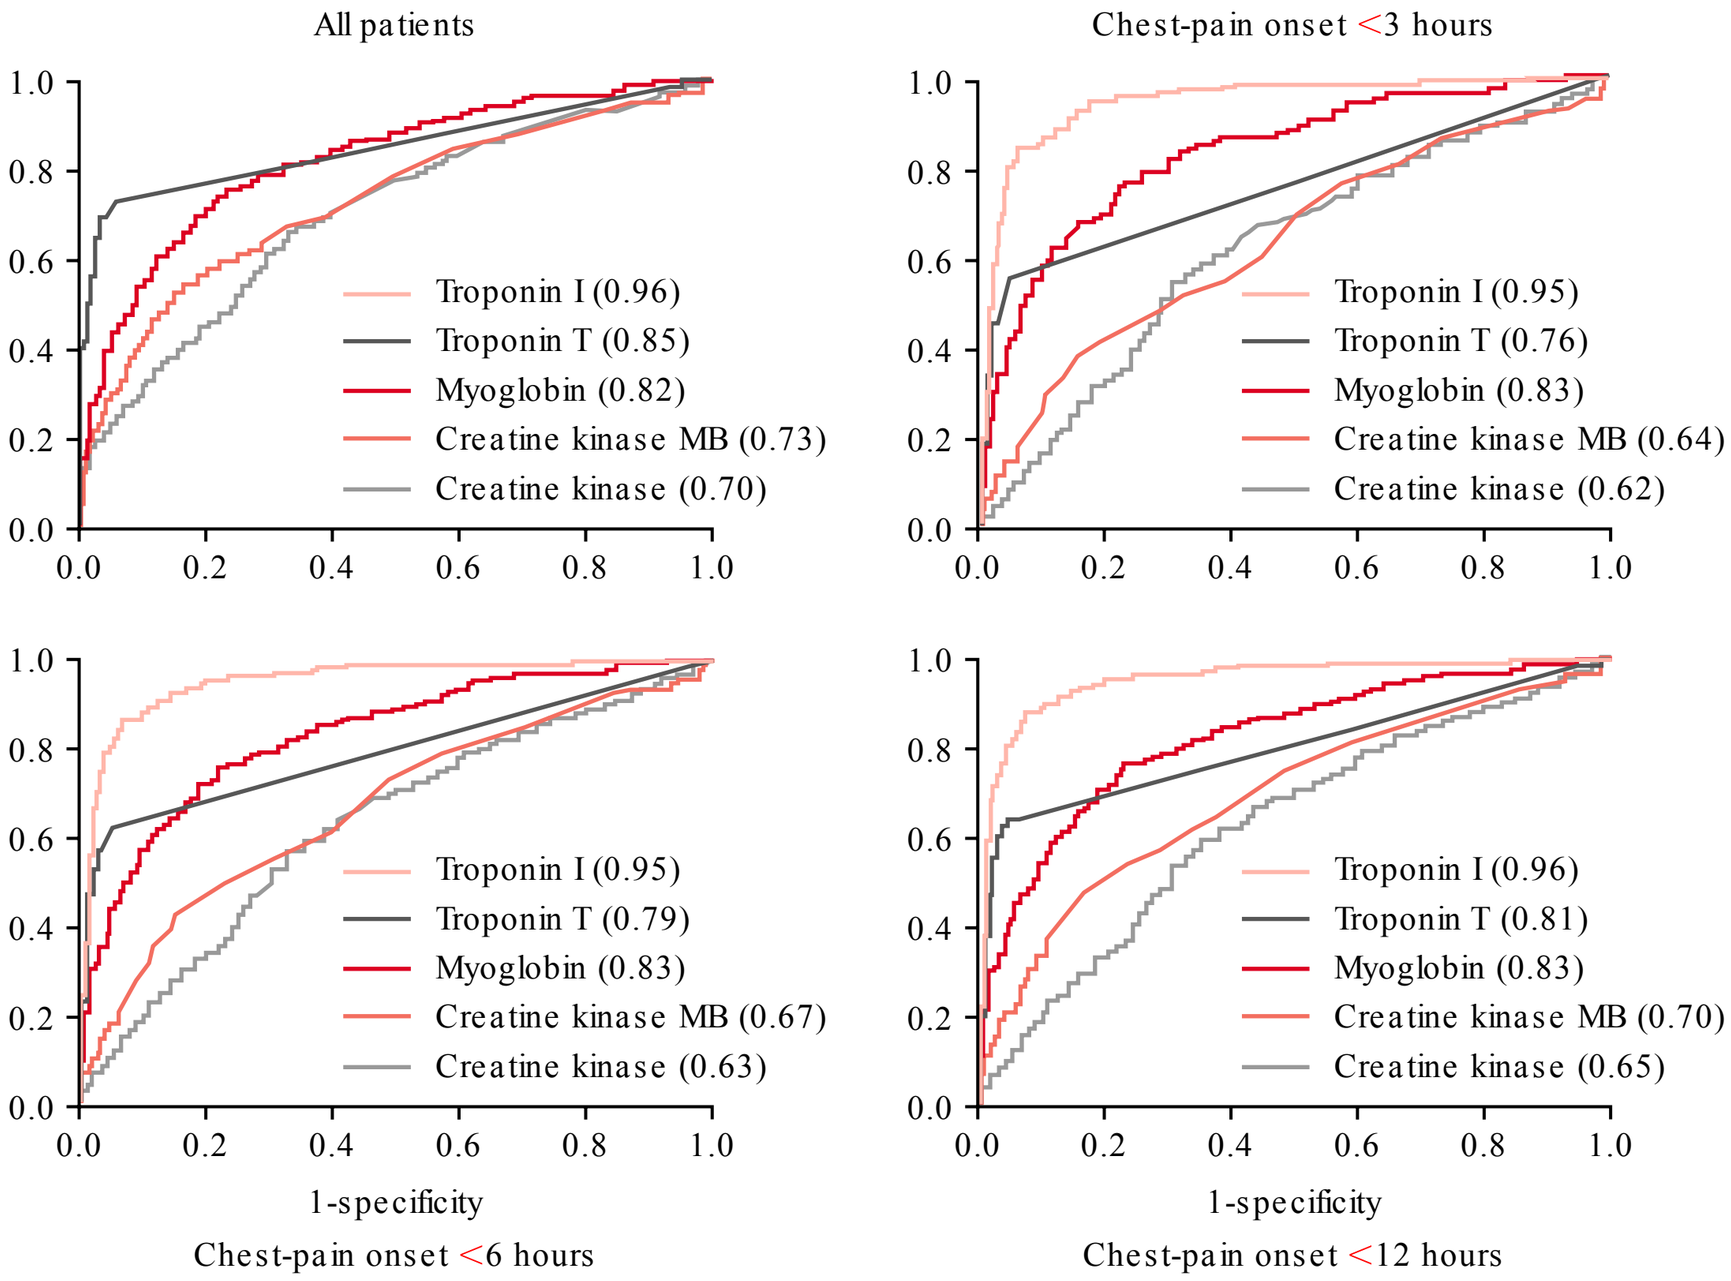

Figure 34-6 Receiver operating characteristic (ROC) curve analysis of troponin, myoglobin, and CK-MB by time from onset of symptoms to presentation.

BOX 34-4 Conditions That Increase Blood Concentrations of Troponins without Overt Ischemic Heart Disease

Trauma (including contusion, ablation, pacing, and cardioversion)
CHF—acute and chronic*
Aortic valve disease and HOCM with significant LVH*
Hypertension
Hypotension, often with **arrhythmias**
Postoperative noncardiac surgery patients who seem to do well*
Renal failure*
Critically ill patients, especially with diabetes; respiratory failure*
Drug toxicity (e.g., Adriamycin, 5-FU, Herceptin, snake venoms)*
Hypothyroidism
Coronary vasospasm, including apical ballooning syndrome
Inflammatory diseases (e.g., myocarditis, with parvovirus B19, Kawasaki disease, sarcoidosis, smallpox vaccination, or myocardial extension of PE)
Post-PCI patients who appear to be uncomplicated*
Pulmonary embolism, severe pulmonary hypertension*
Sepsis*
Burns, especially if TBSA >30%*
Infiltrative diseases, including amyloidosis, hemochromatosis, sarcoidosis, and scleroderma*
Acute neurologic disease, including CVA, subarachnoid hemorrhage*
Rhabdomyolysis with cardiac injury
Transplant vasculopathy
Vital exhaustion

*Troponin concentrations have been reported to carry prognostic information in these conditions.

have either STEMI or NSTEMI as indicated by their ECG pattern. For patients with STEMI, immediate treatment aimed at opening the occluded artery is mandatory and is initiated based on the ECG pattern alone. (Note: T is is even before the cTn values become available to assist with diagnosis.) Primary PCI and/or prescription of thrombolytic agents currently are the treatments of choice for opening the artery. Primary PCI is preferred whenever the two treatments are available in similar timeframes. With prompt coronary recanalization, the amount of myocardium that is lost is minimized, and mortality is reduced. (Note: Coronary recanalization increases the rapidity of cTn release; thus the rate of rise of the time-concentration curve is increased, and the time to peak values is shortened.)

An NSTEMI is typically not associated with total coronary occlusion and is identified by ECG changes. Such changes show ST segment depression or T wave changes. Given the sensitivity of cTn for this diagnosis, the ECG is sometimes totally normal. Patients who have symptoms of chest pain due to CAD should have (1) risk factors, (2) an appropriate presentation, or (3) imaging evidence of this syndrome. Patients with an increased concentration of cTn are known to have more severe coronary heart disease than individuals without increased cTns. T us, they also have more procoagulant activity and multiple intervention studies have shown that these patients benefit from aggressive anticoagulation. T is therapy includes (1) treatment with heparin, (2) administration of glycoprotein IIb/IIIa antiplatelet agents, and (3) an early invasive strategy consisting of PCI or coronary artery bypass grafting

(CABG). Use of these strategies in patients without increased cTn values has been shown to be of no benefit and, in some trials, has actually proved detrimental.[3]

Brain Natriuretic Peptide

In 1981, the Canadian physiologist Adolfo de Bold and his colleagues reported that infusion of atrial tissue extracts produced (1) an increase in the renal excretion of sodium and water, (2) a rapid decrease in BP, and (3) an increase in blood hematocrit. The responsible substance was named the atrial natriuretic *f*actor. This factor was subsequently purified and identified as a peptide comprising 28–amino acid residues and renamed atrial natriuretic peptide (ANP). Later, brain natriuretic peptide (BNP) and C-type natriuretic peptide (CNP), two structurally related peptides, were isolated and identified in the porcine brain. However, as BNP is mainly expressed in the heart, it was later renamed B-type natriuretic peptide (Figure 34-7).

Biochemistry[14]

B-type natriuretic peptide (BNP) is a hormone that is mainly released from the myocardial ventricles.[22] Figure 34-8 illustrates the synthesis of the preprohormone and subsequent secretion of BNP from the cardiac myocytes. It is not known whether proBNP is split in the myocyte or later in the plasma. It is known, however, that there are circulating proteases that are capable of cleaving the N-terminal and the active BNP moiety. The major circulating forms are the N-terminal portion (or fragment) of proBNP (NT-proBNP), which has unknown function; proBNP, function unknown; and BNP (the physiologically active hormone, which is the C-terminal part of pro-BNP). BNP is cleared via degradation by (neutral) endopeptidases, by receptor-mediated clearance, and perhaps via the kidneys, which also secretes BNP. The NT-proBNP fragment is not cleared via receptor-mediated mechanisms, but is thought

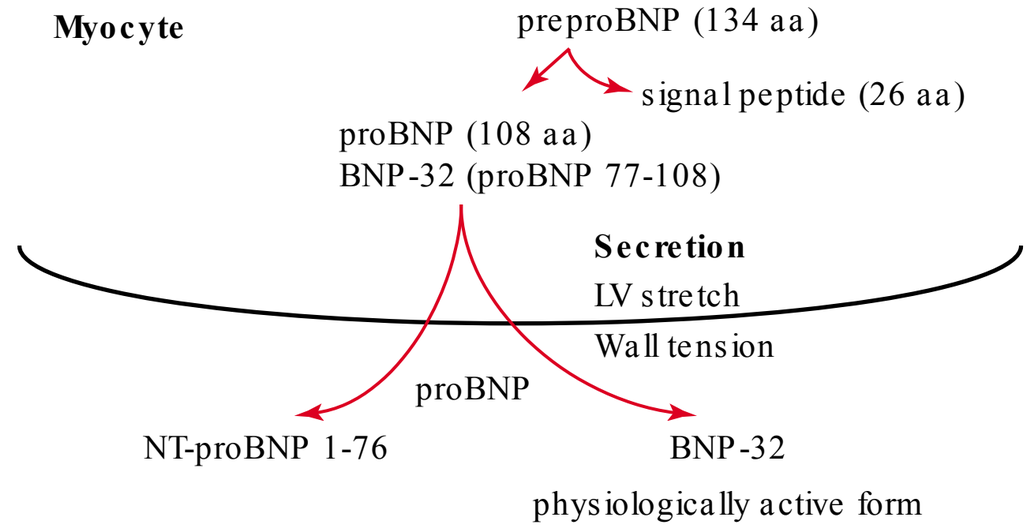

Figure 34-8 The biotransformation and release of BNP and NT-proBNP from the myocyte into the circulation (aa, amino acid).

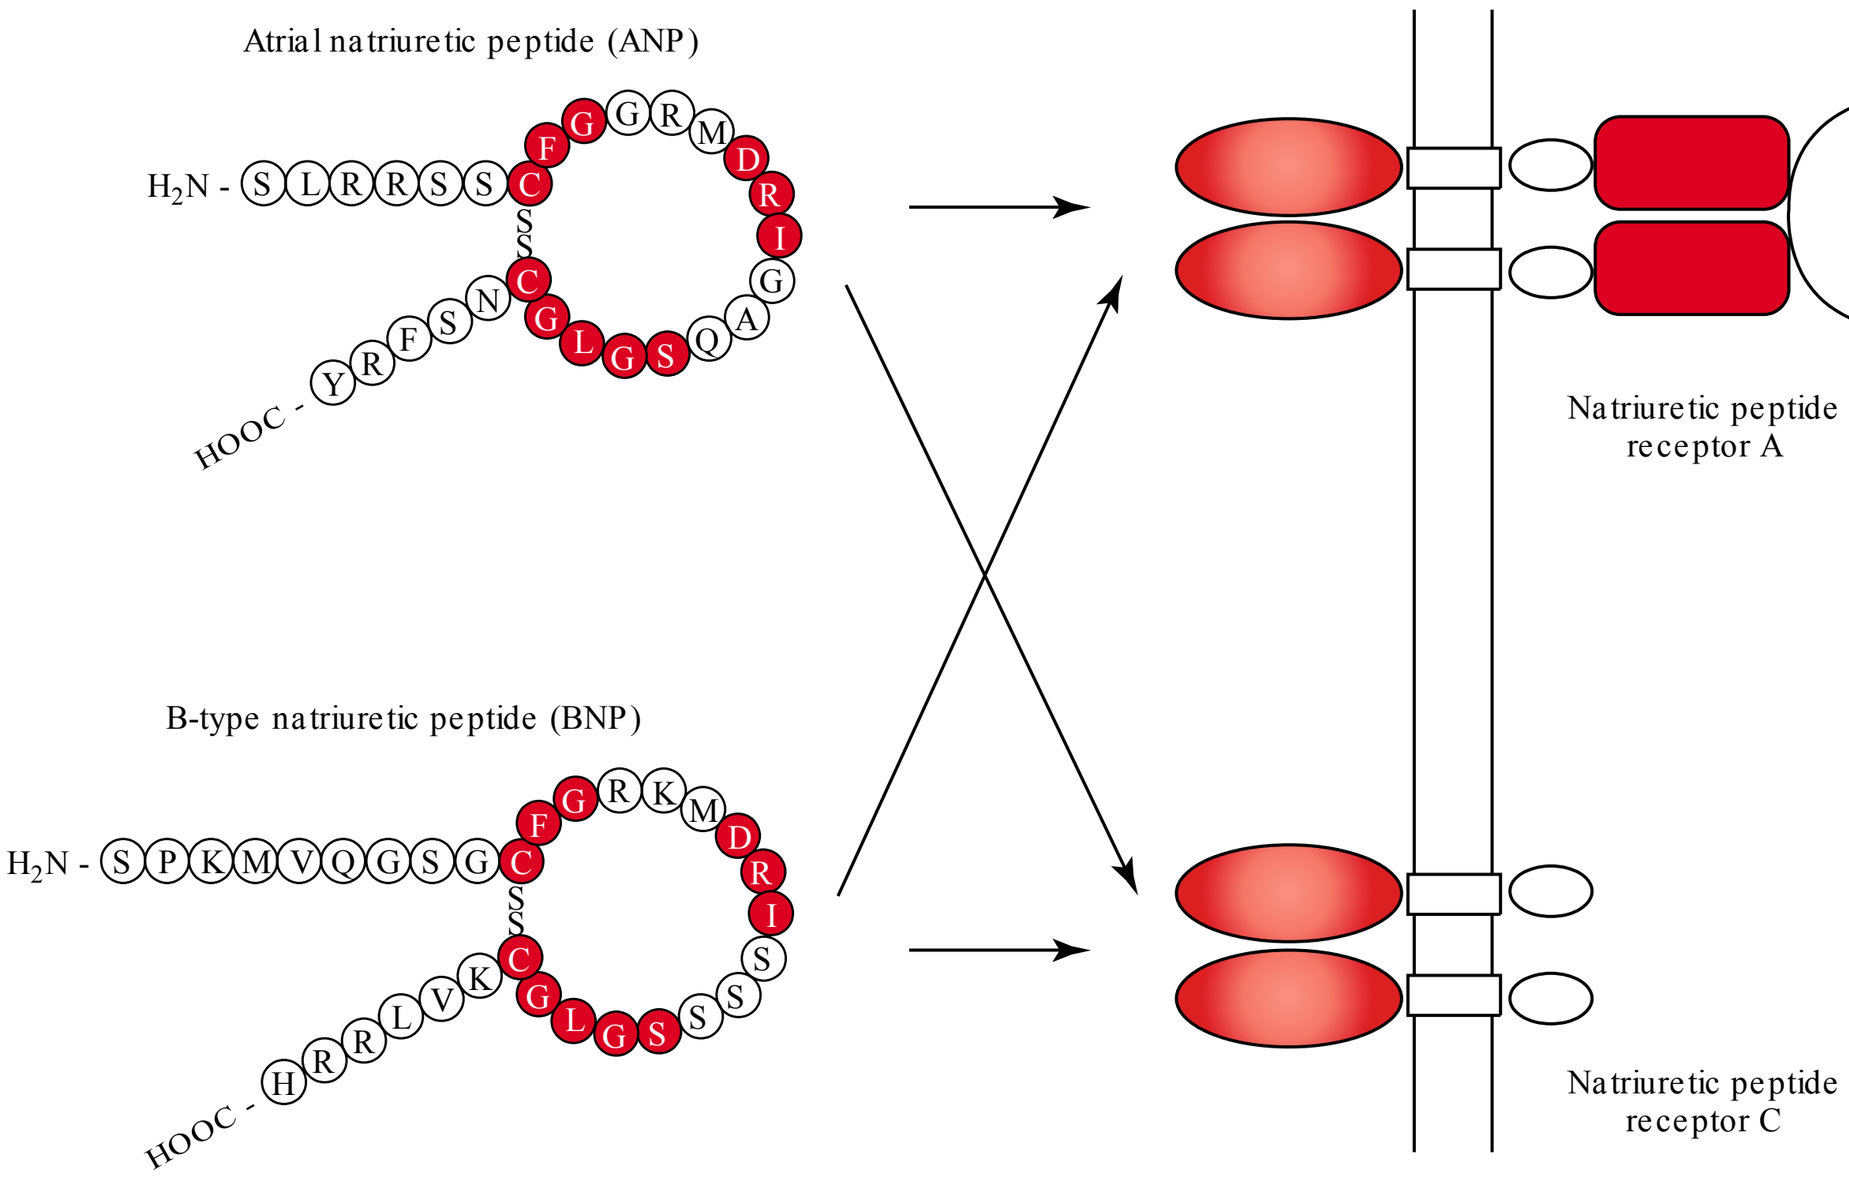

Figure 34-7 Schematic presentation of human atrial and B-type natriuretic peptides (BNPs) with their principal receptors. Homolog amino acid residues between the natriuretic peptides (NPs) are marked in bold circles. The natriuretic peptide receptor (NPR)-A mediates atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) signal transduction through induction of cyclic guanosine monophosphate (cGMP); NPR-C lacks the intracellular domain and has been classed primarily as a clearance receptor.

to be cleared predominantly by the kidneys. Therefore, it is more sensitive to changes in renal function. The majority of research on NPs in CHF has focused on BNP and NT-proBNP. However, investigations have now described substantial amounts of circulating proBNP, which cross-reacts in BNP and NT-proBNP assays.

Analytical Considerations

Generally, the concentrations of BNP and NT-proBNP are measured by immunoassay. A number of immunoassays are available that use antibodies directed to different epitopes located on the antigen molecules.[4] Degradation of BNP is known to occur by cleavage at serine and proline residues in vivo and in vitro (Figure 34-9); cleavage is mediated by proteases, which make the concentration of BNP unstable in collected blood.[7] For monitoring of patients by measurements of NT-proBNP (amino acids 1-76), an improved understanding of potential cross-reactivity with split products of the N-terminal portion of NT-proBNP and proBNP itself is needed.[17] For both assays—BNP and NT-proBNP—minimizing interference from heterophilic antibodies and rheumatoid factor, for example, needs to be optimized. For BNP, EDTA-anticoagulated whole blood or plasma appears to be the only acceptable specimen choice. For NT-proBNP, serum, heparin plasma, and EDTA plasma appear acceptable, although results are 10% lower with the latter. Plastic blood collection tubes are necessary for BNP; for NT-proBNP, either glass or plastic is acceptable.

Guidelines

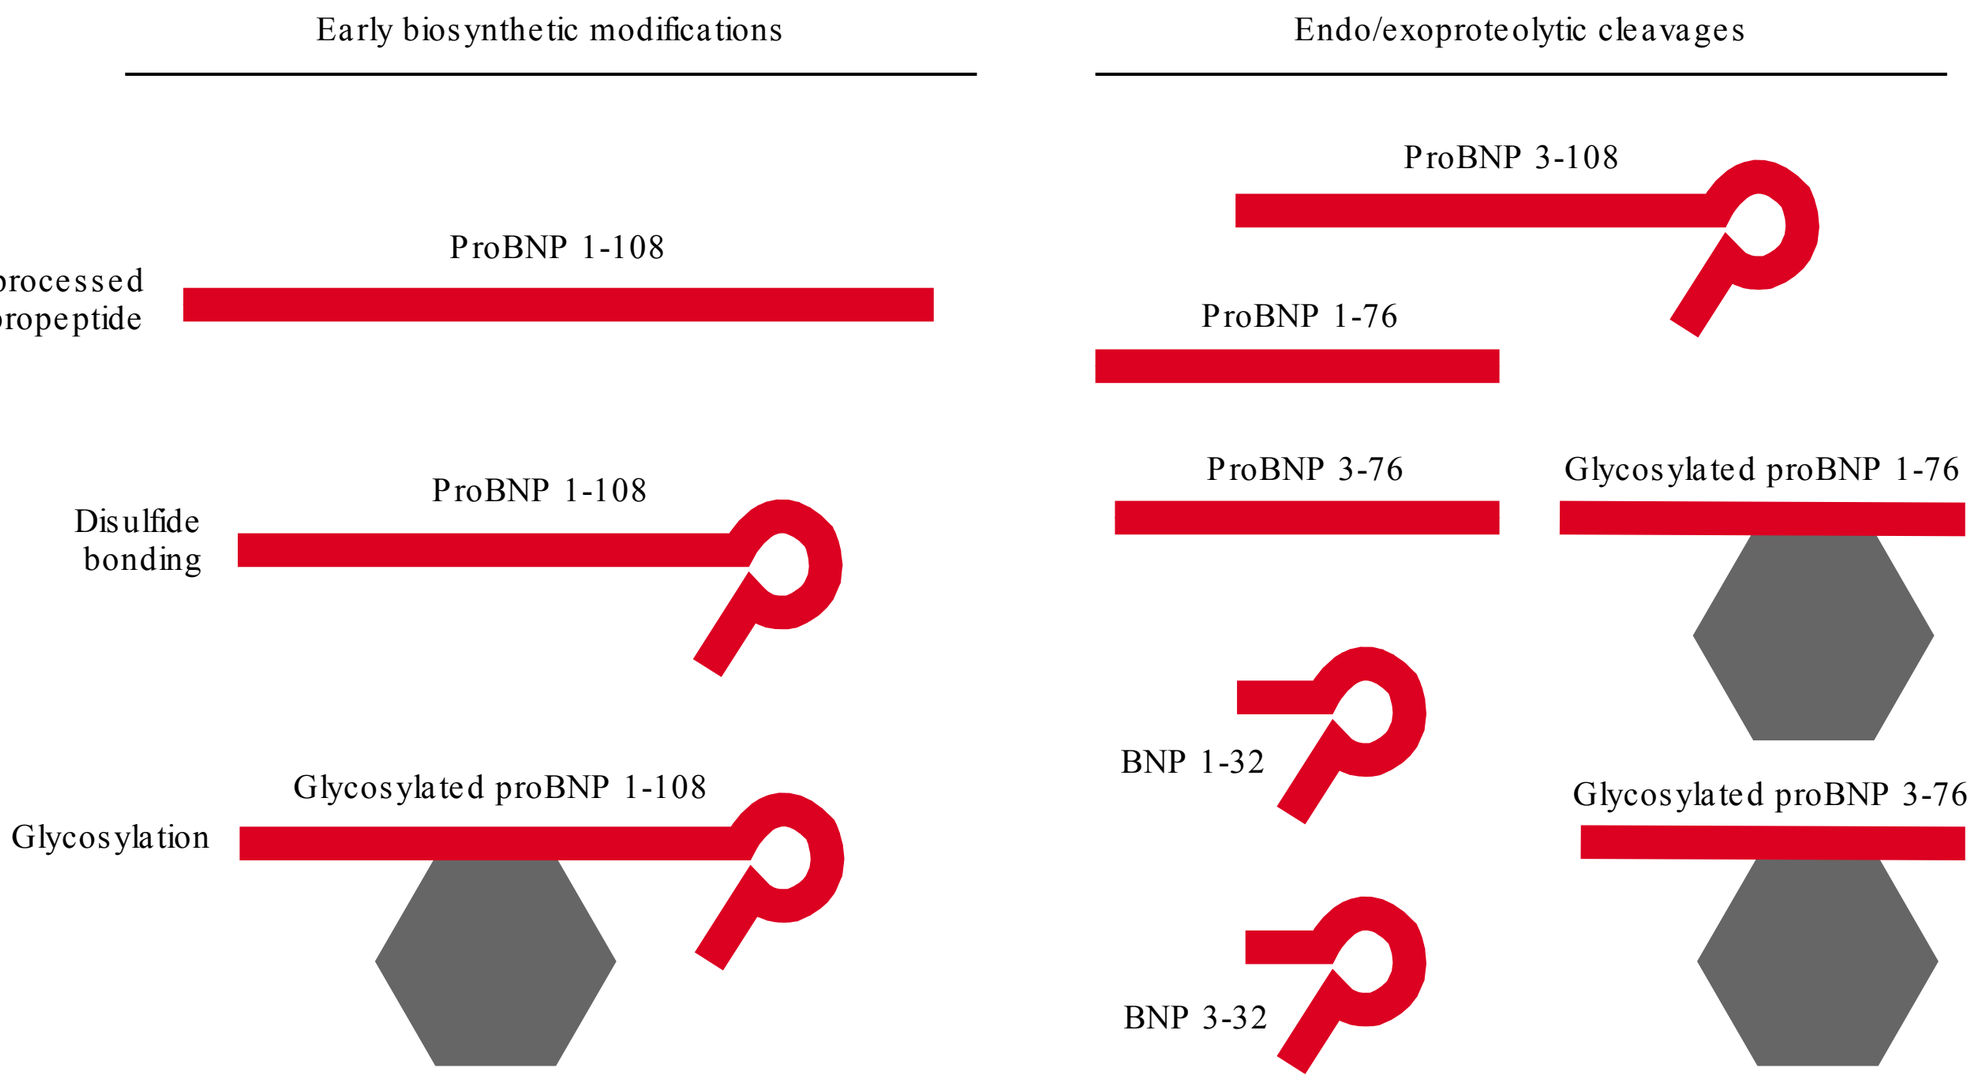
In 2005, the IFCC C-SMCD established recommended analytical and preanalytical quality specifications for NP assays.[6] These specifications were intended for use by the manufacturers of commercial assays and by clinical laboratories utilizing NP assays. The overall goal of this committee was to establish uniform analytical and clinical criteria for their measurement and clinical use. Subsequently, the NACB and the IFCC committee developed guidelines pertaining to analytical issues for biomarkers of heart failure.[4]

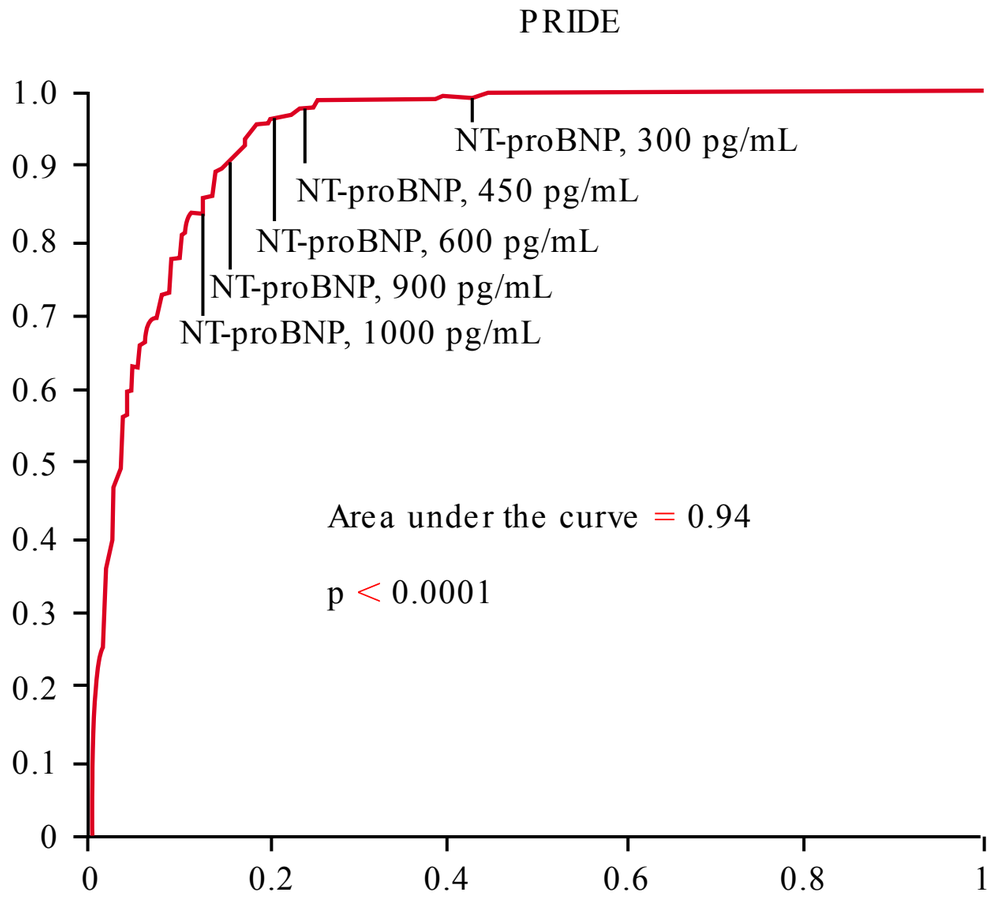
Recommendations from these guidelines include:

1. Reference limits (95th or 97.5th percentile) should be established independently for both BNP and NT-proBNP based on age (by decade) and by sex. Each commercial assay should be validated separately. The effects of ethnicity and renal function need to be evaluated as possible independent variables.
2. Receiver operating characteristic (ROC) curves (Figure 34-10) should be established to evaluate clinical effectiveness and to establish optimal medical decision cutoffs for BNP and NT-proBNP assays for diagnostic usefulness.
3. Assays for BNP and NT-proBNP should have total imprecision (%CV) ≤15% at their age- and sex-defined upper reference limits, as well as at the NYHA-defined medical decision concentrations.

Before introduction into clinical practice, BNP and NT-proBNP assays must be characterized with respect to the following preanalytical and analytical issues:

1. Preanalytical:
   a. Effects of storage time and temperature
   b. Influence of different anticoagulants
   c. Influence of gel separator tubes
   d. Need for plastic blood collection tubes for BNP; for NT-proBNP, either glass or plastic is acceptable





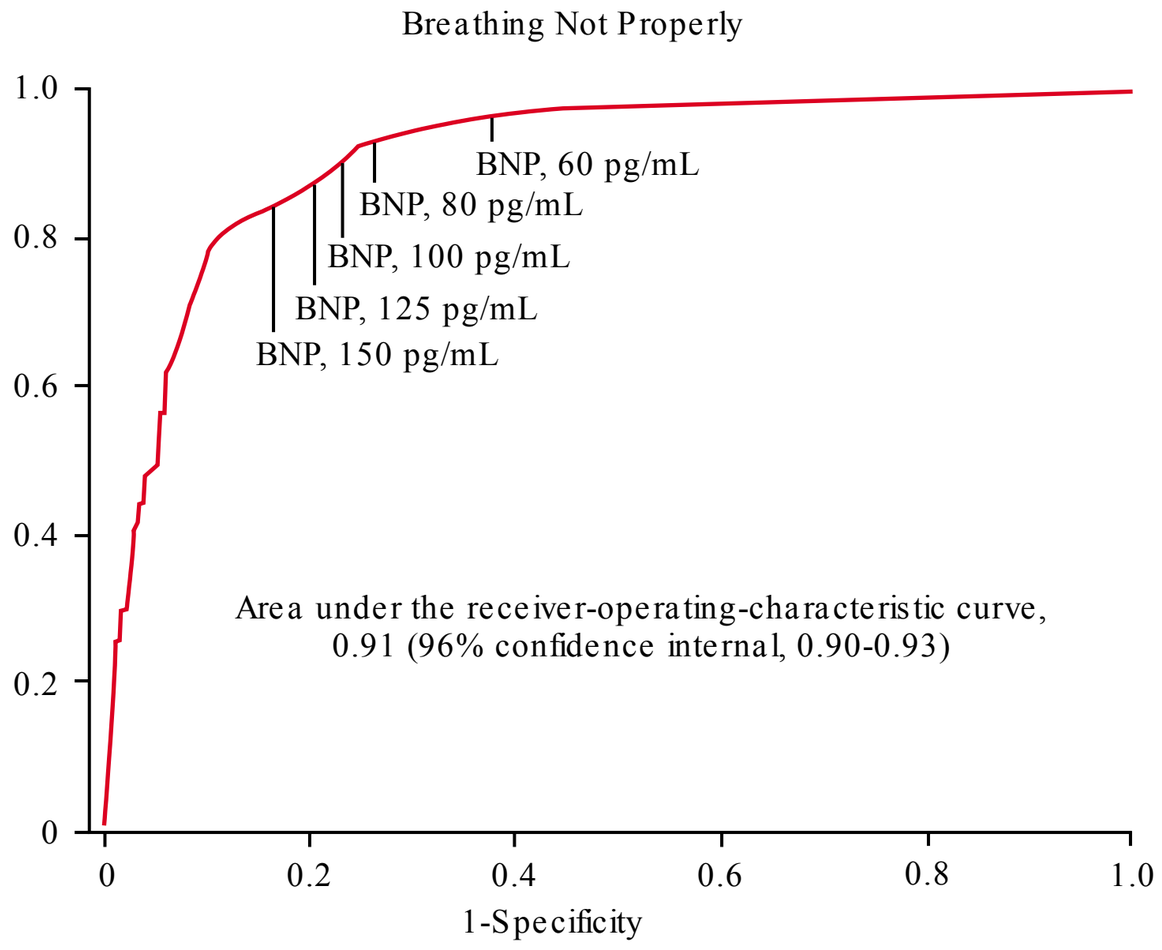


Figure 34-9 Schematic presentation of possible proBNP-derived peptide products. Note that most peptides are not chemically identified but rather are suggested by biochemical methods that rely on antibody recognition. Carbohydrate is indicated by the shaded hexagons.

Cut point	Sensitivity	Specificity	Positive predictive value	Negative predictive value	Accuracy
300 pg/mL	99%	68%	62%	99%	79%
450 pg/mL	98%	76%	68%	99%	83%
600 pg/mL	96%	81%	73%	97%	86%
900 pg/mL	90%	85%	76%	94%	87%
1000 pg/mL	87%	86%	78%	91%	87%

BNP pg//mL	Sensitivity	Specificity	Positive predictive value	Negative predictive value	Accuracy
50	97 (98-98)	62 (60-66)	71 (68-74)	96 (94-97)	79
80	98 (91-96)	74 (70-77)	77 (76-80)	92 (89-94)	83
100	90 (88-92)	76 (73-78)	79 (78-81)	92 (87-91)	83
125	87 (86-90)	79 (78-82)	80 (78-83)	87 (84-89)	83
150	86 (82-88)	83 (80-86)	83 (80-86)	85 (83-88)	84

Figure 34-10 Receiver operating characteristic (ROC) analysis for brain natriuretic peptide (BNP) and N-terminal pro B-type natriuretic peptide (NT-proBNP) for the diagnosis of acute heart failure.

2. Analytical:
   a. Identification of the epitopes in the NP that are recognized by the reagent antibodies
   b. Cross-reactivity characteristics with related NPs, including NT-proANP, ANP, CNP, BNP, and glycosylated and nonglycosylated NT-proBNP and proBNP
   c. Identification of interference from heterophile antibodies, rheumatoid factors, human antimouse antibodies
   d. Description of calibration material used, how the material was defined, and the concentration value assigned
   e. Clarification of dilution response
3. For both BNP and NT-proBNP, in the interim until a primary reference material is defined for either assay for appropriate calibration of assays, measurements should be reported in ng/L, not in pmol/L; and patient specimen comparisons and regression analysis should be performed, in accordance with CLSI guidelines, to establish the degree or lack of harmonization across the dynamic range of each assay. Specifically, harmonization around the current presumed optimal diagnostic medical decision cutoff of 100 ng/L for BNP should be validated.
4. For both BNP and NT-proBNP, biological variability has been determined to be at least 50%,. T erefore, caution should be exercised in interpreting concentration changes of less than 50% to 80% as reflective of medical therapy. However, consistent trends should be followed as clinically important.

Reference Intervals

As recommended (Chapters 5 and 50), each laboratory should determine a reference interval based on a reference group for with the specific assay used in clinical practice or validate the reference interval in the literature. In the case of BNP and NT-proBNP, there are several practical issues regarding the use of serum/plasma/whole blood monitoring of them. First, reference intervals vary depending on which assay is used and the nature of the reference population used. Second, a number of clinical factors affect the BNP and NT-proBNP concentrations, most importantly (1) age, (2) sex, (3) obesity, and (4) renal function. Significant differences are observed between men and women (higher), and concentrations increase with age, as shown in Figure 34-11 for NT-proBNP. For both BNP and NT-proBNP, there is an inverse relationship between concentrations and body mass index. For NT-proBNP, establishing reference intervals has been challenging. For example, review of both the FDA-approved U.S. package insert and the European assay package insert reveals substantial differences in the concentrations that are considered as reference intervals by age and sex.

For BNP, a single cutoff has been designated at 100 pg/mL. However, as shown in Figure 34-11, many subjects older than 75 years have concentrations above the 100 pg/mL cutoff. For NT-proBNP, the FDA-cleared cutoff concentrations are based on age. For example, for patients younger than 75 years the cutoff concentration is 125 pg/mL. For patients older than 75 years, the cutoff concentration is 450 pg/mL.

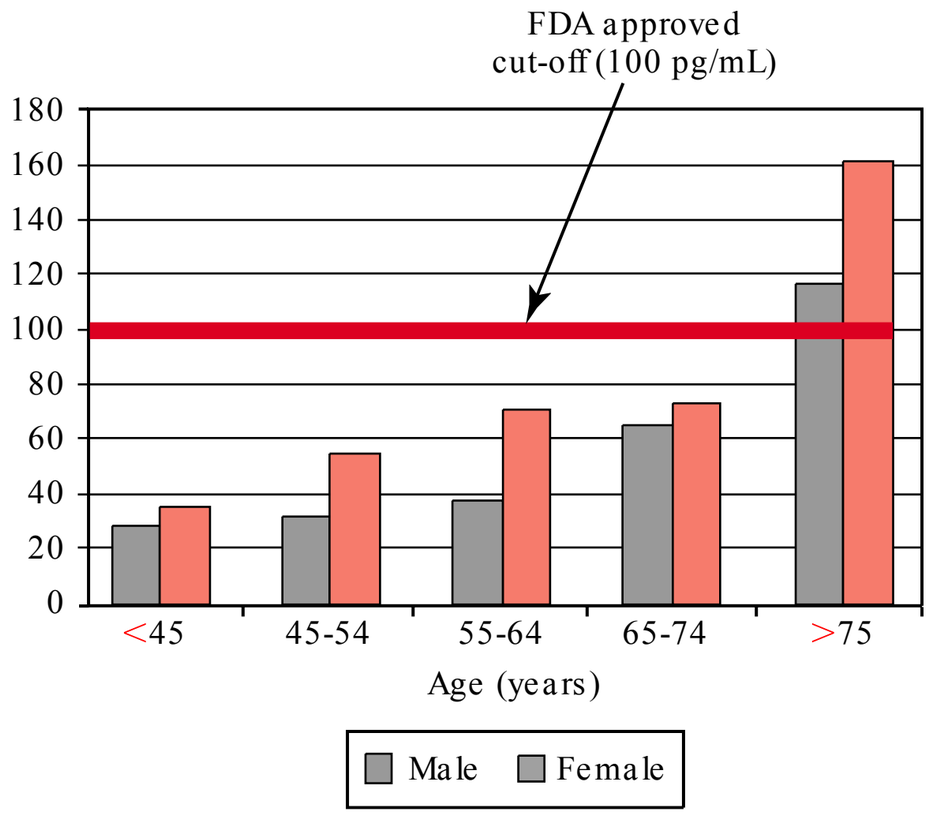

Figure 34-11 Representative brain natriuretic peptide (BNP) concentration distributions in normal males and females by decade (years) with indication of the U.S. Food and Drug Administration (FDA)-cleared 100 pg/mL cutoff value.

Clinical Utility[15]

BNP has a multiplicity of cardiac functions and is released as a counter-regulatory hormone in response to a variety of cardiac stresses but most particularly cardiac stretch. It is significantly affected by changes in volume and in cardiac performance, and among its effects are fluid-volume reduction and vasodilation. T us, this hormone is a sensitive biomarker for changes in ventricular physiology.[15] Circulating concentrations of BNP and NT-proBNP depend on age and sex (see Figure 34-11). In addition, they are increased in chronic heart failure and are correlated with its severity. Early studies have demonstrated that BNP secretion reflects regional wall stress in the ventricles and is thus associated with adverse ventricular remodeling and poor prognosis after AMI. It is now apparent that BNP measurements are useful (1) in identifying patients with moderate to severe CHF and (2) **risk stratif cation**[13] of CHF patients and of patients who present with ACS. T e data suggest that both BNP and NT-proBNP assays provide information that is synergistic with the measurement of troponin in these settings and is especially useful for risk stratification when cTn concentrations are within the reference intervals.

Creatine Kinase Isoenzymes and Isoforms

CK is an enzyme present in (1) heart muscle, (2) skeletal muscle, and (3) the brain (see Chapter 19 for details of its measurement). T ree cytosolic isoenzymes (CK-3, CK-2, CK-1) and one mitochondrial isoenzyme (CK-Mt) of CK (approximately 80,000 Da for all 4 isoenzymes) have been identified. T e cytosolic enzymes are dimers of two subunits called M and B. Distinct genes encode the M and B subunits, and a third encodes mitochondrial CK. CK-3 (CK-MM) is predominant in both heart and skeletal muscle, and CK-1 (CK-BB) is the dominant form in brain and smooth muscle. CK-2 (CK-MB) is sometimes called the cardiac isoenzyme

because 10% to 20% of the total CK activity in myocardium is from CK-MB, whereas in skeletal muscle this percentage ranges from less than 2% to 5%. Electrophoresis of CK isoenzymes, using extended electrophoresis times or electrophoresis at high voltages, reveals at least three CK-MM isoforms and at least 4 CK-MB isoforms (subtypes of the individual isoenzymes).

The proportion of CK-MB is much lower in the surrounding normal areas of tissue than in infarcted myocardium in humans. When studied more completely in humans, CK-MB concentrations ranged from 15% to 24% of total CK in myocardial tissue obtained from patients with either (1) left ventricular hypertrophy (LVH) caused by aortic stenosis, (2) CAD without LVH, or (3) CAD and LVH due to aortic stenosis. In contrast, patients with normal left ventricular tissue had a low percentage of CK-MB (less than 2%). Diseased cells also have less total CK per cell. Normal skeletal muscle, depending on its location, contains very little CK-MB. Percentages as high as 5% to 7% have been reported, but less than 2% is most common. Severe skeletal muscle injury following trauma or surgery is known to lead to elevations of CK-MB above the upper reference limit of CK-MB in serum. However, the percent CK-MB in serum is less than 5%. Increases in serum total CK and CK-MB often present a diagnostic challenge to the clinician as they are also increased in other conditions. For example, elevations of serum CK-MB resulting from chronic muscle disease occur in (1) muscular dystrophy, (2) end-stage renal disease, (3) polymyositis, and (4) healthy subjects who undergo extreme exercise or physical activities (for example, the increase in serum CK-MB in runners). In all these pathologies, cTn has been shown to be normal when the myocardium is not injured.

C-Reactive Protein

C-reactive protein (CRP) is an acute-phase reactant that was initially developed to evaluate patients with infection. It now appears that concentrations below those seen in infection but above healthy values (as measured by so-called high-sensitivity CRP, or hsCRP, assays) are biomarkers of the atherosclerotic process (see Chapter 23 for further information on the use of hsCRP for this purpose).[16]

Myoglobin

Myoglobin is an oxygen-binding protein of cardiac and skeletal muscle with a molecular mass of 17,800 Da. Measurement of serum myoglobin was advocated because it appeared to increase sooner than CK-2 after AMI. Increases in serum myoglobin occur after trauma to either skeletal or cardiac muscle, as in crush injuries or AMI. Increases of the serum concentrations of myoglobin are cleared rapidly, leading to false-negative results after a few hours. Even minor injury to skeletal muscle may result in increased serum concentrations of myoglobin, creating a potential for misinterpretation as myocardial injury (false-positive results for AMI). Myoglobin is cleared by the kidneys so that abnormalities in renal function can cause elevations.

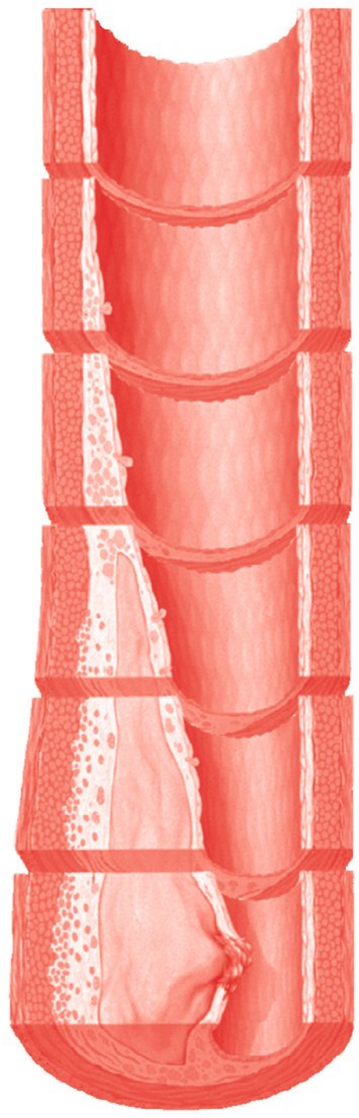

Figure 34-12 Spectrum of acute coronary pathophysiological process from initiation of atherosclerosis to cell death with potential biomarkers listed for each. (From personal communication, Robert Jesse, MD.)

Other Potential Biomarkers

Figure 34-12 portrays a biochemical profile in coronary vascular disease that correlates staging of biomarker release into the circulation with various pathophysiologic mechanisms of ACS and heart failure. As shown in Tables 34-2 and 34-3, numerous biomarkers have been studied and used for different clinical reasons, and other promising novel biomarkers are trying to establish themselves alongside cTn and NPs as routine clinical tools.[9] In this section, selected characteristics of several of these are briefly discussed (in alphabetical order). It should also be noted that, in general, these potential biomarkers do not have (1) standardized assays, (2) reference interval studies, and (3) consistent assay validations.

Adhesion Molecules

Adhesion molecules are a wide variety of molecules that can potentially be measured as a way of assessing the adherence of leukocytes and/or platelets or other adhesive proteins to the endothelial matrix. Some are receptors. Examples include platelet-endothelial adhesion molecule 1 (PECAM-1), P-selectin, e-selectin, and vascular cell adhesion molecule 1 (VCAM-1).

sCD40 Ligand

sCD40 Ligand is a transmembrane protein related to tissue necrosis factor (TNF) alpha. It has multiple prothrombotic and proatherogenic effects. Assays are usually designed to measure the circulating soluble form of the receptor, which

has been shown to be a predictor of events after acute ACS presentations.

Choline

Choline is released after stimulation of phospholipase D and has been touted as a test of prognosis in patients with chest discomfort.

Copeptin

Copeptin is a 30-amino-acid glycoprotein that constitutes the C-terminal portion of arginine vasopressin. Measurement of copeptin serves as a rapid and early rule-out biomarker for AMI at presentation in patients with symptoms suggestive of ACS with a normal cTn value.

Cytokines

A variety of stimulatory and inhibitory interleukins (ILs) (TNF, IL-1, IL-6, IL-8, IL-12, and IL-18) are thought to help mediate the elaboration of CRP and the development of atherosclerosis and acute events. These cytokines may stimulate or inhibit leukocytes, often through T cell–mediated processes and effects on monocytes. In some studies, IL-6 has been found to be more prognostic than hsCRP.[3] These cytokines often have inhibitors and/or binding proteins that modulate their effects.

Galectin-3

Galectin-3 is protein that is a member of the lectin family that contains a carbohydrate-recognition-binding domain (CRD) of about 130 amino acids that enable the specific binding of β-galactosides. It has been shown to be involved in several biological processes including (1) cell adhesion, (2) cell activation, (2) chemoattraction, (3) cell growth and differentiation, (4) cell cycle, and (5) apoptosis. Clinically, galectin-3 has been found to be involved in (1) cancer, (2) inflammation, (3) fibrosis, (4) stroke, and (5) heart disease. It has also been shown that the expression of galectin-3 is implicated in a variety of processes associated with (1) heart failure, (2) myofibroblast proliferation, (3) fibrogenesis, (4) tissue repair, (5) inflammation, and (6) remodeling of ventricles.

Isoprostanes

Isoprostanes are the end breakdown products of lipid peroxidation; urinary levels have been used to assess the level of oxidative stress. It is thought that oxidation of low-density lipoprotein (LDL) is essential for the development of atherosclerosis, and that high-density lipoprotein (HDL) and other antioxidants work by antagonizing this oxidative stress. Urinary isoprostanes give some assessment of this critical process. The most commonly measured are F_2-isoprostanes, but a large number of others are available for measurement.

Lipoprotein-Associated Phospholipase A_2

Lipoprotein-associated phospholipase A_2 (Lp-PLA_2) is a phospholipase enzyme associated with LDL that is thought to be an inflammatory biomarker. It was previously known as platelet-activating *f*actor (PAF) acetyl hydrolase. It is synthesized by monocytes and lymphocytes and is thought to cleave oxidized lipids to produce lipid fragments that are more atherogenic and that increase endothelial adhesion.

Matrix Metalloproteinases

Matrix metalloproteinases (MMPs) degrade the collagen matrix in the coronary artery or myocardium. They are integral to remodeling of the coronary artery and/or the heart after acute events. Elaboration of MMP-9, a gelatinase, is thought to be important in plaque destabilization; thus some have tried to measure it as a prognostic index. Other MMPs participate in the elaboration of extracellular matrix in the heart. Many MMPs also have inhibitors (such as, tissue inhibitors of metalloproteinase [TIMPs]) that modulate their effects.

Monocyte Chemotactic Protein

Monocyte chemotactic protein (MCP-1) is a chemokine that is thought to be responsible for the recruitment of monocytes into atherosclerotic plaque. It has been reported to be elevated in patients with ACS and to have long-term predictive value.[3]

Myeloperoxidase

MPO is released when neutrophils aggregate. This release may indicate an active inflammatory response in blood vessels. It is elevated chronically when chronic CAD is present. Also, it is increased when patients present with ACS. A multi-biomarker study has shown that MPO as a prognostic tool was dependent on the outcomes studied (cardiac death) and the demographics of the patient population enrolled.

Nourin

Nourin I is a small protein released rapidly by "stressed myocytes." It induces changes in a variety of inflammatory cytokines and attracts neutrophils. Preliminary studies have been done to attempt to validate its use.

Oxidized Low-Density Lipoprotein

Oxidized LDL has been attributed a key role in the development of atherosclerosis (see Chapter 23). Several methods have been used to measure it, but they yield potentially different data. Some have correlated malondialdehyde LDL with the development of atherosclerosis and short-term events. Direct identification with antibodies suggests that oxidized LDL may be released from vessels and may colocalize with lipoprotein a (Lp[a]) after acute events.

Placental Growth Factor

Placental growth factor is an angiogenic factor related to vascular endothelial growth factor (VEGF), which stimulates smooth muscle cells and macrophages. It also increases TNF and MCP-1. A novel assay for this analyte is thought to provide additional prognostic information on patients who present with ACS.[3]

Pregnancy-Associated Plasma Protein A

Pregnancy-associated plasma protein A (PAPP-A) is a metalloproteinase that is thought to be expressed in plaques that may be prone to rupture. Although the literature in this regard is mixed concerning its use, data suggest that heparin administration in myocardial infarction patients is associated with increased PAPP-A concentrations.

Secreted Platelet Granular Substances

Both platelet factor 4 (PF4) and beta thromboglobulin (BTG) are secreted when platelets aggregate. PF4 has a short half-life and is released by heparin. BTG is not released by heparin and has a longer half-life. Both biomarkers have been used to assess platelet aggregation.

Serum Amyloid Protein A

Serum amyloid protein A is an acute-phase protein and an apolipoprotein. It has been used with hsCRP in cross-sectional studies. It thought to be synergistic with hsCRP but is much less commonly used than the assay for hsCRP.

ST2

ST2 is a receptor protein that is a member of the IL-1 receptor family and a marker of cardiac stress. It signals the presence and severity of adverse cardiac remodeling and tissue fibrosis, which occurs in response to (1) myocardial infarction, (2) ACS, or (3) heart failure. The ST2 protein has two isoforms and is directly implicated in the progression of cardiac disease: a soluble form (referred to as soluble ST2 or sST2) and a membrane-bound receptor form (referred to as the ST2 receptor or ST2L). The ligand for ST2 is the cytokine IL-33.

Tissue Plasminogen Activator Antigen and Plasminogen Activator Inhibitor 1

Tissue plasminogen activator (t-PA) is the body's physiologic fibrinolytic activator. Plasminogen activator inhibitor 1 (PAI-1) is the endogenous inhibitor of t-PA and binds to it. Inhibition of fibrinolysis has been suggested to cause recurrent infarction. As maximal inhibition usually occurs in the early morning hours, this may explain the circadian variability of AMI. It may also be the reason that persons with diabetes have such an unstable disease, because the growth factor properties of insulin stimulate increases in PAI-1.

Unbound Free Fatty Acid

Unbound free fatty acid (uFFA) has also been touted as a marker of ischemia. Most fatty acid in plasma is bound (to proteins), and ischemia is thought to increase the small unbound fraction.

Urinary Thromboxane

Urinary thromboxane is the end metabolite of thromboxane A2, which is a measure of platelet aggregation. Urinary concentrations are elevated in patients with unstable coronary disease.

Review Questions

1. The technique of choice for measuring cTns is a(n):
   a. Photometric assay
   b. Immunoassay
   c. Potentiometric assay
   d. Amperometric assay
2. What are the names of the contractile proteins that are located in the striated muscle fibers of the heart?
   a. Natriuretic peptides
   b. Modified albumins
   c. Troponins
   d. Actin and myosin
3. Which one of the following cardiac biomarkers is important in detecting moderate to severe CHF?
   a. B-type natriuretic peptide
   b. Troponin
   c. Nourin
   d. Myoglobin
4. An oxygen-binding protein of cardiac and skeletal muscle that is thought to increase sooner than the isoform CK-2 after an AMI is:
   a. Troponin
   b. Myoglobin
   c. B-type natriuretic peptide
   d. CK
5. A protein that is involved in a number of disease processes including cancer, inflammation, and heart disease and that is expressed in the process of cardiac ventricular remodeling is:
   a. Isoprostane
   b. Phospholipase A_2
   c. Galectin-3
   d. MPO
6. The most common cause of ACS is:
   a. Myocardial ischemia due to incomplete occlusion of a coronary artery
   b. Atherosclerosis in coronary arteries
   c. Reduced outflow of blood from left side of heart
   d. Decreased output of the right side of the heart due to cardiac valve destruction
7. Which one of the following is not a requirement for an ideal cardiac biomarker?
   a. Specificity
   b. Rapid release from heart into circulation
   c. Rapid removal from circulation
   d. Sensitivity
8. Which one of the following CK isoenzymes is referred to as the "cardiac isoenzyme" because it makes up at least 10% of total CK activity in the myocardium?
   a. CK-1
   b. CK-2
   c. CK-3
   d. Total CK
9. Loss of oxygen in the form of arterial blood supply to an area of cardiac tissue is referred to as:
   a. Ischemia
   b. Infarct

c. Necrosis
d. Atherosclerosis

10. The condition resulting from ineffective pumping of blood to the body's tissues is referred to as:
a. Coronary artery syndrome
b. AMI
c. Atable angina
d. CHF

CHAPTER

35

Kidney Disease*

Michael P. Delaney, B.Sc., M.D., F.R.C.P., Christopher P. Price, Ph.D., F.R.C.Path., and Edmund J. Lamb, Ph.D., F.R.C.Path.

Objectives

1. Define the following:
   - Bence-Jones protein
   - Clearance
   - Cystatin-C
   - Diabetes insipidus (DI)
   - Diabetic nephropathy
   - Dialysis
   - Diuretic
   - Glomerulus
   - Glomerular filtration rate (GFR)
   - Juxtaglomerular apparatus
   - Micturition
   - Nephrolithiasis
   - Nephron
   - Pyelonephritis
   - Renal pelvis
   - Renal replacement therapy (RRT)
   - Ureter
   - Urine
2. Describe the following components of the renal system, including structure, function, contribution to urine formation and clinical significance:
   - Bladder
   - Bowman capsule
   - Collecting tubules
   - Distal convoluted tubule
   - Glomerulus
   - Juxtaglomerular apparatus
   - Kidneys
   - Loop of Henle
   - Nephron
   - Proximal convoluted tubule
3. State the significance of kidney blood supply in the formation of urine within the structure of the glomerulus; list the arteries that form the glomerular capillary bed.
4. List and describe the three major functions of the kidneys, including processes involved, laboratory analytes affected in each process, and how each function is controlled.
5. Describe glomerular filtration rate (GFR) and clearance in terms of clinical usefulness and effects of renal disease and age on each process; list the markers used to assess clearance; state and calculate the formula used to determine GFR.
6. Describe the renal handling of electrolytes and water, including normal physiology, hormones involved, and effect of disease on each function.
7. List and describe the proteins found in urine including their characteristics, how they are affected in disease and laboratory methods of protein measurement.
8. Discuss the following conditions including the causes (such as, drugs and toxins), symptoms, acid-base disturbances (if any), laboratory methods used to assess, and pertinent laboratory results obtained:
   - Acute kidney injury (AKI)
   - Acute nephritic syndrome
   - Acute tubular necrosis (ATN)
   - Chronic kidney disease (CKD)
   - Diabetes insipidus (DI)
   - End-stage renal disease (ESRD) (including uremic syndrome)
   - Glomerular disease
   - Interstitial nephritis
   - Nephrotic syndrome
   - Pyelonephritis
   - Renal tubular acidoses (RTAs)
   - Uremic syndrome
   - Urinary tract obstruction
9. Describe two options for renal replacement therapy (RRT), including the clinical need for the therapy and laboratory assessment of each therapy.
10. Evaluate and analyze case studies related to renal disease and laboratory analysis of renal disease.

*We are grateful for data supplied by the US Renal Data System (USRDS). Interpretation and reporting of these data are the responsibility of the authors and in no way should be seen as an official policy or interpretation of the US government. We are also grateful for data supplied by the UK Renal Registry. Interpretation and reporting of these data are the responsibility of the authors and in no way should be seen as an official policy or interpretation of the UK Renal Registry.

Key Words and Definitions

Acidosis Accumulation of acid and hydrogen ions or depletion of the alkaline reserve (bicarbonate content) in the blood and body tissues.

Acute kidney injury (AKI) A rapid decline in kidney function that occurs over hours and days.

Acute nephritic syndrome The sudden onset of hematuria, proteinuria, diminished urine production, azotemia, hypertension, and edema.

Acute tubular necrosis (ATN) Acute renal failure with mild to severe damage or necrosis of tubule cells.

Antidiuretic hormone (ADH; vasopressin) An octapeptide hormone formed by the neuronal cells of the hypothalamic nuclei and stored in the posterior lobe of the pituitary gland (neurohypophysis). It has both antidiuretic and vasopressor actions.

Azotemia An excess of urea or other nitrogenous compounds in the blood.

Bartter syndrome Hypertrophy and hyperplasia of the juxtaglomerular cells, producing hypokalemic alkalosis and hyperaldosteronism.

Bence-Jones protein An abnormal plasma or urinary protein, consisting of monoclonal immunoglobulin light chains, excreted in some neoplastic diseases. It is a characteristic protein found in the urine of most patients with multiple myeloma.

Bowman capsule The double-walled globular kidney structure that forms the beginning of a renal tubule and surrounds the glomerulus.

Chronic kidney disease (CKD) Abnormalities of kidney structure or function, present for greater than 3 months, with implications for health.

Continuous ambulatory peritoneal dialysis (CAPD) A common method of peritoneal dialysis, involving the continuous presence of dialysis solution in the peritoneal cavity.

Dent disease Tubulopathy of the proximal renal tubules with low molecular weight proteinuria, hypercalciuria, hypokalemia, nephrocalcinosis, rickets, and progressive renal failure.

Diabetes insipidus (DI) A diabetic (defined as the excessive production of urine) disorder due either to insufficient synthesis of antidiuretic hormone (ADH) or defective ADH receptors or end-organ resistance to its action. This results in failure of tubular reabsorption of water in the kidney.

Diabetic nephropathy The nephropathy that commonly accompanies later stages of diabetes mellitus; it begins with hyperfiltration, renal hypertrophy, albuminuria, and hypertension.

Dialysis The removal of certain elements from the blood by virtue of the difference in the rates of their diffusion through a semipermeable membrane, for example, by means of a hemodialysis (HD) machine or filter.

End-stage renal disease (ESRD) A condition where renal function is inadequate to support life.

Erythropoietin A glycoprotein hormone secreted chiefy by the kidney in the adult; it increases production of red blood cells.

Fanconi syndrome A rare recessive disorder with a poor prognosis, characterized by pancytopenia, bone marrow hypoplasia, and patchy brown skin and multiple congenital anomalies of the musculoskeletal and genitourinary systems.

Gitelman syndrome A syndrome of hypertrophy of juxtaglomerular cells similar to Bartter syndrome but with hypocalciuria and hypomagnesemia.

Glomerular filtration rate (GFR) The rate in milliliters per minute at which small molecules are filtered through the kidney's glomeruli. It is a measure of the number of functioning nephrons.

Glomerulonephritis Nephritis accompanied by inflammation of the capillary loops of the glomeruli of the kidney. It occurs in acute, subacute, and chronic forms.

Glomerulus A tuft of blood vessels found in each nephron of the kidney that are involved in the filtration of the blood.

Hematuria Blood in the urine.

Hemodiafltration A type of hemofiltration with a dialytic component added. With it, blood flow is accelerated to twice that of conventional dialysis.

Hypertension A medical condition characterized by high arterial blood pressure.

IgA nephropathy A common, chronic form of glomerulonephritis marked by hematuria and proteinuria and by deposits of immunoglobulin A in the mesangial areas of the renal glomeruli.

Interstitial nephritis Primary or secondary disease of the renal interstitial tissue.

Juxtaglomerular apparatus (JGA) A complex in the kidney whose function is the autoregulation of the glomerular filtration rate.

Liddle syndrome A rare autosomal dominant syndrome resulting from epithelial sodium channel mutations that lead to abnormally increased channel function.

Lithotripsy The crushing of a calculus within the urinary system or gallbladder, followed at once by the washing out of the fragments; it is done either surgically or by several different noninvasive methods.

Loop of Henle The U-shaped part of the renal tubule, extending through the medulla from the end of the proximal convoluted tubule to the beginning of the distal convoluted tubule.

Metabolic acidosis Any of the various kinds of acidosis in which the acid-base status of the body shifts toward the acid side because of loss of base or retention of acids other than carbonic acid.

Nephritis Inflammation of the kidney with focal or diffuse proliferation or destructive processes that may involve the glomerulus, tubule, or interstitial renal tissue.

Nephrolithiasis A condition marked by the presence of renal calculi (stones).

Nephron The anatomical and functional unit of the kidney, consisting of the (1) renal corpuscle, (2) proximal convoluted tubule, (3) descending and ascending limbs of loop of Henle, (4) distal convoluted tubule, and (5) collecting tubule.

Nephrotic syndrome General name for a group of diseases involving defective kidney glomeruli, characterized by massive proteinuria and lipiduria with varying degrees of edema, hypoalbuminemia, and hyperlipidemia.

Obstructive uropathy Uropathy resulting from an obstruction in the tract.

Oliguria Diminished urine production and excretion.

Key Words and Definitions—cont'd

Peritoneal dialysis (PD) Diffusion of solutes and convection of fluid through the peritoneal membrane. The dialyzing solution is introduced into and removed from the peritoneal cavity as either a continuous or an intermittent procedure.

Polycystic kidney disease The most common renal cystic condition, with deterioration of renal function.

Polyuria The passage of a large volume of urine in a given period

Proteinuria Excessive serum proteins in the urine, such as in renal disease, after strenuous exercise, and with dehydration.

Pseudohypoaldosteronism type 1 A hereditary disorder of infancy characterized by severe salt wasting, failure to thrive, and other signs of aldosterone deficiency.

Pyelonephritis An inflammation of the kidney and its pelvis as a result of infection.

Rapidly progressive glomerulonephritis (RPGN) Acute glomerulonephritis marked by a rapid progression to end-stage renal disease.

Renal clearance The volume of plasma from which a given substance is completely cleared by the kidneys per unit of time.

Renal replacement therapy (RRT) Any treatment that replaces kidney function, including dialysis and transplantation.

Renal tubular acidosis (RTA) A variety of metabolic acidosis resulting from impairment of renal function.

Renin An enzyme of the hydrolase class that catalyzes cleavage of the leucine-leucine bond in angiotensinogen to generate angiotensin I

Toxic nephropathy Kidney damage caused by the effects of a nephrotoxin.

Uremia An excess in the blood of urea, creatinine, and other nitrogenous end products of protein and amino acid metabolism; also referred to as azotemia.

Uremic syndrome The spectrum of symptoms accompanying uremia.

X-linked hypophosphatemia A form of familial hypophosphatemic rickets, with X-linked dominant inheritance.

The kidneys play a central role in the homeostatic mechanisms of the human body. Reduced renal function strongly correlates with increasing morbidity and mortality. The basic anatomy and physiology of the kidneys are described as a foundation to understanding the pathophysiology of disease and the rationale for diagnostic and management strategies in kidney disease. The key analytical methods employed during the investigation of kidney disease are discussed in Chapter 21.

Anatomy

The kidneys are a paired organ system located in the lumbar region. Their function is to (1) filter the blood and excrete the end-products of body metabolism in the form of urine; (2) regulate the concentrations of (a) hydrogen, (b) sodium, (c) potassium, (d) phosphate, and (e) other ions in the extracellular fluid; and (3) produce hormones in an adult, each kidney is about 12 cm long and weighs about 150 g in men and 135 g in women. A kidney is of a characteristic bean shape through which pass the (1) vessels, (2) nerves, and (3) ureter (Figure 35-1).

Nephron

The functional unit of the kidney is the **nephron**. Each kidney may contain up to 1 million nephrons. The nephron consists of a (1) glomerulus, (2) proximal tubule, (3) **loop of Henle**, (4) distal tubule, and (5) collecting duct (Figure 35-2). The collecting ducts ultimately combine to develop into the renal calyces, where the urine collects before passing along the ureter and into the bladder. The kidney is divided into several lobes. The cortex is the outer, darker region of each lobe and consists of most of the glomeruli and the proximal and distal tubules. It surrounds a paler inner region, the medulla, which is further divided into a number of conical areas known as the renal pyramids, the apex of which extends toward the renal pelvis, forming papillae. Medullary rays are visible striations in the renal pyramids, which connect the kidney cortex with the medulla. They are composed of (1) descending (straight proximal) and (2) ascending (straight distal) thick limbs of Henle, and (3) collecting ducts and associated blood vessels

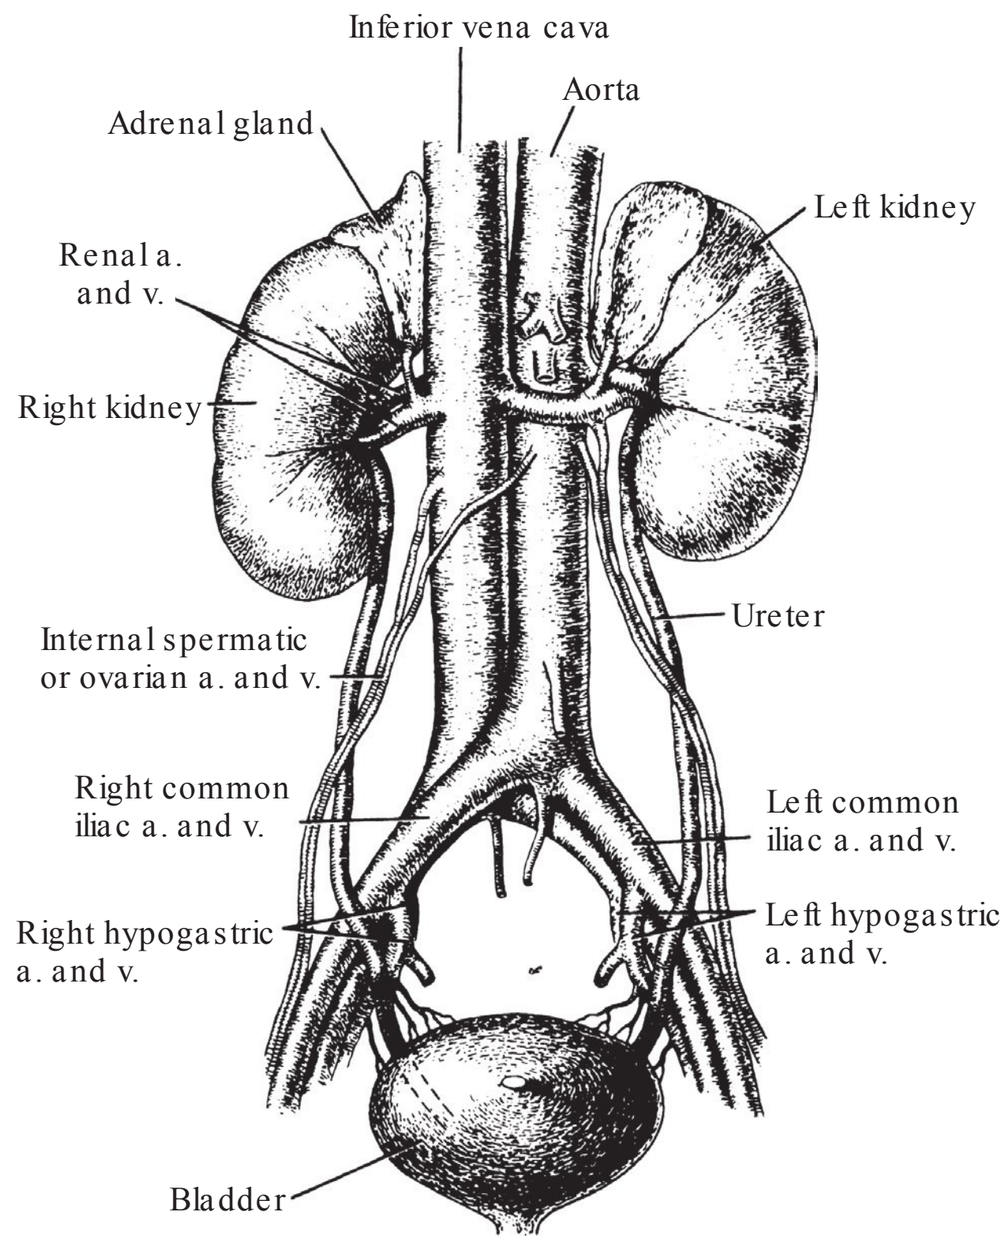

Figure 35-1 The vascular and anatomical relationships of the kidneys in humans. (From Leaf A, Cotran RS. Renal pathophysiology, 3rd edition. Oxford: Oxford University Press, 1985. By permission of Oxford University Press, Inc.)

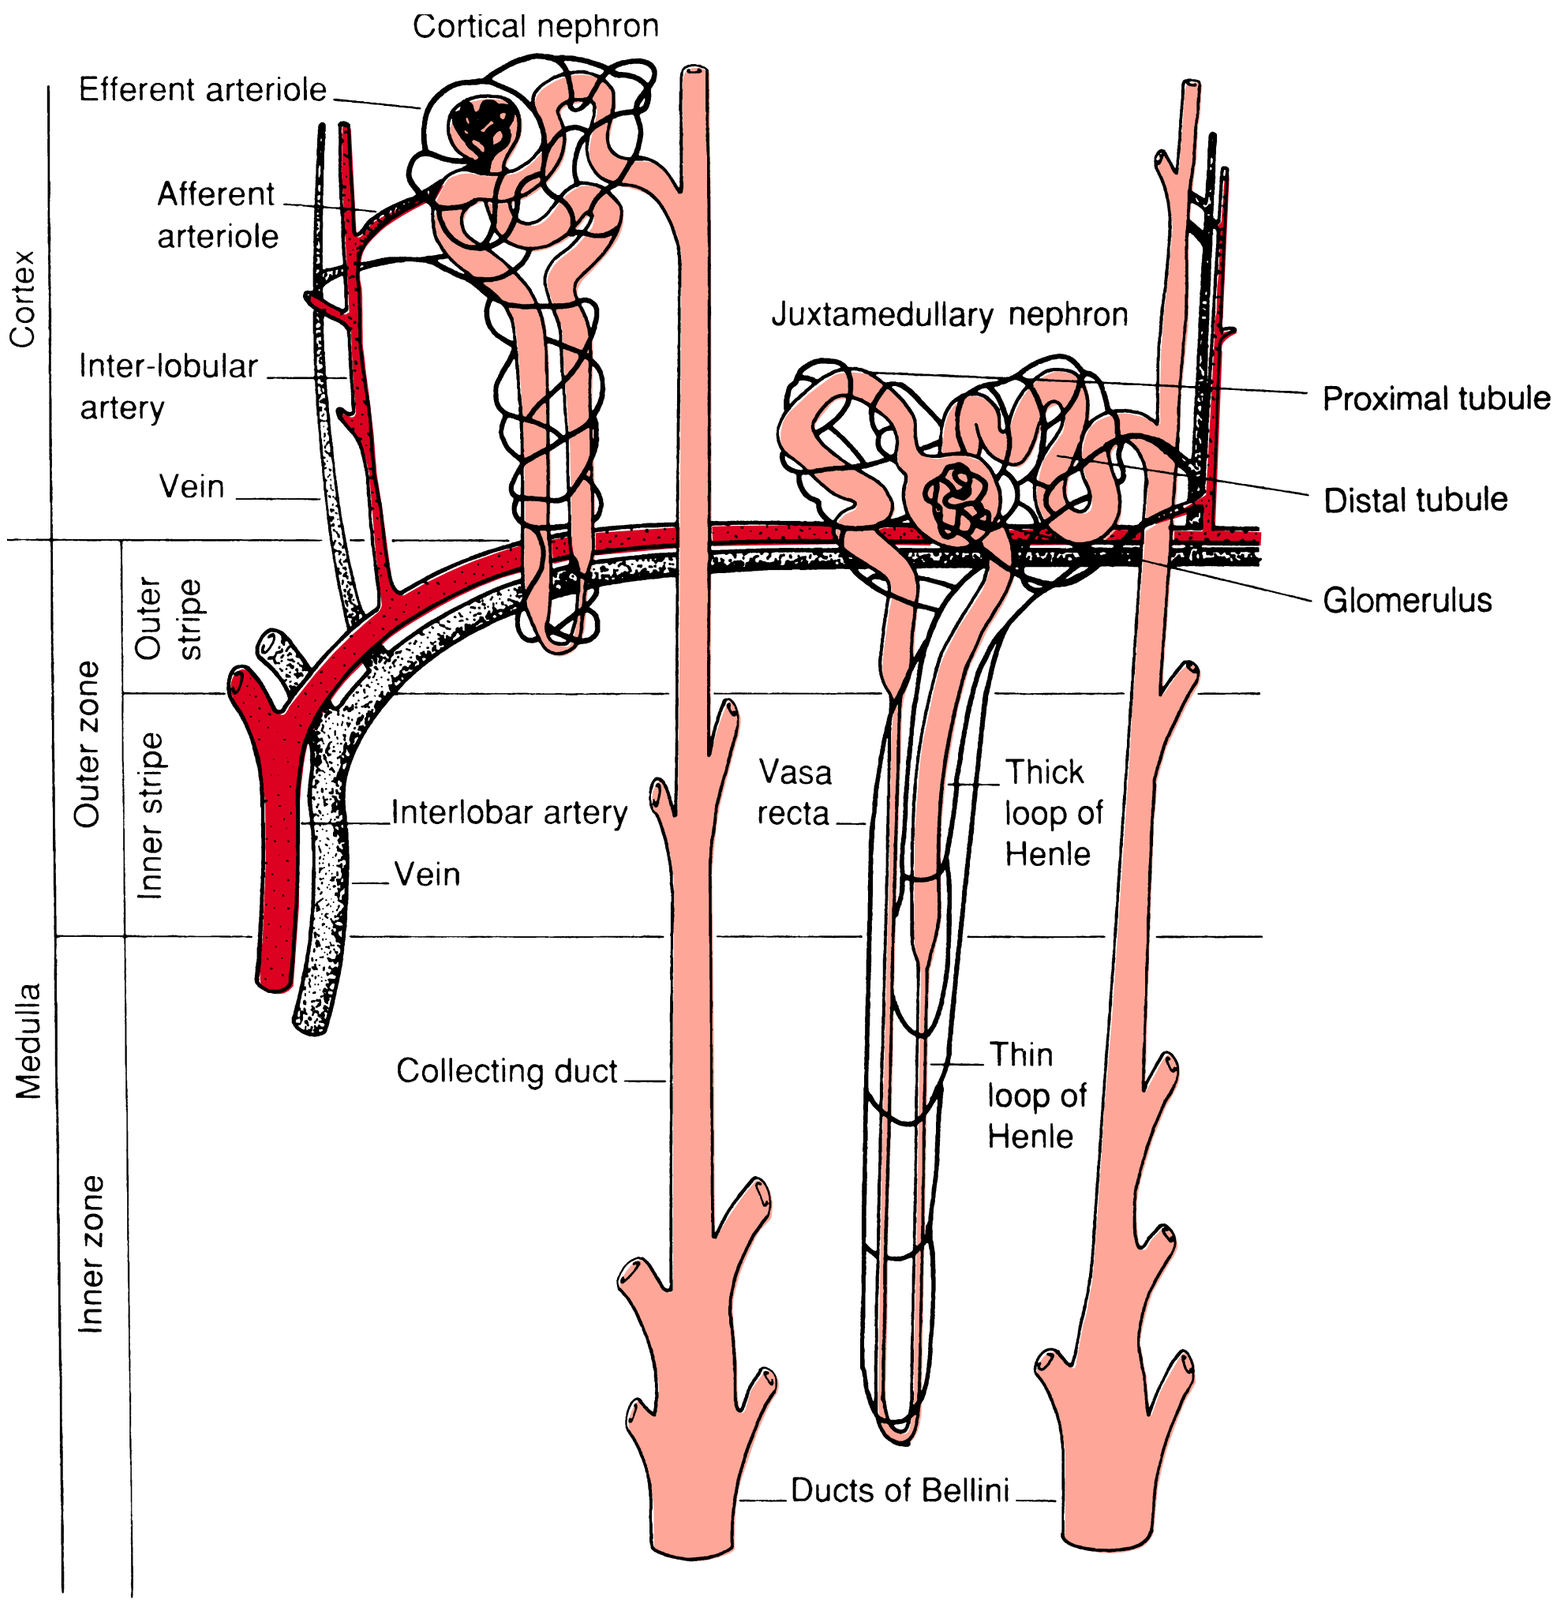

Figure 35-2 Diagrammatic representation of the nephron, the functional unit of the kidney, illustrating the anatomical and vascular arrangements. (From Pitts RF. Physiology of the kidney and body fluids, 3rd edition. Chicago: Year Book Medical Publishers, 1974.)

(the vasa recta). The central hilus is where blood vessels, lymphatics, and the renal pelvis (containing the ureter) join the kidney.

The **glomerulus** is formed from a specialized capillary network. Each capillary develops into approximately 40 glomerular loops around 200 μm in size and consisting of a variety of different cell types supported on a specialized basement membrane (see Figure 35-2). There are endothelial and epithelial cells that act in concert with the specialized glomerular basement membrane to form the glomerular filtration barrier. The glomerular capillaries are supported by a network of mesangial cells and mesangial matrix that act as connective tissue for the glomerular apparatus. The basement membrane forms the main size-discriminant barrier to protein passage into the tubular lumen.

The **Bowman capsule** forms the beginning of the tightly coiled, proximal convoluted tubule (pars convoluta), which on its progress toward the renal medulla becomes straightened and is then called the pars recta. The human proximal tubule is about 15 mm long. The proximal tubule is the most metabolically active part of the nephron, facilitating the reabsorption of 60% to 80% of the glomerular filtrate volume—including 70% of the filtered load of (1) sodium and (2) chloride, most of the (3) potassium, (4) glucose, (5) bicarbonate, (6) phosphate, and (7) sulfate—and secreting 90% of the (8) hydrogen ion excreted by the kidney.

The pars recta drains into the descending thin limb of the loop of Henle, which after passing through a hairpin loop becomes first the ascending thin limb and then the thick ascending limb. At the end of the thick ascending limb, there is a cluster of cells known as the macula densa (Figure 35-3). The main role of the loop of Henle is to provide the ability to generate a concentrated urine, hypertonic with respect to plasma.

The cells forming the distal tubule of the nephron start at the macula densa and extend to the first fusion with other tubules to form the collecting ducts. Sodium chloride reabsorption and some potassium and hydrogen ion excretion occur at this site.

The collecting ducts are formed from approximately six distal tubules. These are successively joined by other tubules to form ducts of Bellini, which ultimately drain into a renal calyx.

Juxtaglomerular Apparatus

Where the ascending loop of Henle passes very close to the Bowman capsule of its own nephron, the cells of the tubule and the afferent arteriole show regional specialization (see Figure 35-3). The tubule forms the macula densa and the

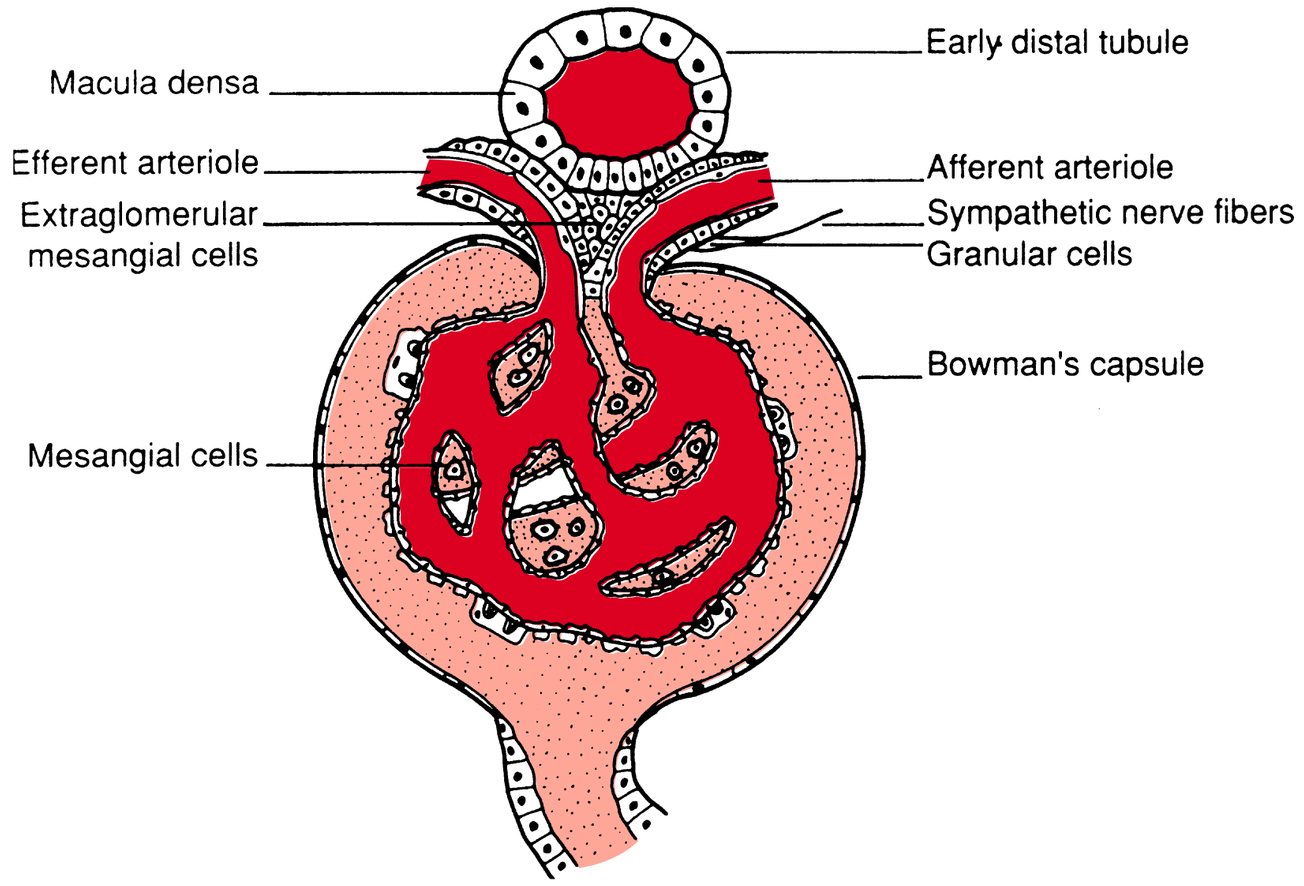

Figure 35-3 The juxtaglomerular apparatus. The beginning of the distal tubule (i.e., where the loop of Henle reenters the cortex) lies very close to the afferent and efferent arterioles, and the cells of both the afferent arteriole and the tubule show specialization. The cells of the afferent arteriole are thickened granular (juxtaglomerular) cells and are innervated by sympathetic nerve fibers. The mesangial cells are irregularly shaped and contain filaments of contractile proteins. Identical cells are found just outside the glomerulus and are termed extraglomerular mesangial cells or Goormaghtigh cells. (From Lote CJ. Principles of renal physiology, 4th edition. London: Kluwer Academic Publishers, 2000. With kind permission of Springer Science and Business Media.)

arteriolar cells are filled with granules (containing **renin**) and are innervated with sympathetic nerve fibers. This area is called the **juxtaglomerular apparatus (JGA)**. The JGA plays an important part in maintaining systemic blood pressure through regulation of the circulating intravascular blood volume and sodium concentration. The proteolytic enzyme renin is released primarily in response to decreased afferent arteriolar pressure and decreased intraluminal sodium delivery to the macula densa. Renin release from the macula densa is also influenced by renal cortical prostaglandins (predominantly PGI_2) and the sympathetic nervous system. The released renin then acts on the plasma protein angiotensinogen to generate angiotensin I. This is converted in the lungs by angiotensin converting enzyme (ACE) to the potent vasoconstrictor and stimulator of aldosterone release, angiotensin II (AII). The vasoconstriction and aldosterone release (with increased distal tubular sodium retention) act in concert with the other action of AII, to increase the release of **antidiuretic hormone (ADH, vasopressin)** and to increase proximal tubular sodium reabsorption, intravascular volume, and pressure. AII also has an inhibitory effect on renin release as part of a negative feedback loop.

Blood Supply

The renal artery divides into posterior and anterior elements, which then divide into interlobar, arcuate, interlobular, and ultimately into the afferent arterioles, which expand into the capillary bed that forms the glomerulus (see Figure 35-2). These capillaries then rejoin to form the efferent arteriole, which then forms the capillary plexuses and the elongated vessels (the vasa recta). These pass around the remaining parts of the (1) nephron, (2) proximal and distal tubules, (3) loop of Henle, and (4) collecting duct, providing oxygen and nutrients and removing ions, molecules, and water, which are reabsorbed by the nephron. The efferent arteriole then merges with renal venules to form the renal veins, which emerge into the inferior vena cava. The complex architecture of the intrarenal vascular tree is ordered in three dimensions in a characteristic arrangement that probably serves to distribute the blood pressure and flow appropriately to the glomeruli.

In the adult, the kidneys receive approximately 25% of the cardiac output. In the newborn infant, however, it is 5%, only reaching adult proportions by the end of the first year of life. About 90% of this blood flow supplies the renal cortex, maintaining the highly active tubular cells. The maintenance of renal blood flow is essential to renal function, and there is a complex array of intrarenal regulatory mechanisms that ensure that it is maintained across a wide range of systemic blood pressures. The renal glomerular perfusion pressure is independent of the systemic pressure between 90 and 200 mm Hg, being maintained at a constant 45 mm Hg.

Kidney Function

The main biological functions of the kidneys are (1) excretion, (2) homeostatic regulation, and (3) endocrine. The kidneys integrate these functions to maintain homeostasis and regulate the internal milieu.

Excretory Function

Urine is (1) excreted by the kidneys, (2) passed through the ureters, (3) stored in the bladder, and (4) discharged through the urethra. In health, it (1) is sterile and clear, (2) has an amber color, (3) has a slightly acidic pH (5.0 to 6.0), and (4) has a characteristic odor, and specific gravity of about 1.024. In addition to dissolved compounds, it contains a number of (1) cellular fragments, (2) complete cells, (3) proteinaceous casts, and (4) crystals (formed elements). Changes in these formed elements are studied using urine microscopy.

Urination, also termed micturition, is the discharge of urine. In normal adults, adequate homeostasis is maintained with a urine output of about 500 mL/day. Alterations in urinary output are described as anuria (<100 mL/day), **oliguria** (<400 mL/day), or **polyuria** (>3 L/day or 50 mL/kg body weight/day). The most

common disorder of urination is altered frequency, which may be associated with increased urinary volume or with partial urinary tract obstruction (e.g., in prostatic hypertrophy).

The first step in urine formation is filtration of plasma water at the glomeruli. A net filtration pressure of about 17 mm Hg in the capillary bed of the tuft drives the ultrafiltrate through the glomerular membrane. Each nephron produces about 100 µL of ultrafiltrate per day. Overall, approximately 170 to 200 L of ultrafiltrate pass through the glomeruli in 24 hours. In the passage of ultrafiltrate through the tubules, reabsorption of solutes and water in various regions of the tubules reduces the total urine volume, which typically varies from 0.4 to 2 L/day.

Transport of solutes and water occurs both across and between the epithelial cells that line the renal tubules. Transport is both active (energy requiring) and passive. Direct coupling of adenosine triphosphate (ATP) hydrolysis is an example of an active transport process. The most important of these in the nephron is Na^+,K^+-ATPase, which is located on the basolateral membranes of the tubuloepithelial cells. This enzymatic transporter accounts for much of renal oxygen consumption and drives more than 99% of renal sodium reabsorption.

Renal epithelial cell membranes also contain proteins that act as ion channels. For example, there is one for sodium that is closed by amiloride and modulated by hormones such as atrial natriuretic peptide (ANP). Ion channels enable much faster rates of transport than ATPases, but are relatively fewer in number—approximately 100 sodium and chloride channels as against 10^7 Na^+,K^+-ATPase molecules per cell.

In the tubules, the solute composition of the ultrafiltrate is altered by the processes of reabsorption and secretion, so the urine excreted may have a very different composition from that of the original filtrate. Different regions of the tubule have been shown to specialize in certain functions. For example, in the proximal tubule, 60% to 80% of the ultrafiltrate is reabsorbed in an obligatory fashion, along with (1) sodium, (2) chloride, (3) bicarbonate, (4) calcium, (5) phosphate, (6) sulfate, and (7) other ions. Glucose is virtually completely reabsorbed, predominantly in the proximal tubule by a passive process. Uric acid is also reabsorbed in the proximal tubule by a passive sodium-dependent mechanism, but there is also an active secretory mechanism.

In the loop of Henle, chloride and more sodium without water are reabsorbed, generating dilute urine. Water reabsorption in the more distal tubules and collecting ducts is then regulated by hypothalamic ADH. In the distal tubule, secretion is the prominent activity with (1) organic, (2) potassium, and (3) hydrogen ions being transported from the blood in the efferent arteriole into the tubular fluid. It is also this region that secretes hydrogen ions and reabsorbs sodium and bicarbonate to aid in acid-base regulation. Paracellular (between cell) movement is driven predominantly by concentration, osmotic, or electrical gradients.

Regulatory Function

The regulatory function of the kidneys has a major role in homeostasis. The mechanisms of differential reabsorption and secretion, located in the tubule of a nephron, are the effectors of regulation. The mechanisms operate under a complex system of control in which both extrarenal and intrarenal humoral factors participate.

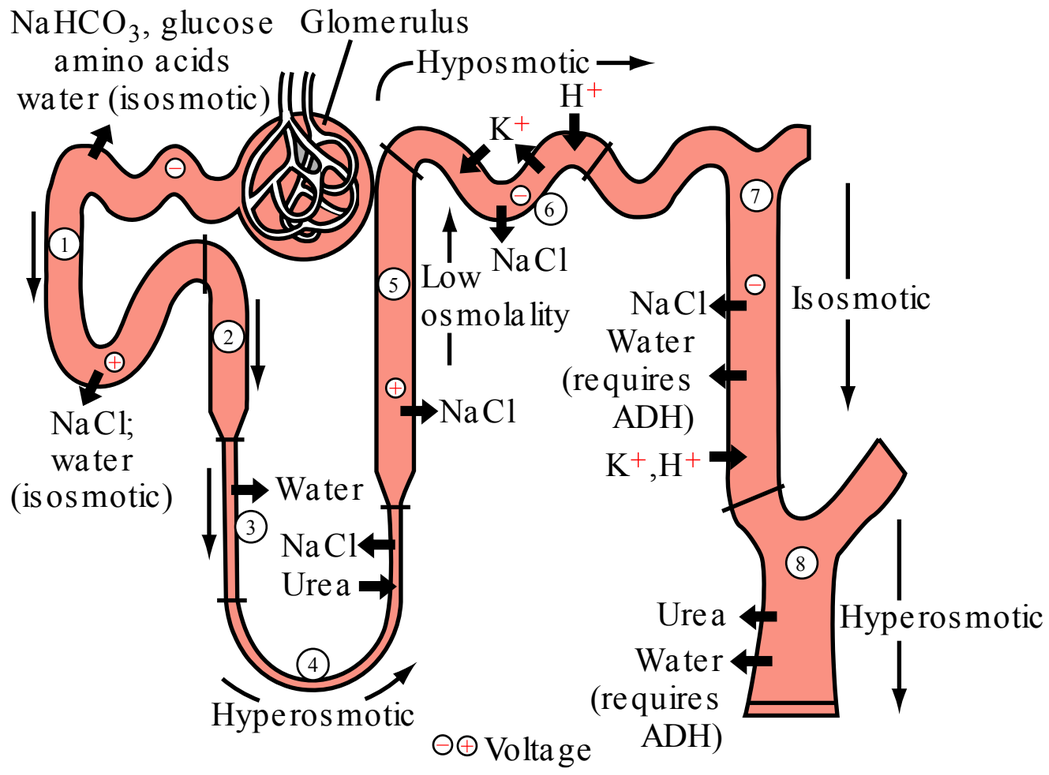

Figure 35-4 Countercurrent multiplication mechanism: schematic representation of the principal processes of transport in the nephron. In the convoluted portion of the proximal tubule (1), salts and water are reabsorbed at high rates in isotonic proportions. Bulk reabsorption of most of the filtrate (65% to 70%) and virtually complete reabsorption of glucose, amino acids, and bicarbonate take place in this segment. In the pars recta (2), organic acids are secreted and continuous reabsorption of sodium chloride takes place. The loop of Henle comprises three segments: the thin descending (3) and ascending (4) limbs and the thick ascending limb (5). The fluid becomes hyperosmotic, because of water abstraction, as it flows toward the bend of the loop, and hyposmotic, because of sodium chloride reabsorption, as it flows toward the distal convoluted tubule (6). Active sodium reabsorption occurs in the distal convoluted tubule and in the cortical collecting tubule (7). This latter segment is water-impermeable in the absence of ADH, and the reabsorption of sodium in this segment is increased by aldosterone. The collecting duct (8) allows equilibration of water with the hyperosmotic interstitium when ADH is present. (From Burg MB. The nephron in transport of sodium, amino acids, and glucose. Hosp Pract 1978;13:100. Adapted from a drawing by A. Iselin.)

Electrolyte Homeostasis

The proximal convoluted tubule is predominantly concerned with reabsorption (Figure 35-4). Water reabsorption in the proximal convoluted tubule is termed "obligatory" because its volume is related to the heavy load of solutes being returned to the blood in the efferent arteriole. The amount of bicarbonate reabsorption is related to the **glomerular filtration rate (GFR)** and the hydrogen ion secretory rate. The amount of phosphate reabsorption is controlled in part by (1) plasma calcium concentration and (2) the effect of parathyroid hormone (PTH) on the tubular cells. Normally, the high-threshold substances such as glucose and, to a great extent, amino acids are reabsorbed here by means of specific intracellular active transport systems. Uric acid may be either reabsorbed or secreted in the proximal convoluted tubule by a two-way carrier-mediated process.

In the ascending limb of the loop of Henle, 20% to 25% of filtered sodium is reabsorbed without concomitant reabsorption of water. This process generates dilute urine with an osmolality of 100 to 150 mOsm/kg of water and helps establish the corticomedullary osmotic gradient. The resulting hypertonicity of the interstitium is important in the pathogenesis of renal infections because the hypertonic environment interferes with leukocyte function. Subsequent water reabsorption is regulated by ADH.The distal tubule is functionally the most active region of the nephron for the homeostatic regulation of plasma electrolytes and plasma acid-base concentrations. Here a combination of secretion and reabsorption takes place among Na^+, K^+, and H^+. Although excess plasma hydrogen ions are secreted all along the tubule, it is in the distal tubule that exchange of H^+ for Na^+ (which is reabsorbed) fine tunes the balance between H^+ loss and retention (see Chapter 36). Potassium ions are also secreted in the distal tubule. The aldosterone produced by the adrenal gland is a potent modulator of Na^+ reabsorption in the distal tubule, particularly when the need arises to conserve Na^+. Production of aldosterone in the adrenal cortex is stimulated by the renin-angiotensin system and by high plasma potassium concentration. Renal secretion of renin is complex, but is at least partly regulated by renal perfusion and plasma sodium concentration. Both inadequate perfusion and a low concentration of plasma sodium stimulate renin secretion. Organic anions, such as acetoacetate and β-hydroxybutyrate, also consume H^+ as they are eliminated in part in their nondissociated acid form. When H^+ must be conserved to maintain blood pH, distal tubule cells (1) reduce the secretion of H^+, (2) reduce NH_4^+ generation, (3) reduce Na^+-H^+ exchange, and (4) increase bicarbonate excretion. The net effect is a reduction in plasma bicarbonate and restoration of normal blood pH.

Water Homeostasis

The production of glomerular filtrate normally amounts to about 180 L/day. The unique physiology of the kidney enables approximately 99% of this to be reabsorbed in the production of urine with variable osmolality: between 50 and 1400 mOsmol/kg H_2O at extremes of water intake. Different segments of the nephron show differing permeability to water, enabling the body to both retain water and produce urine of variable concentration. Approximately (1) 70% of the water content of the tubular fluid is reabsorbed in the proximal tubule, (2) 5% in the loop of Henle, (3) 10% in the distal tubule, and (4) the remainder in the collecting ducts.

Water reabsorption occurs both isosmotically, in association with electrolyte reabsorption in the proximal tubule, and differentially, in the (1) loop of Henle, (2) distal tubule, and (3) collecting duct in response to the action of the nonapeptide ADH. Absorption of water depends on the driving force for water reabsorption (predominantly active sodium transport) and the osmotic equilibration of water across the tubular epithelium. The generation of concentrated urine depends upon medullary hyperosmolality, which in turn requires low water permeability in some kidney segments (ascending limb of the loop of Henle). In other kidney segments there is a requirement for high water permeability. This difference in permeability and the need for hormonal control is largely caused by the differential expression along the nephron of a family of proteins known as the aquaporins (AQP), which act as water channels.

Urinary concentration is predominantly achieved by countercurrent multiplication in the loop of Henle (see Figure 35-4). Although the descending thin limb is very permeable to water, the ascending limb and the collecting duct are not (the collecting ducts are also poorly permeable to urea). The fluid entering the loop of Henle is isotonic to plasma but is hypotonic on leaving it. The ascending limb has active sodium reabsorption driven by Na^+, K^+-ATPase with electroneutralizing transport of chloride, a combined process that is inhibited by the so-called loop diuretics (e.g., furosemide). In this section of the nephron, sodium reabsorption is not accompanied by water, creating a hypertonic medullary interstitium and facilitating water reabsorption from the anatomically adjacent descending limb. The descending limb cells are permeable to sodium chloride, which is cycled from the descending limb back to the ascending limb. The continuous flow along the loop generates an osmotic gradient at the tip of the loop that can reach 1400 mOsmol/kg/H_2O.The regulation of ADH excretion is of vital importance to fluid homeostasis. The normal plasma osmolality is maintained very tightly between 280 and 290 mOsmol/kg H_2O and is regulated by means of specific osmoreceptors found in the anterior hypothalamus. These receptors modulate the release of ADH and also affect thirst. ADH release may also be stimulated by (1) hypotension, (2) hypovolemia, and (3) vomiting independently of osmoregulation.

Endocrine Function

The endocrine functions of the kidneys may be regarded either as (1) primary, because the kidneys are endocrine organs producing hormones, or (2) secondary, because the kidneys are a site of action for hormones produced or activated elsewhere. In addition, the kidneys are a site of degradation for hormones, such as insulin and aldosterone. In their primary endocrine function, the kidneys produce (1) **erythropoietin** (EPO), (2) prostaglandins and thromboxanes, (3) renin, and (4) 1,25(OH_2) vitamin D_3.

Erythropoietin

EPO is a glycoprotein hormone secreted chiefly by the kidney in the adult and by the liver in the fetus that acts on the bone marrow cells to stimulate erythropoiesis. It is an α-globulin having a molecular weight of 38 kDa. Physiologically, the kidneys sense a reduction in O_2 delivery to tissue by blood and release EPO, thereby stimulating the bone marrow to produce more red blood cells (RBCs). Conversely, with a surplus of O_2 in blood traversing the kidneys, as in some forms of polycythemia, the release of EPO into blood is diminished. The use of recombinant human erythropoietin (rhEPO, Epoetin) in the management of anemia of kidney disease is discussed later.

Prostaglandins and Thromboxanes

Prostaglandins and thromboxanes are synthesized from arachidonic acid by the cyclooxygenase enzyme system (see Chapter 23). This system is present in many parts of the kidneys. The predominant metabolite of its vascular endothelial activity is prostacyclin (PGI_2). Prostaglandin E_2 (PGE_2) appears to be the major metabolite of mesangial and tubular cells. The production and activity of these biologically active compounds have an important role in regulating the physiological action of other hormones on (1) renal vascular tone, (2) mesangial contractility, and (3) tubular processing of salt and water.

Renin

Renin is produced within the juxtaglomerular cells after processing and cleavage of prorenin, which is produced in the liver. Increased production of renin results in formation of angiotensin II in the liver, which is a powerful intrarenal vasoconstrictor and also a key stimulus of aldosterone release from zona glomerulosa cells in the adrenal glands. The net effect is (1) systemic vasoconstriction, (2) intrarenal vasoconstriction, and (3) increased aldosterone release. Aldosterone controls salt and water balance in the kidney. Its effect is predominantly on the distal tubular network, effecting an increase in sodium reabsorption in exchange for potassium.

1,25(OH_2) Vitamin D_3

The kidneys are primarily responsible for producing 1,25(OH_2) vitamin D_3 from 25-hydroxycholecalciferol as a result of the action of the enzyme 25-hydroxycholecalciferol 1α-hydroxylase found in proximal tubular epithelial cells. The regulation of this system is discussed in Chapter 39.

Kidney Physiology

The (1) GFR, (2) renal blood flow, and (3) glomerular permeability are important physiological components of renal function.

Glomerular Filtration Rate

The GFR is considered to be a reliable measure of the functional capacity of the kidneys and is often thought of as indicative of the number of functioning nephrons. As a physiological measurement, it has proved to be a useful marker of changes in overall renal function. The rate of formation of the glomerular filtrate depends upon the balance between hydrostatic and oncotic forces along the afferent arteriole and across the glomerular filter. The net pressure difference must be sufficient not only to drive filtration across the glomerular filtration barrier but also to drive the ultrafiltrate along the tubules against their inherent resistance to flow. In the absence of sufficient pressure, the lumina of the tubules will collapse.

A decrease in GFR precedes kidney failure in all forms of progressive disease. Different pathological kidney conditions have been known to progress to (1) **end-stage renal disease (ESRD)** and (2) **dialysis** dependency at rates varying from weeks to several decades. The symptoms accompanying progressive kidney disease and their correlation with falling GFR are influenced by this rate of progression. Measuring GFR in established disease is useful in (1) targeting treatment, (2) monitoring progression, and (3) predicting when **renal replacement therapy (RRT)** will be required and (4) as a guide to dosage of drugs excreted by the kidneys to prevent potential drug toxicity. A number of methods are used to measure the GFR; most involve the kidneys' ability to clear either an exogenous or endogenous marker.

The Concept of Renal Clearance

GFR measurements may be based on either the urinary or plasma clearance of a marker. The **renal clearance** of a substance is defined as "the volume of plasma from which the substance is completely cleared by the kidneys per unit of time." For a substance (S) to be used to measure renal clearance, it must be (1) in stable concentration in the plasma; (2) physiologically inert; (3) freely filtered at the glomerulus; (4) neither secreted; (5) neither reabsorbed; (6) neither synthesized; and (7) not metabolized by the kidney. If a substance possesses these qualities, then the amount of that substance filtered at the glomerulus is equal to the amount excreted in the urine. The amount of S filtered at the glomerulus is equal to the GFR multiplied by plasma S concentration: $GFR \times [P_S]$. The amount of S excreted equals the urine S concentration (U_S) multiplied by the urinary flow rate (V, volume excreted per unit of time).

Since filtered S = excreted S, then

$$GFR \times [P_S] = [U_S] \times V \quad (1)$$

$$GFR = ([U_S] \times V) / [P_S] \quad (2)$$

where GFR = clearance in units of milliliters of plasma cleared of a substance per minute

$[U_S]$ = urinary concentration of the substance
V = volumetric flow rate of urine in milliliters per minute
$[P_S]$ = plasma concentration of the substance

The term $([U_S] \times V)/[P_S]$ is defined as the clearance of substance S and is an accurate estimate of GFR providing the aforementioned criteria are satisfied. Inulin satisfies these criteria and has long been regarded as the most accurate estimate of GFR (see later). Kidney size and GFR are roughly proportional to body size. It is conventional therefore to adjust clearance estimates to a standard body surface area (BSA) of 1.73 m^2.

Markers Used

A variety of exogenous and endogenous markers have been used to estimate clearance (Table 35-1). Measurement of clearance may require accurate measurements of both plasma and urinary concentrations of the marker used plus a reliable urine collection. For a reliable plasma measurement, the substance must have reached a steady-state concentration and not be rapidly changing. For a reliable urine collection (1) the urine flow must be adequate (several mL/min), (2) the collection

TABLE 35-1 Markers Used to Measure Glomerular Filtration Rate

Hierarchy	Marker	Advantages	Disadvantages
Gold standard	Inulin (sinistrin) continuous infusion urinary clearance method	Gold standard	Exogenous Time-consuming Requires a timed urine collection Poor specificity of analysis Extrarenal clearance = 0.083 mL/min/kg
Silver standard	Inulin (sinistrin) single bolus plasma clearance method		Exogenous Time-consuming Poor specificity of analysis Extrarenal clearance = 0.083 mL/min/kg
	^{51}Cr-EDTA	Radioisotopic (simple measurement) Close correlation with inulin clearance	Exogenous Radioisotopic (risks of ionizing radiation) Time-consuming Extrarenal clearance = 0.079 mL/min/kg ^{51}Cr less readily available than ^{99m}Tc
	^{99m}Tc-DTPA	Radioisotopic (simple measurement) Has been used for gamma camera imaging	Exogenous Radioisotopic (risks of ionizing radiation) Time-consuming Protein binding
	^{125}I-iothalamate	Radioisotopic (simple measurement)	Exogenous Radioisotopic (risks of ionizing radiation) Not available in all countries Reports of allergic reactions
	Iohexol	Nonradioisotopic	Exogenous Extrarenal clearance = 0.087 mL/min/kg Reports of allergic reactions
Bronze standard	Creatinine	Endogenous Inexpensive Is used to generate GFR from formula (e.g., MDRD Study)	Poor sensitivity and specificity
	Cystatin C	Not secreted/reabsorbed Constitutively expressed More sensitive and specific than creatinine	Influence of thyroid function
Of uncertain clinical use	Creatinine clearance	Endogenous Inexpensive	Requires a timed urine collection Inaccurate
	Urea	Endogenous Inexpensive	Poor sensitivity and specificity
	RBP	Endogenous Not secreted/reabsorbed	Nonrenal influences on production rate
	α_1-microglobulin	Endogenous Not secreted/reabsorbed	Nonrenal influences on production rate Less freely filtered than RBP

EDTA, Ethylenediaminetetraacetic acid; DTPA, diethylenetriaminepentaacetic acid; GFR, glomerular filtration rate; MDRD, Modification of Diet in Renal Disease; RBP, retinol-binding protein; Tc, technetium.

period of long enough duration (typically more than 4 hours), and (3) complete bladder emptying achieved. In addition, to ensure accuracy when measuring GFR using urinary clearance methods, it is essential that (1) renal tubular secretion or reabsorption does not contribute to the elimination of the compound and (2) plasma protein binding of the pharmaceutical is negligible.

Exogenous Markers of Glomerular Filtration Rate

Both nonradioisotopic and radioisotopic markers are used as exogenous markers. Nonradioactive compounds used to measure GFR include inulin and iohexol. Radiopharmaceuticals that have been used include (1) ^{51}Cr-ethylenediaminetetraacetic acid (EDTA), (2) ^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA), and (3) ^{125}I-iothalamate. Using these markers, the biological variability of GFR in patients with kidney disease has been reported to be between 6% and 12%.

Inulin Clearance. The fructose polymer inulin (molecular mass approximately 5 kDa) satisfies the criteria as an ideal marker of GFR. Inulin clearance using a constant infusion urinary clearance approach has long been regarded as the "gold standard" measure of GFR. Acceptable single

bolus plasma clearance approaches have also been evaluated. However, lack of availability of simple laboratory methods of measurement of inulin remains an impediment to universal usage.

Iohexol Clearance. The clearance of the nonradioactive x-ray contrast agent iohexol has been proposed as a simpler alternative to inulin clearance. In one method, plasma iohexol is measured by high-performance liquid chromatography (HPLC) with reversed-phase separation and ultraviolet (UV) detection, following prior deproteinization with perchloric acid. Analytical imprecision (CV) is less than 3% intraassay and 5% interassay. Isotope-dilution mass spectrometry (ID-MS) methods have also been used. Single-bolus plasma clearance of iohexol demonstrates excellent agreement with constant-infusion urinary inulin clearance.

Single-bolus plasma clearance methods have obvious practical advantages compared with the complex continuous-infusion methods. A single dose of the marker such as (1) inulin, (2) iohexol or (3) Cr-EDTA, 50 to 100 μCi) is injected and venous blood samples are then collected at timed intervals (e.g., typically 120, 180, and 240 minutes after the start of the injection of the marker). The GFR is calculated using the amount of marker injected and the decrease in marker concentration (or radioactivity) as a function of time. The elimination of the marker is described by a two-compartment model (see Chapter 31). This comprises an initial equilibration or distribution phase while the marker mixes between the vascular and extravascular space while also being cleared from the plasma by the kidney. The distribution phase lasts between 2 and 8 hours, depending on the (1) size of the subject, (2) distribution volume of the molecule (e.g., longer in patients with an excessive accumulation of serous fluid), and (3) GFR of the subject (the lower the GFR, the longer the distribution phase). This gives rise to a biexponential clearance curve. However, GFR is normally calculated using single-exponential analysis by plotting log marker concentration against time. The half-life is calculated from the slope (k) and the volume of distribution (C_0) of the marker just after injection.

$$GFR = k \times C_0 \quad (3)$$

Because this model ignores the distribution phase, GFR is overestimated. Various corrections are used to adjust for this.

Endogenous Markers of Glomerular Filtration Rate

Although the clearance of infused exogenous markers is generally considered an accurate assessment of GFR, to date these procedures have been considered too costly and cumbersome for routine use, particularly in cases where the GFR is assessed on a regular basis. Creatinine and certain low molecular weight proteins (such as cystatin C) have been used as endogenous markers of GFR. These markers obviate the necessity for injection and require only a single blood sample thereby simplifying the procedure and increasing its utility.

Creatinine Concentration. The most widely used endogenous marker of GFR is creatinine,[10] expressed as its (1) plasma concentration, (2) serum concentration plasma and serum concentrations of creatinine are equivalent, or (3) renal clearance (see Chapter 21) and efforts continue to standardize the measurement of creatinine.[6,14,18] Creatinine (molecular mass 113 Da) is freely filtered at the glomerulus and its concentration is inversely related to GFR. As a GFR marker, it is convenient and inexpensive to measure but its measured concentration is affected by (1) age, (2) sex, (3) exercise, (4) certain drugs (e.g., cimetidine and trimethoprim), (5) muscle mass, (6) nutritional status, and (7) meat intake. Further, a small (but significant) and variable proportion of the creatinine appearing in the urine is derived from tubular secretion. Typically, 7% to 10% is due to tubular secretion, but this percentage is increased in the presence of renal insufficiency. Significant analytical interferences continue to be a problem. Perhaps most importantly, plasma creatinine remains within the reference interval until significant renal function has been lost. Since plasma creatinine is derived from creatine and phosphocreatine breakdown in muscle, the reference interval encompasses the variety of muscle mass observed in the population. This contributes to the insensitivity of creatinine as a marker of diminished GFR. Additionally, in patients with **chronic kidney disease (CKD)**, extrarenal clearance of creatinine further blunts the anticipated increase in plasma creatinine in response to falling GFR. Consequently, plasma creatinine measurement does not detect mild CKD (GFR 60 to 89 mL/min/1.73 m^2) and also fails to identify many patients with moderate CKD (GFR 30 to 59 mL/min/1.73 m^2). Thus, although an increased plasma creatinine concentration does generally equate with impaired kidney function, a healthy plasma creatinine does not necessarily equate with normal kidney function. Because of all these limitations, it is recommended that plasma creatinine measurement alone not be used to assess kidney function.

Creatinine Clearance. Because creatinine is endogenously produced and released into body fluids at a constant rate, its clearance has been measured as an indicator of GFR. Historically, creatinine clearance has been seen as more sensitive for detection of renal dysfunction than measuring plasma creatinine. However, it requires a timed urine collection, which (1) introduces its own inaccuracies, (2) is inconvenient, and (3) is unpleasant. In addition, it is imprecise as the intraindividual day-to-day coefficient of variation (CV) for repeated measures of creatinine clearance can exceed 25%. Hence, at best creatinine clearance only provides a crude index of GFR.

Estimated Glomerular Filtration Rate. The mathematical relationship between plasma creatinine and GFR is improved by correcting for the confounding variables that make that relationship nonlinear. Many equations have been derived that estimate GFR using plasma creatinine corrected for some or all of (1) sex, (2) body size, (3) race, and (4) age. Their use is thought to produce a better estimate of GFR than plasma creatinine alone. The Modification of Diet in Renal Disease (MDRD) study equation was developed in 1999 by Levey and

co-workers among 1628 predominantly middle-aged patients enrolled in the MDRD Study. An abbreviated version of this equation was subsequently published and later aligned for use with creatinine assays with standardization traceable to the international reference system[10,11]:

$$\begin{aligned}\text{GFR } (\text{mL/min/1.73 m}^2) &= 175 \\ &\times [\text{plasma creatinine (mg/dL)}]^{-1.154} \\ &\times [\text{age}]^{-0.203} \\ &\times [1.210 \text{ if black}] \\ &\times [0.742 \text{ if female}]\end{aligned}$$

or,

$$\begin{aligned}\text{GFR } (\text{mL/min/1.73 m}^2) &= 175 \\ &\times [\text{plasma creatinine } (\mu\text{mol/L}) \times 0.011]^{-1.154} \\ &\times [\text{age}]^{-0.203} \\ &\times [1.210 \text{ if black}] \\ &\times [0.742 \text{ if female}]\end{aligned}$$

The MDRD Study equation has been widely adopted internationally; although it is acknowledged that at GFR levels greater than 60 mL/min/1.73 m^2, it suffers from negative bias. An alternative equation, the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation has been proposed.[12] This is favored by some workers on the basis that, at least in people with less advanced kidney disease, it is less biased than the MDRD Study equation and enables GFR values in excess of 90 mL/min/1.73 m^2 to be reported. It also has a smaller coefficient for black ethnicity than the MDRD Study equation, and there are some indications that it is possible to use it without adjustment for race in some other ethnic groups.

$$\begin{aligned}\text{GFR } (\text{mL/min/1.73 m}^2) &= 141 \\ &\times \min(\text{Scr}/\kappa, 1)^{\alpha} \\ &\times \max(\text{Scr}/\kappa, 1)^{-1.209} \\ &\times 0.993^{\text{Age}} \\ &\times 1.018 \text{ [if female]} \\ &\times 1.159 \text{ [if black]},\end{aligned}$$

where Scr is serum creatinine in mg/dL, κ is 0.7 for females and 0.9 for males, α is -0.329 for females and -0.411 for males, min indicates the minimum of Scr/κ or 1, and max indicates the maximum of Scr/κ or 1.

Alternative equations are available for use in children (e.g., the Schwartz equation). These equations are clearly complex: software is available for such calculations (e.g., see http://www.nkdep.nih.gov/; accessed September 16, 2013).

It must be remembered, however, that plasma creatinine is an imperfect marker of GFR and therefore equations based upon it are imperfect. Use of the equation does not circumvent the very significant optical interferences affecting plasma creatinine measurement, such as (1) hemolysis, (2) icterus, and (3) lipemia, and (4) it does not address the inter-individual variability in concentrations of non-creatinine chromogens.

Low-Molecular-Weight Proteins. A number of proteins with molecular weights of less than 30 kDa are mostly cleared from the circulation by renal filtration and are considered to be relatively freely filtered at the glomerular filtration barrier. These include (1) α_2-microglobulin, (2) retinol-binding protein (RBP), (3) α_1-microglobulin, (4) β-trace protein, and (5) cystatin C.[2] These proteins are (1) filtered at the glomerulus, (2) reabsorbed and metabolized in the proximal tubule or excreted into the urine, and (3) entirely eliminated from the circulation. Therefore they have the potential to meet the criteria for use as a marker of GFR. However, all these proteins have been shown to have plasma concentrations that are influenced by other, nonrenal factors, such as (1) inflammation (α_2-microglobulin), (2) liver disease (RBP, α_1-microglobulin) and (3) thyroid disease (cystatin C). The relationship between the circulating concentrations of these proteins shows the same curvilinear form as plasma creatinine, but several groups have demonstrated that cystatin C measurement may offer a more sensitive and specific means of monitoring changes in GFR than plasma creatinine.

Cystatin C is a low molecular weight (12.8 kDa) protein synthesized by all nucleated cells whose physiological role is that of a cysteine protease inhibitor. With regard to renal function, its most important attributes are its small size and high isoelectric point (pI = 9.2), which enable it to be more freely filtered than the above-mentioned proteins at the glomerulus. Plasma concentrations of cystatin C appear to be unaffected by (1) muscle mass, (2) diet, or (3) sex. Also, there are no known extrarenal routes of elimination, and clearance from the circulation is only by glomerular filtration. Further, cystatin C measurement appears unaffected by the optical interferences affecting creatinine assays. Because of its multiple advantages, cystatin C is considered by some to be a superior marker for determining GFR. It appears to be especially useful when trying to detect mild to moderate impairment of kidney function. A GFR estimating equation based upon cystatin C has recently been proposed by the CKD-EPI collaboration[2,3,4]:

$$\begin{aligned}\text{GFR } (\text{mL/min/1.73 m}^2) &= 133 \\ &\times \min(\text{Scys}/0.8, 1)^{-0.499} \\ &\times \max(\text{Scys}/0.8, 1)^{-1.328} \\ &\times 0.996^{\text{Age}} \\ &\times 0.932 \text{ [if female]}\end{aligned}$$

where Scys is serum cystatin C in mg/L, min indicates the minimum of Scr/κ or 1, and max indicates the maximum of Scr/κ or 1.

Glomerular Filtration Rate and Age

GFR is not constant throughout life. For example, in utero, urine is produced by the developing fetus from about the ninth week of gestation. The GFR at birth is approximately 30 mL/min/1.73 m^2. It increases rapidly during the first weeks of life to reach approximately 70 mL/min/1.73 m^2 by age 16 days with adult values of BSA-corrected GFR being achieved by 2 years of age. On average, GFR declines with

age by approximately 1 mL/min/1.73 m^2/yr over the age of 40 and the rate of decline in GFR accelerates after age 65 years.

Recommendations and Reference Intervals

The measurement of the urinary clearance of inulin, after continuous infusion, is considered the reference method for the determination of GFR. However, because the necessary plasma and urine assays for inulin often are not practical in clinical laboratories, plasma creatinine or creatinine clearance has almost universally been used for assessment of GFR. With increasing recognition of the importance of early detection and management of CKD, the requirement for more accurate assessment of GFR is being emphasized. Consequently, creatinine clearance is no longer considered acceptable as a measure of GFR and plasma creatinine measurements should not be reported in isolation but should be used to generate estimations of GFR. However, the susceptibility of these equations to creatinine assay calibration variations must be recognized. The success of alternative markers (such as cystatin C) will depend on understanding the benefit of the superior diagnostic accuracy and improved clinical and economic outcomes in relation to the greater cost of the assay when compared with the Jaffe creatinine methods.

As indicated earlier, reference data for GFR are dependent on the age of the population studied. A reference value in young adult men and women of approximately 125 mL/min/1.73 m is used by many.

Glomerular Permeability, Filtration, and Protein Loss

The glomerular permeability and filtration capabilities of the kidney control the amount of protein lost in the urine.

Glomerular Permeability and Filtration

The glomerulus acts as a selective filter of the blood passing through its capillaries. The combination of a (1) fenestrated (porous) endothelial layer, (2) basement membrane rich in negatively charged proteoglycans, and (3) highly specialized terminally differentiated epithelial cell barrier produces a filter that restricts the passage of macromolecules in a (1) size-, (2) charge-, and (3) shape-dependent manner. The epithelial cells (podocytes) have foot processes that are connected to the glomerular basement membrane and form the final barrier to filtration via interdigitating with neighboring cell foot processes connected by a slit diaphragm. Examples of the relationships between (1) size, (2) charge, and (3) mass of the major urinary proteins and their glomerular processing are listed in Table 35-2. In general, proteins of molecular weights greater than albumin (66 kDa, diameter 3.5 nm) are retained by the healthy glomerulus and are termed high molecular weight proteins. However, lower molecular weight proteins are also retained to a significant extent.

Urinary Protein Loss

Increased urinary protein loss (**proteinuria**) results from (1) any increase in the filtered load, (2) increased circulating concentration of low molecular weight proteins, or (3) decrease in reabsorptive capacity. Historically, the pattern of urinary protein loss has been used to identify the cause and to classify the proteinuria, of which there are three main types: (1) glomerular, (2) overflow, and (3) tubular proteinuria.

The normal urinary total protein loss is less than 150 mg/24 hr. The proteins lost are made up of mostly albumin (50% to 60%) and some smaller proteins, together with proteins secreted by the tubules, of which Tamm-Horsfall glycoprotein (THG) is one. The normal concentrations of proteins found in urine are listed in Table 35-2. Investigation for increased urinary protein loss is required for the examination of any patient with suspected kidney disease. Clinical or overt proteinuria is often detected using reagent strip methods, the detection limit of which is 200 to 300 mg/L. Proteinuria above 300 mg/day is generally pathological. However, there are exceptions to this. For example, proteinuria has been observed to occur as a result of fever

TABLE 35-2 Characteristics of the Major Urinary Proteins

Protein	M_r (kDa)	Free Plasma Concentration (g/L)	Diameter (nm)	Glomerular Sieving Coefficient*	Filtered Load (mg/L)†	Urinary Concentration (mg/L)	% Reabsorbed
IgG	150	10	5.5	0.0001	1	0.1	99

and exercise (functional) or related to posture (orthostatic). T ese sporadic changes cause interpretative difficulties when pathology is suspected. Upright posture increases protein loss in both normal subjects and those with kidney disease. Proteinuria above 1000 mg/day implies glomerular proteinuria. Glomerular proteinuria may be heavy and a mixed proteinuria with the elevation of both high and low molecular weight proteins may be observed.

T ere is a growing consensus that urinary total protein measurement should be replaced by urinary albumin measurement when assessing patients for proteinuria in most clinical situations. Albumin is the predominant protein in urine in the majority of kidney diseases and is accurately and specifically measured using immunoassay techniques.[8]

Consequences of Proteinuria

Many physicians believe that proteinuria is not just a consequence of, but contributes directly to, progression of kidney disease. T e accumulation of proteins in abnormal amounts in the tubular lumen may trigger an inflammatory reaction, which contributes to interstitial structural damage and expansion, and progression of kidney disease. Evidence gathered from in vitro studies suggests that glomerular filtration of an abnormal amount or types of protein induces mesangial cell injury, leading to glomerulosclerosis, and that these same proteins also have adverse effects on proximal tubular cell function. Numerous studies have demonstrated that proteinuria is a potent risk marker for progression of renal disease in both nondiabetic and diabetic kidney disease. Furthermore, reducing protein excretion slows the rate of progression of proteinuric kidney disease. T is has been observed in clinical trials in patients treated with (1) angiotensin-converting enzyme (ACE) inhibitors and (2) angiotensin II receptor blockers (ARBs), either alone or in combination. T ese drugs reduce protein loss by reducing intraglomerular filtration pressure and possibly by stabilizing the glomerular epithelial cell slit diaphragm proteins. Consequently, reduction of proteinuria is an important therapeutic target.

Sample Collection Considerations

Extensive discussion has occurred in the literature about the appropriate urine sample to use for the investigation of protein loss. It is generally recognized that a 24-hour sample is the definitive means of demonstrating the presence of proteinuria. However, in practice, (1) overnight, (2) first void in the morning (early morning urine [EMU]), (3) second void in the morning, or (4) random sample collections have also been used. Since creatinine excretion in the urine is fairly constant throughout the 24-hour period, measurement of protein/creatinine (or albumin/creatinine) ratios allows correction for variations in urinary concentration. It is now a generally accepted practice to substitute the protein/creatinine ratio for 24-hour total protein excretion measured from a 24-hour collection. An EMU sample is preferred since it correlates well with 24-hour protein excretion and is required to exclude the diagnosis of orthostatic (postural) proteinuria. However, a random urine sample is acceptable if no early morning sample is available. If required, daily protein excretion (in mg/24 hours) is roughly estimated as numerically equal to the protein/creatinine ratio (measured as mg/g) as creatinine excretion is about 1g/day. In SI units, multiply the protein/creatinine ratio (measured in mg/mmol) by a factor of ten since an average figure of 10 mmol creatinine per day is assumed. A suitable protocol for the further investigation of patients found to have proteinuria at screening is given in Figure 35-5.

Measurement of Urinary Protein

T ere are numerous methods used for the measurement of total protein in urine. Discussion of several of these methods is found in Chapter 18. Detection of protein using reagent strips is discussed later.

Pathophysiology of Kidney Disease

Despite the diverse initial causes of injury to the kidney, progression of kidney disease leading to loss of function and ultimately to kidney failure is a process characterized by (1) early inflammation, (2) accumulation and deposition of extracellular matrix, (3) tubulointerstitial fibrosis, (4) tubular atrophy, and (5) glomerulosclerosis (scarring). Upregulation of angiotensin II within the kidney directly (causing increasing glomerular permeability to protein) and indirectly (stimulating pro-inflammatory cytokines) contributes to these changes. Proteinuria is one of the most important risk factors for progression of kidney disease. Angiotensin II is an important therapeutic target in kidney disease.

T e kidneys have considerable ability to increase their functional capacity in response to injury. T us, a significant reduction in functioning renal mass (50% to 60%) may occur before any major biochemical alterations appear and symptoms appear. T e most sensitive and specific measure of functional change, the GFR, is reduced to less than 60 mL/min/1.73 m^2 before signs and symptoms of kidney failure are observed. An increase in workload per nephron is thought to be an important cause of progressive renal injury.

Diagnosis and Screening for Kidney Disease

T e patient with kidney disease generally presented with (1) an abnormality detected on a routine biochemical blood screen or urinalysis, (2) a symptom or physical sign, or (3) with a systemic disease with a known renal involvement, such as diabetes mellitus. Unfortunately, as many as 30% of individuals see a clinician very late in their disease and may require urgent dialysis with no previous experience with the specialist nephrology service. T ese patients have a poor prognosis. T erefore, early recognition of kidney disease is thought to be of vital importance to outcome.

Effective management of the patient with kidney disease is dependent upon establishing a definitive diagnosis. Initial management includes a (1) detailed clinical history, (2) clinical examination, and (3) urinalysis and assessment of the urinary sediment.

Urinalysis

Examination of the urine is an important step in the assessment of a patient suspected of having, or confirmed to have

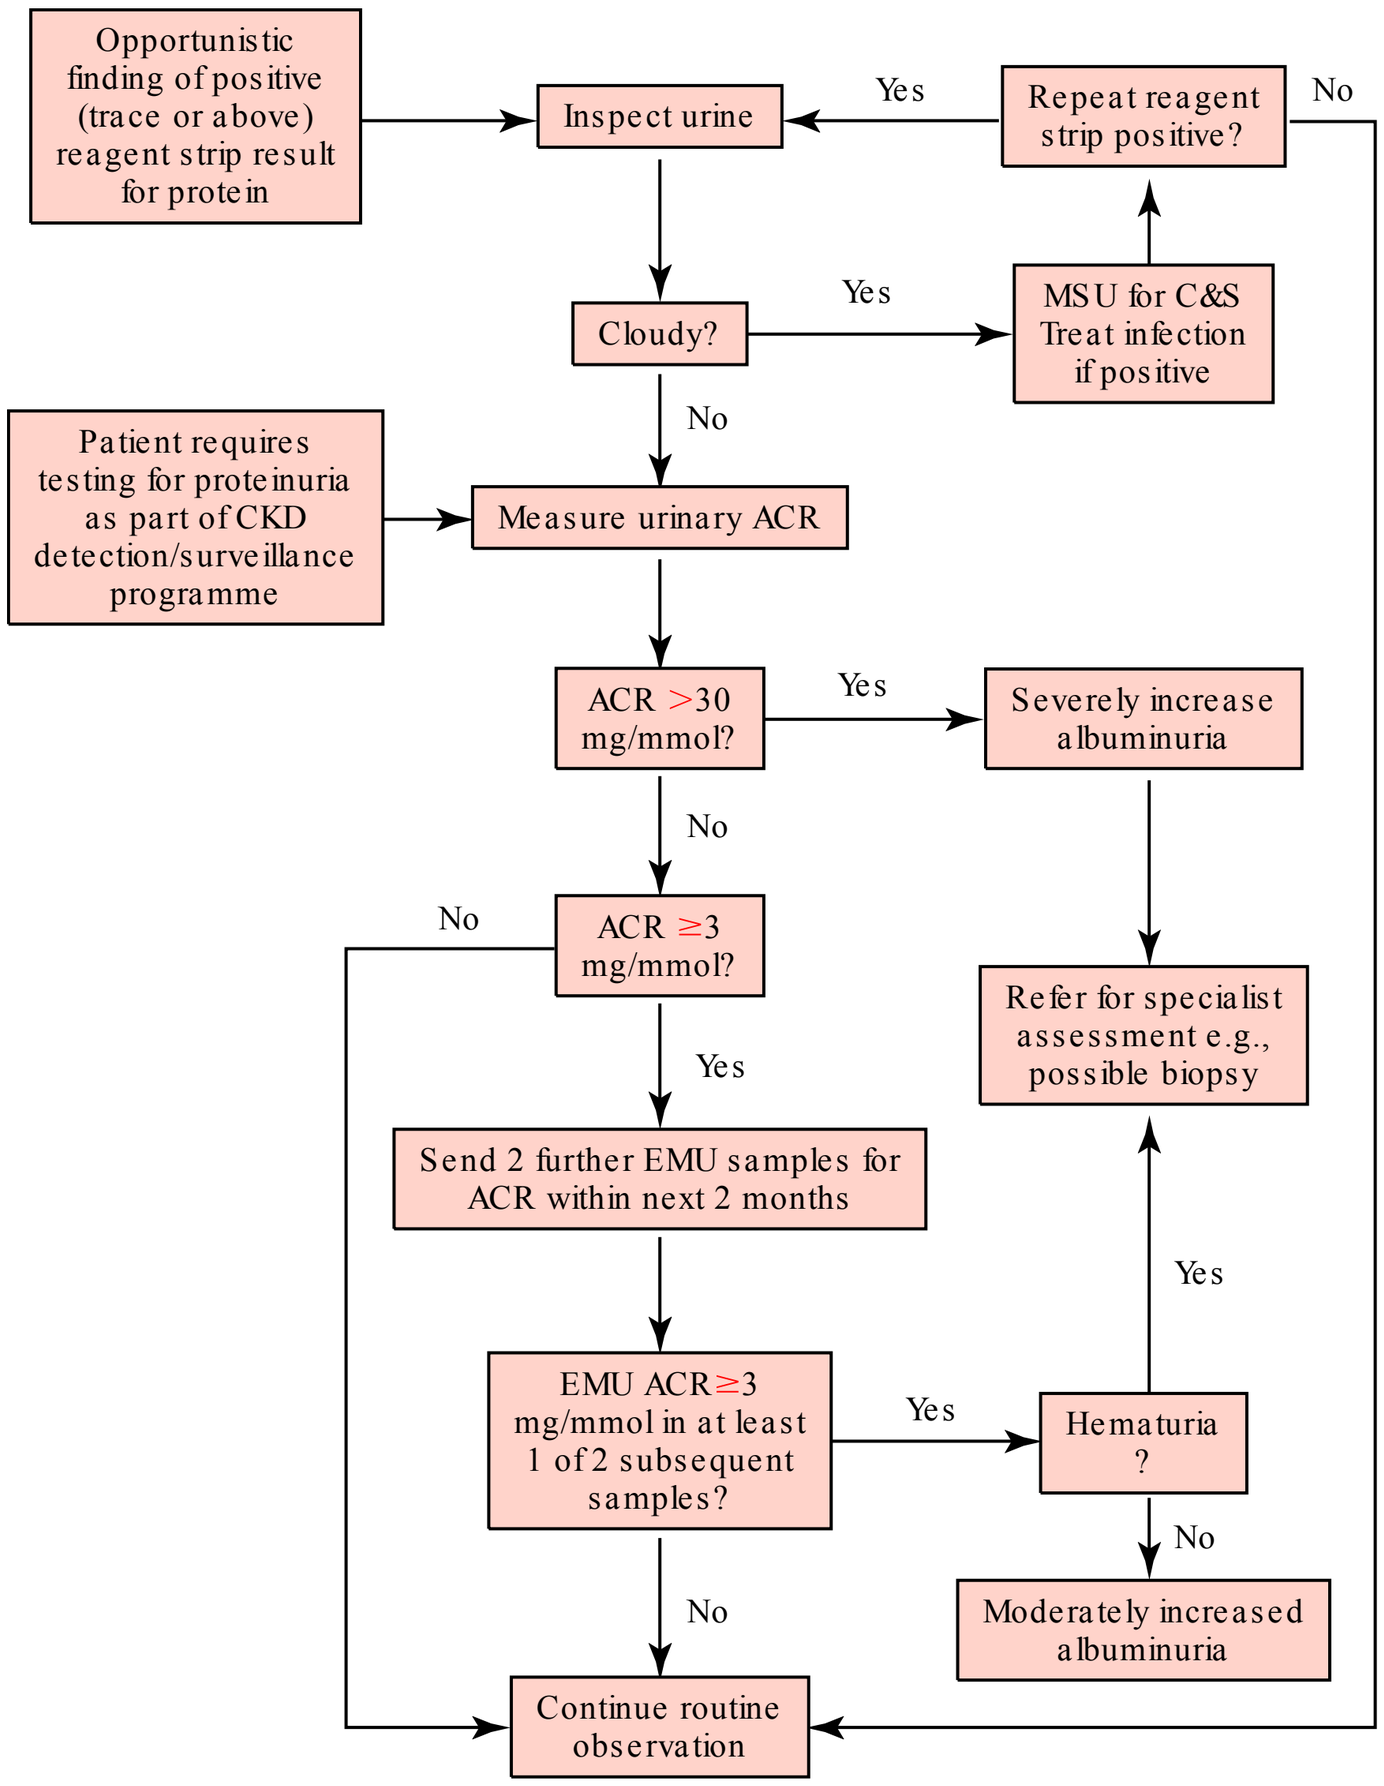

Figure 35-5 Suggested protocol for the further investigation of an individual demonstrating a positive reagent strip test for albuminuria/proteinuria or quantitative albuminuria/proteinuria test. Reagent strip device results should be confirmed using laboratory testing of the albumin-to-creatinine ratio (ACR) on at least two further occasions. Patients with two or more positive (≥ 3 mg albumin/mmol creatinine) tests on early morning samples 1 to 2 weeks apart should be diagnosed as having persistent albuminuria. The possibility of postural proteinuria should be excluded by the examination of an early morning urine (EMU) specimen. Protein-to-creatinine ratio (PCR) measurement can be substituted for the ACR but is insensitive in the detection of moderately increased albuminuria/proteinuria: approximate PCR equivalent to an ACR of 30 mg/mmol is 50 mg/mmol. Consider other causes of increased ACR, such as (1) menstrual contamination, (2) uncontrolled hypertension, (3) symptomatic urinary tract infection, (4) heart failure, (5) other transitory illnesses, and (6) strenuous exercise, especially in the case of type 1 diabetes present for less than 5 years. The presence of hematuria may indicate non-diabetic renal disease. C&S, Culture and sensitivity; CKD, chronic kidney disease; MSU, mid-stream urine.

deterioration in kidney function. In the laboratory, urine is examined (1) visually, (2) chemically, and (3) microscopically. The appearance (color and odor) of urine itself is often helpful with a darkening from the pale normal straw color indicating more concentrated urine or the presence of another pigment. Hemoglobin and myoglobin give a pink-red-brown coloration, depending on the concentration. Turbidity in a fresh sample may indicate infection, but may also be due to fat particles in a patient with **nephrotic syndrome**. Excessive foaming of urine when shaken suggests proteinuria. Urine is often chemically evaluated with the help of reagent strip ("dipstick") tests. Regarding dipstick technology, many tests of renal significance have been adapted for use on strips of cellulose or pads of cellulose on strips of plastic that have been coated or impregnated with reagents for the analyte in question. A reagent strip may contain reagents for just one test per stick or reagents for multiple tests on a single stick. For example, up to 10 constituents are now measured on a single strip allowing for detection of multiple abnormalities simultaneously. Clinically, proteinuria and **hematuria** are the most important of these in suspected kidney disease. Urine samples for testing should be collected in sterile containers and testing performed on the fresh urine. Reagent strips should be used only if they have been stored properly desiccated, because some deteriorate in a matter of hours.

Proteinuria is a common finding in patients with kidney disease, and the use of a reagent strip is a common screening test in any individual suspected of having renal disease. Annual urinalysis for proteinuria is accepted as a useful way of identifying patients at risk of progressive kidney disease but is inadequate for the detection of CKD among patients with diabetes, who should undergo annual testing for albuminuria using sensitive immunoassay techniques. Increasingly, it is argued that quantitative measurement of albumin or total protein should replace reagent strip approaches in all patients with, or at risk of, CKD. The reagent strip for total protein includes a cellulose test pad impregnated with tetrabromophenol blue and a citrate buffer having a pH of 3. The reaction

is based on the "protein error of indicators" phenomenon in which certain chemical indicators demonstrate one color in the presence of protein and another in its absence. T us tetrabromophenol blue is green in the presence of protein at pH 3 but yellow in its absence. T e color is read after exactly 60 s and the test has a lower limit of detection of 150 to 300 mg/L, depending on the type and proportions of proteins present. T e reagent is most sensitive to albumin and less sensitive to (1) globulins, (2) **Bence-Jones protein**, (3) mucoproteins, and (4) hemoglobin.

T e presence of hemoglobin in the urine may be due to (1) glomerular, (2) tubulointerstitial, or (3) postrenal disease, although the latter two causes are the more common. T e presence of blood in urine is detected by the use of a phase contrast microscope to determine the presence of red cells in urine sediment or by use of a reagent strip test. T e chemical detection of hemoglobin in urine depends on the peroxidase activity of the protein, employing a peroxide substrate and an oxygen acceptor. For this test, the reagent pad is impregnated with buffered tetramethyl benzidine (TMB) and an organic peroxide, cumene hydroperoxide. T e color change varies from orange through pale to dark green, and red cells or free hemoglobin are detected together with myoglobin. Again the color of the reagent pad should be compared with a color chart after exactly 60 s. Two reagent pads are employed for the low hemoglobin concentration. If intact red cells are present, the low-concentration pad will have a speckled appearance; a solid color indicates hemolyzed red cells. T e test is equally sensitive to hemoglobin and to myoglobin. T e presence of free hemoglobin or red cells in the urine indicates the presence of renal or bladder disease. Hematuria is often present in a number of kidney diseases, including (1) **glomerulonephritis**, (2) polycystic kidney disease, (3) sickle cell disease, (4) vasculitis, and (5) several infections. A spectrum of urological diseases may also give rise to hematuria, including (1) bladder malignancy, (2) prostate malignancy, (3) pelvic malignancy, (4) ureteral malignancy, (5) kidney stones, (6) trauma, (7) bladder damage, and (8) ureteral stricture.

Microscopic examination of the sediment obtained from the centrifugation of a fresh urine sample will show the presence of (1) a few cells (erythrocytes, leukocytes, and cells derived from the kidney and urinary tract), (2) casts (composed predominantly of THG), and (3) possibly fat or pigmented particles. An increase in red cells or casts implies hematuria, possibly caused by glomerular disease. White cells or casts imply the presence of white cells in the tubules. Inflammation of the upper urinary tract may result in polymorphonuclear leukocytes and various types of casts, and in lower urinary tract inflammation the casts will not be present. In acute glomerulonephritis, hematuria may lead to coloration of urine and the presence of large numbers of red cells and white cells; as the duration of the disease increases, the amount of sediment diminishes.

Biochemical measurements, particularly of plasma creatinine concentration (see earlier and Chapter 21) and estimated GFR, play an important role in the discovery that kidney damage has occurred and in monitoring progress and treatment.

Noninvasive imaging using ultrasonography is invaluable for identifying the size and shape of the kidneys along with any evidence of obstruction. However, percutaneous kidney biopsy is routinely performed to (1) confirm the diagnosis, (2) guide treatment, and (3) gain information regarding prognosis.

Classification of Kidney Failure

T e terminology associated with kidney diseases has been revised. Previously, renal failure was divided into either acute renal failure (ARF) or chronic renal failure (CRF). T ese terms indicate the rate at which damage occurs rather than the mechanism by which it occurs. Seminal guidelines published in 2002 by the United States National Kidney Foundation-Kidney Disease Outcomes Quality Initiative (NKF KDOQI) classified CKD by categories of GFR, characterized by differing levels of metabolic decompensation (Table 35-3).[15] T e term "renal" has largely been replaced by "kidney" when referring to chronic disease since it is more easily understood by patients and nonspecialists. In addition, "acute renal failure" has been replaced by **acute kidney injury (AKI)**.

Acute Kidney Injury

T e definition of AKI, endorsed by the Kidney Disease Improving Global Outcomes (KDIGO) during 2012, is the occurrence of any one of the following[4,7]:

(1) Increase of plasma creatinine by ≥ 0.3 mg/dL (≥ 26 umol/L) within 48 hours
(2) Increase in plasma creatinine to ≥ 1.5 times baseline, which is known or presumed to have occurred within the prior 7 days
(3) Reduction in urine output (documented oliguria < 0.5 mL/kg/h for > 6 hours)

In addition, AKI is staged 1 to 3, depending on severity. In the UK, the National Confidential Enquiry into Patient Outcome and Death reported that failure (1) to identify intravascular volume depletion, (2) to withhold nephrotoxic drugs, and (3) of early diagnosis of causative conditions (such as, sepsis) directly contributed to in-hospital mortality associated with AKI (http://www.ncepod.org.uk/2009report1/Downloads/AKI_summary.pdf/accessed September 16, 2013).

Patients at risk for AKI include (1) older persons; those with (2) pre-existing CKD, (3) sepsis, (4) diabetes, and (5) heart disease; and (6) patients receiving nephrotoxic drugs, particularly in the setting of hypovolemia. Clinical assessment of AKI should consider whether the precipitant is (1) prerenal, (2) intrarenal (intrinsic), or (3) postrenal. T e most common causes are listed in Box 35-1. As intrinsic AKI is caused by primary (1) vascular, (2) glomerular, or (3) interstitial disorders, it is important that all patients presenting with AKI undergo urinalysis to test for (1) infection, (2) hematuria, and (3) proteinuria. In most cases, the kidney lesion seen on histology is referred to as **acute tubular necrosis (ATN)**. ATN is caused by ischemic or nephrotoxic

TABLE 35-3 Kidney Disease Improving Global Outcomes 2012 Classification of Chronic Kidney Disease by Glomerular Filtration Rate and Albumin Excretion Rate*

Glomerular Filtration Rate (GFR)

Category	GFR (mL/min/1.73 m^2)	Terms	Metabolic consequences	Management
G1†	≥ 90	Normal or high		• Diagnosis and treatment • Treatment of comorbid conditions • Slowing progression • CVD risk reduction
G2†	60-89	Mildly decreased‡	• Concentration of PTH starts to rise (GFR 60-80)	• Estimating progression
G3a	45-59	Mildly to moderately decreased	• Decrease in calcium absorption (GFR < 50) • Lipoprotein lipase activity falls	• Evaluating and treating complications
G3b	30-44	Moderately to severely decreased	• Malnutrition • Onset of LVH • Onset of anemia (EPO deficiency)	
G4	15-29	Severely decreased	• Triglyceride concentrations start to rise • Hyperphosphatemia • Metabolic acidosis • Tendency to hyperkalemia	• Preparation for RRT if appropriate
G5	< 15	Kidney failure (add D if treated by dialysis)	• Uremic syndrome	• RRT if appropriate

Albumin Excretion Rate (AER)

Category	AER	Approximately Equivalent ACR		Terms
	(mg/d)	(mg/mmol)	(mg/g)	
A1	< 30	< 3	< 30	Normal to mildly increased
A2	30-300	3-30	30-300	Moderately increased†
A3	> 300	> 30	> 300	Severely increased§

*Broad metabolic consequences and management are indicated.
†Neither GFR category G1 nor G2 without markers of kidney damage fulfil the criteria for chronic kidney disease (CKD).
‡Relative to young adult level.
§Including nephrotic syndrome (albumin excretion usually >2200 mg/d).
AER, Albumin exretion rate; ACR, albumin-to-creatinine ratio; CVD, cardiovascular disease; EPO, erythropoietin; GFR, glomerular filtration rate; LVH, left ventricular hypertrophy; PTH, parathyroid hormone; RRT, renal replacement therapy.

BOX 35-1 Causes of Acute Kidney Injury

Prerenal AKI
- Hemorrhage
- Diarrhea
- Postoperative fuid and blood losses
- Sepsis
- Acute cardiac failure

Intrinsic renal disease
- Tubular
- Glomerular
- Vascular

Any of the prerenal causes that are severe or that are not corrected promptly leading to ATN

Other causes of ATN
- Drug nephrotoxicity
- NSAIDs, ACE inhibitors
- Aminoglycoside antibiotics
- Amphotericin

TIN
- Allergic TIN associated with antibiotics and NSAIDs
- Sarcoidosis
- Pyelonephritis

Renal parenchymal disease

RPGN: (1) ANCA-associated vasculitides, (2) Goodpasture disease, (3) SLE, (4) other crescentic glomerulonephritides
- Thrombotic microangiopathies
- Cryoglobulinemia

Myeloma

Miscellaneous
- Contrast nephropathy
- Poisoning
- Rhabdomyolysis
- Atheroembolism
- Urate nephropathy
- Hepatorenal syndrome

Vascular causes
- Aortic dissection
- Renal vein thrombosis

Postrenal AKI

Bladder outfow obstruction
- Benign and malignant prostate disease
- Invasive bladder carcinoma

Bilateral renal calculi or calculi within a single kidney

Retroperitoneal fibrosis

ACE, Angiotensin-converting enzyme; AKI, acute kidney injury; ANCA, antineutrophil cytoplasmic antibody; ATN, acute tubular necrosis; NSAIDs, nonsteroidal antiinfammatory drugs; RPGN, rapidly progressive glomerulonephritis; SLE, systemic lupus erythematosus; TIN, tubulointerstitial nephritis.

TABLE 35-4 Investigation of Acute Kidney Injury

Test	Indication/Comments
Urine Testing	
Urine reagent strip ("dipstick")	Hematuria and proteinuria may indicate glomerular origin
Red cell casts on microscopy	Not available universally; may need bedside microscope
Urine microscopy and culture	Identify urinary tract infection
Urine protein electrophoresis and immunofixation	
Blood Tests	
Baseline Studies	
Urea, electrolytes, creatinine, and calcium, phosphate, albumin	Check previous laboratory reports: AKI or AKI with preexisting CKD
Liver function tests	Suspected multiorgan involvement or abnormal coagulation
Acid-base studies	Arterial blood gas or venous plasma bicarbonate concentration
Full blood count	Anemia, hemolysis, thrombocytopenia
Coagulation studies	Evidence of intravascular coagulation; need to normalize if considering kidney biopsy and central line insertion
Selected Additional Investigations	
Blood culture	Any infection but especially endocarditis, severe pneumonia, or urinary tract sepsis
CK	Very high in cases of muscle inflammation and necrosis (rhabdomyolysis)
LD	If high, suspect renal infarction and consider hemolysis
Antineutrophil cytoplasmic antibodies	Vasculitides
Anti–glomerular basement membrane antibody	Anti–glomerular basement membrane disease
Antinuclear antibodies	SLE
Anti-dsDNA antibodies, ENAs	SLE
Low C4 complement	SLE, atheroembolism, cryoglobulinemia
Cryoglobulin	Cryoglobulinemia
Urate	Urate nephropathy
Serum protein electrophoresis	Myeloma
Virology studies	Hepatitis serology, antistreptolysin O titer, HIV
Imaging	
Chest x-ray	Pulmonary edema, pneumonia, effusions, malignancy, granulomas
Abdominal x-ray (kidney, ureter, and bladder)	Renal stones
Renal tract ultrasound scan	Identify size and symmetry of kidneys Evidence of an obstructed system Small shrunken kidneys in advanced CKD
CT scan	Anatomy and perfusion
Magnetic resonance imaging	Angiography to identify renovascular lesions
Formal angiography	Critical renal artery stenosis
Kidney biopsy	Reserved for patients with unexplained AKI in whom ATN is not suspected; it is anticipated that additional therapy (such as, steroids, cytotoxic drugs, and plasma exchange) may be required

AKI, acute kidney injury; ATN, acute tubular necrosis; CK, creatine kinase; CKD, chronic kidney disease; CT, computed tomography; dsDNA, double-stranded DNA; ENA, extractable nuclear antigen; HIV, human immunodeficiency virus; LD, lactate dehydrogenase; SLE, systemic lupus erythematosus.

injury to the kidney. In 50% of cases of hospital-acquired AKI, the cause is multifactorial.[17]

Laboratory testing of blood is crucial in the management of AKI. Blood tests also assist in establishing the underlying diagnosis, and specific investigations are requested if kidney function has not improved following volume correction. An acute renal screen should clearly focus on most likely diagnoses and include the tests shown in Table 35-4.

In addition to biochemical testing, there is a role for ultrasound and radiological imaging in kidney disease and in particular exclusion of obstruction is important. Kidney biopsy is generally reserved for cases of AKI wherein an ultrasound scan has excluded obstructed kidneys, kidney sizes are maintained and the cause of AKI is otherwise unexplained, and an intrinsic pathology is suspected.

Metabolic acidosis is the most common acid-base disorder in patients with AKI. Reduced renal excretion of potassium and the effects of **acidosis** on the generation of extracellular potassium may lead to a very high concentration of potassium in the plasma. Severe hyperkalemia (plasma potassium concentration more than 6.5 mmol/L) is associated with life-threatening cardiac arrhythmias. Emergency treatment of hyperkalemia should be instituted as necessary. When hyperkalemia persists despite appropriate medical measures, then dialysis should be considered. Recovery from AKI usually occurs within days or weeks following removal of the initiating event. However, uncomplicated AKI has a mortality rate of 5% to 10% although AKI complicating nonrenal organ system failure in the intensive care unit setting is associated with mortality rates approaching 50% to 70%.

Chronic Kidney Disease

Studies established to identify the (1) incidence, (2) causes, and (3) complications of CKD have focused on advanced disease and kidney failure. Markers used to to identify CKD include (1) plasma creatinine, (2) estimated GFR, and (3) measured creatinine. Guidelines introduced over the past 10 years have attempted to evaluate, classify, and stratify CKD (see Table 35-3).[5,9,15] In these Guidelines, CKD is defined as abnormalities of kidney structure or function, present for more than 3 months with implications for health. A GFR of less than 60 mL/min/1.73 m^2 is considered decreased, and a GFR of less than 15 mL/min/1.73 m is considered kidney failure. Kidney damage is defined by structural abnormalities or functional abnormalities other than decreased GFR and may include (1) albuminuria, (2) urine sediment abnormalities, (3) electrolyte and other abnormalities due to tubular disorders, (4) abnormalities detected by histology, (5) structural abnormalities detected by imaging, or (6) a history of kidney transplantation.[5]

The 2002 NKF KDOQI guideline[15] stratified CKD by GFR from stage 1 at the mild end of the spectrum to stage 5, kidney failure, or a GFR of less than 15 mL/min/1.73 m^2, which encompasses those patients that require RRT to sustain life. Although the cutoff values between these stages are arbitrary, the scheme allows for consistency in prevalence reporting for epidemiological studies and also focused treatment schedules for individual patients (see Table 35-3). Guidelines published in 2013 by KDIGO[5] built upon and refined this classification. The GFR categories have been retained, with the exception that GFR category 3 has been split into 3a (mildly to moderately decreased, 45 to 59 mL/min/1.73 m^2) and 3b (moderately to severely decreased, 30 to 44 mL/min/1.73 m^2s), reflecting the different (1) metabolic, (2) prognostic, and (3) management features of these two situations. In addition, a second dimension has been added to the classification scheme based on the degree of albuminuria (see Table 35-3). Albuminuria categories are assigned based on daily urinary albumin loss, generally measured as an albumin-to-creatinine ratio (ACR): A1 (< 30 mg/day, ACR < 30 mg/g, < 3 mg/mmol), A2 (30 to 300 mg/day, ACR 30 to 300 mg/g, 3 to 30 mg/mmol) and A3 (> 300 mg/day, ACR > 300 mg/g, > 30 mg/mmol). Risk of death and kidney disease progression increases incrementally with declining GFR and increasing albuminuria. As an example of how the system is applied, a patient with a GFR of 50 mL/min/1.73 m^2 and no albuminuria would be assigned CKD stage G3a, A1, whereas a patient with a GFR of 20 mL/min/1.73 m^2 and ACR 50 mg/mmol would be assigned CKD stage G4, A3.

The main causes of CKD leading to kidney failure from 1990 to 2009 in the United States are indicated in Figure 35-6. As indicated, diabetes mellitus is the largest single cause of advanced CKD and accounts for 44% of new dialysis patients in the United States. **Hypertension** is the underlying diagnosis in around 28% of new dialysis patients and is particularly prevalent among African-Americans. In addition the rate of new ESRD in African-Americans is 3.5 times higher than whites. The myriad of kidney diseases, including

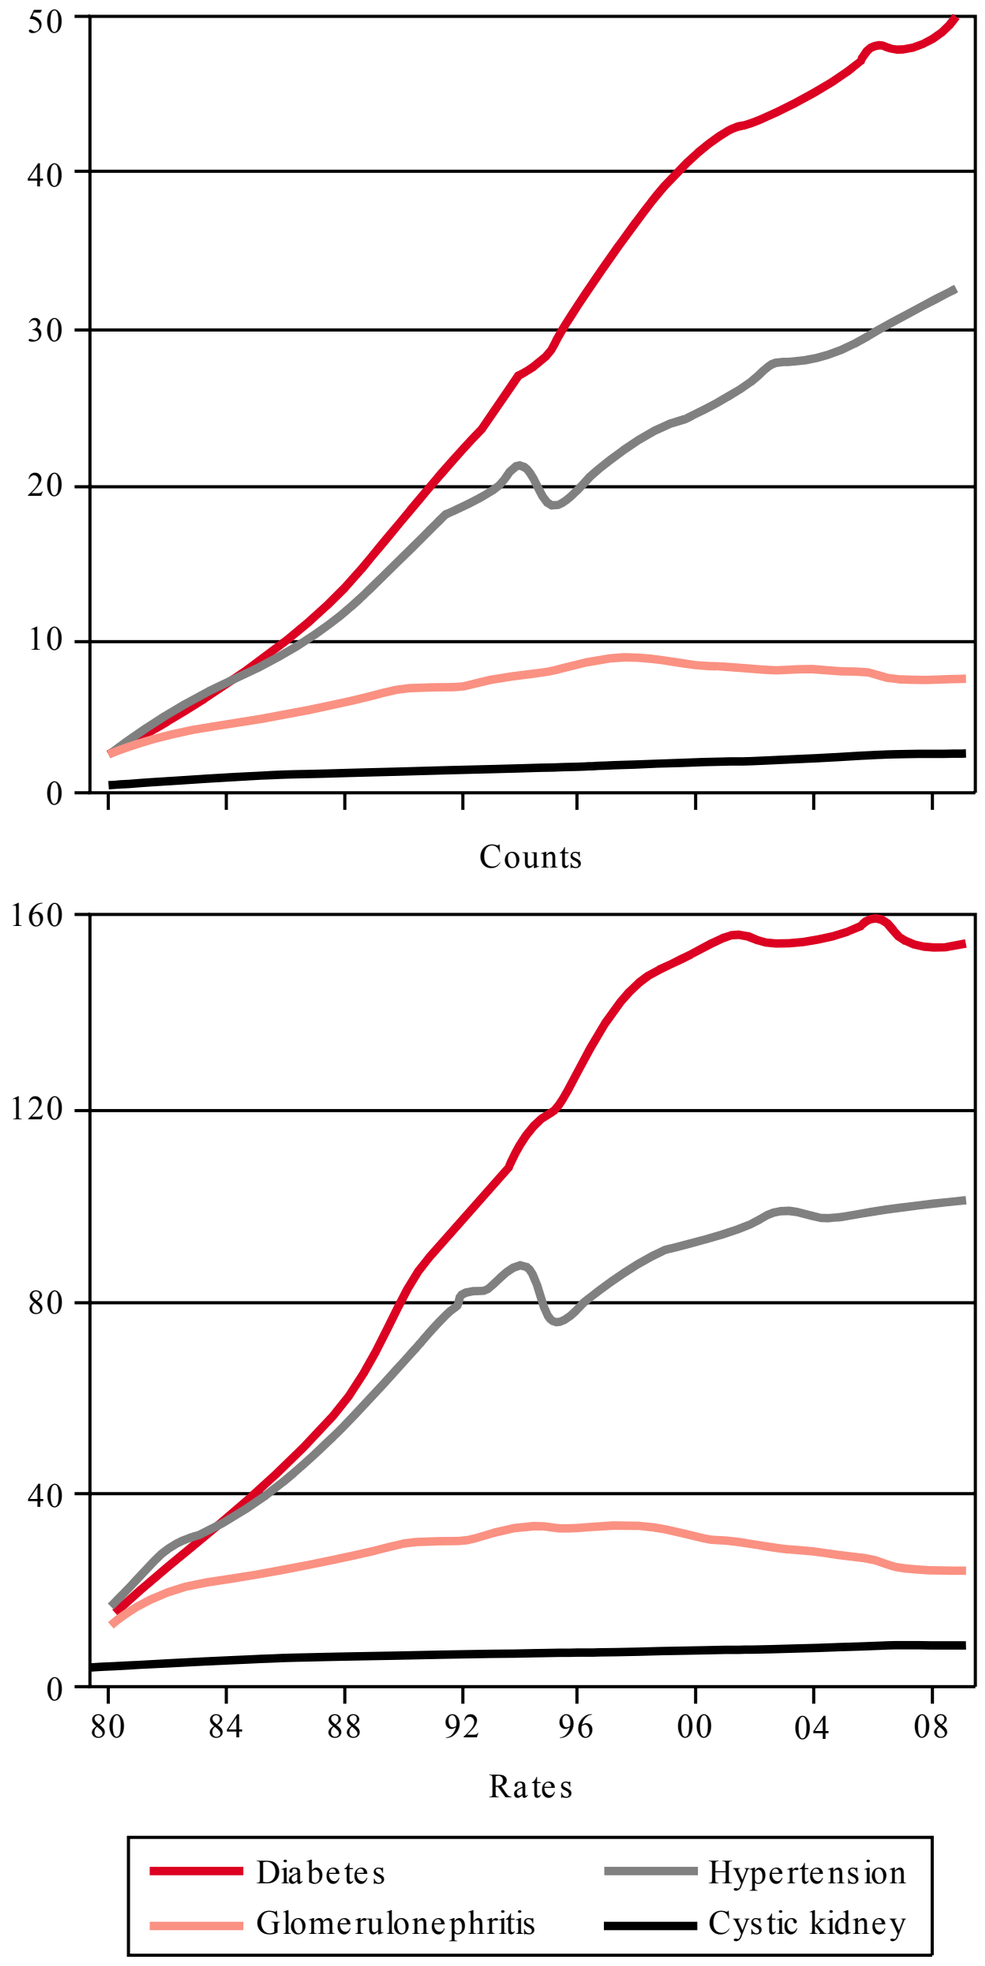

Figure 35-6 Trends in incident rates of end-stage renal disease (ESRD) by primary diagnosis. Diabetes is the primary cause of ESRD in 44% of adult dialysis patients in the United States in 2009. The overall incidence of ESRD has increased since the 1980s, and diabetes and hypertension account for this increase. The incidence of ESRD as a consequence of glomerulonephritis and cystic kidney diseases has not increased. (http://www.usrds.org/2011/pdf/v2_ch01_11.pdf, accessed online April 09, 2013.) (US Renal Data System, USRDS 2011 Annual Data Report: Atlas of End-Stage Renal Disease in the United States, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, 2011. The data reported here have been supplied by the United States Renal Data System (USRDS). The interpretation and reporting of these data are the responsibility of the author(s) and in no way should be seen as an official policy or interpretation of the US government. http://www.usrds.org/2011/pdf/v2_ch01_11.pdf; accessed online September 16, 2013.)

(1) glomerulonephritis, (2) infection, (3) hereditary conditions, (4) systemic conditions, (5) interstitial conditions, (6) obstructive conditions, and (7) those of unknown origin.

Management of Chronic Kidney Disease

Rate of progression of CKD is dependent on both non-modifiable and modifiable factors. Non-modifiable factors include (1) age, (2) sex, (3) race, and (4) level of kidney function at diagnosis. Modifiable factors include (1) proteinuria, (2) blood pressure, and (3) smoking.

Lowering blood pressure and reduction of proteinuria have been shown to decrease the progression of CKD. The MDRD Study compared the rates of decline in GFR in patients with various causes of CKD assigned to either a "usual" or "low" blood pressure goal. Outcome data suggest that the low blood pressure goal had some beneficial effect in those patients with higher concentrations of proteins in their urine. In practice, medications that inhibit parts of the renin-angiotensin-aldosterone system (RAAS) blockade are typically preferred, because these drugs have been demonstrated to reduce proteinuria and rate of progression of CKD.

Protein intake is restricted spontaneously to approximately 0.6 to 0.8 g/kg/day in uremic patients not receiving dietary advice. To prevent malnutrition, patients receive professional dietary advice with diets containing an increased proportion of high quality protein and increased calorie content of up to 35 kcal/kg/day. General health measures, including cessation of cigarette smoking, are encouraged. Complications of CKD that develop before the need for RRT are numerous and include (1) cardiovascular disease, (2) bone disease, and (3) anemia. Albuminuria and proteinuria have been shown to be associated with increased risk of cardiovascular disease, cardiovascular mortality, and all-cause mortality.

Cardiovascular Complications of Chronic Kidney Disease

The incidence of cardiovascular disease is sevenfold to tenfold greater in patients with CKD than in non-CKD age- and sex-matched controls and by the time patients develop the need for RRT the risk increases to approximately seventeen times greater.

The spectrum of cardiovascular disease studied in CKD includes (1) angina, (2) congestive heart failure, (3) myocardial infarction, (4) peripheral vascular disease, (5) stroke, and (6) transient ischemic attack. Structural heart disease, such as left ventricular hypertrophy (LVH) and valvular heart disease, is very common. The risk factors for cardiovascular disease in CKD are a mixture of the traditional and CKD-specific (Table 35-5). Vascular calcification is highly prevalent in dialysis patients and is associated with reduced survival.

Dyslipidemia in Chronic Kidney Disease

The pattern of dyslipidemia (abnormal amount of lipids in the blood) in CKD differs from that seen in non-CKD. Although total cholesterol concentration may be within reference intervals for a healthy population, there is often a highly abnormal lipid subfraction profile with a predominance of atherogenic, small, dense LDL particles. In addition triglyceride concentrations are high. Low cholesterol is associated with increased mortality in dialysis patients, likely reflecting coincident inflammation and malnutrition ("reverse causality").

TABLE 35-5 Traditional and Chronic Kidney Disease–Related Risk Factors for Cardiovascular Disease

Traditional Risk Factors for Cardiovascular Disease	CKD-Related Risk Factors for Cardiovascular Disease
Older age	Extracellular fluid overload
Male sex	LVH
White race	Proteinuria
Hypertension	Anemia
Elevated LDL cholesterol	Abnormal calcium phosphorus metabolism
Decreased HDL cholesterol	Dyslipidemia
Diabetes mellitus	MIA syndrome
	Infection
Smoking	Thrombogenic factors
Sedentary life-style	Oxidative stress
Menopause	Elevated homocysteine
Family history	Uremic toxins

CKD, Chronic kidney disease; HDL, high-density lipoprotein; LDL, Low-density lipoprotein; LVH, left ventricular hypertrophy; MIA, malnutrition inflammation atherosclerosis.

Although there are no data to suggest that statins are of benefit in patients receiving dialysis the Study of Heart and Renal Protection (SHARP) evaluated the use of cholesterol lowering with simvastatin and ezetimibe in 9,000 patients (including 3,000 dialysis patients) and demonstrated significant reductions in stroke and arterial revascularization in the treated patients followed for a median of 4.9 years.[1]

Disturbances in Calcium and Phosphate Metabolism and Bone Disease in Chronic Kidney Disease

Bone disease as a consequence of CKD has long been recognized.[13] As GFR declines, both renal excretion of phosphorus and renal activation of vitamin D decrease reducing ionized calcium. Consequently, the parathyroid glands increase the production of PTH. This increased secretion of PTH stimulates resorption of calcium and phosphate from the bone, the body's major calcium reservoir. Problems develop early, typically once GFR has fallen to approximately 45 mL/min/1.73 m^2. Secondary hyperparathyroidism classically causes (1) bone changes, (2) so-called high turnover bone disease, and (3) increased risk of fracture. In addition, up regulation of the phosphaturic, fibroblast growth factor 23 (FGF23) occurs early in CKD and this contributes to maintaining plasma phosphate concentrations within the reference interval despite GFR falling below 30 mL/min/1.73 m^2 (and often much lower).

"Adynamic" bone disease is also highly prevalent in patients with CKD and is characterized by poor bone formation. It is more common in the elderly and those with diabetes and malnutrition. Adynamic bone is associated with (1) a low PTH concentration, (2) abnormal calcium balance,

(3) hyperphosphatemia, (4) acidosis and (5) the use of high doses of vitamin D analogs. Vascular calcification is commonly associated with adynamic bone disease.

High concentrations of plasma phosphate are associated with increased mortality in hemodialysis (HD) patients. Tactics to reduce phosphate concentrations are employed routinely in the treatment of patients on dialysis. Phosphate is present in many foods and is linearly associated with protein ingestion. The recommended allowance of phosphate is reduced for patients on dialysis to around 800 mg/d. Treatment with vitamin D analogs increases gut absorption of phosphate from approximately 65% to almost 85%. The use of phosphate binders, taken with meals, is almost universal in dialysis patients and reduces phosphate absorption to 30% to 40%. It has been possible to regulate phosphate balance in patients treated by daily HD.

Anemia

The World Health Organization (WHO) defines anemia as a hemoglobin concentration of less than 13 g/dL in men and less than 12 g/dL in women. It is clearly established that anemia is inevitable as CKD progresses. Therapies are available to correct anemia, and therefore it is mandatory to assess a patient with CKD for anemia. The NKF KDOQI guideline recommends that an estimated GFR of less than 60 mL/min/1.73 m^2 should be the cutoff value for determining presence or absence of anemia.[16] Detection is important since treatment may alleviate many of the symptoms of CKD and hopefully reduce risk of LVH. The pathology of anemia in CKD is multifactorial but the predominant cause is loss of peritubular fibroblasts (specialized cells that produce collagen and other materials) within the renal cortex that synthesize EPO. Failure to produce EPO leads to decreased numbers of red cells and concomitant decreased concentrations of hemoglobin. Other causes of anemia include (1) absolute or functional iron deficiency, (2) folic acid and vitamin B_{12} deficiencies, and (3) chronic inflammation. Red cell survival may also be reduced. Treatment with recombinant erythropoiesis stimulating agents is recommended to correct anemia. The gene for human EPO was cloned in 1985 and (1) recombinant forms of EPO (rhEPO), (2) epoetin, or (3) erythropoietin stimulating agents [ESA]) were introduced into clinical practice shortly afterwards. The most common side effect is hypertension, and therefore blood pressure should be controlled before the introduction of treatment. The majority of patients respond to treatment. However, failure to respond requires thorough investigation for many potential causes, such as (1) occult blood loss, (2) hyperparathyroidism, (3) iron deficiency, (4) vitamin B_{12} deficiency (5) folate deficiency, and (6) inadequate dialysis. Many clinical benefits are derived from correcting anemia with ESAs, including (1) improved exercise capacity, (2) improved cognitive function, (3) better quality of life, and (4) increased libido. Later studies have, however, highlighted risks of high doses of ESA in non-dialysis CKD patients with associated increases mortality and cardiovascular morbidity. These studies have been instructive in setting the current hemoglobin target of 10.0 to 12.0 g/dL and in recommending ESA dose adjustments when hemoglobin is less than 10.5 or greater than 11.5 g/dL, to balance benefit versus safety to patients.

Assessment of Iron

Treatment of anemia in CKD requires adequate iron stores. For example, in patients with CKD, a concentration of plasma ferritin of less than 100 µg/L suggests iron deficiency, and a plasma ferritin of 100 to 200 µg/L in association with a transferrin saturation (TSAT) of less than 20% represents "functional" iron deficiency. Parenteral iron is the treatment of choice for absolute and functional iron deficiency since oral iron has low efficacy in CKD.

The Uremic Syndrome

The **uremic syndrome** is the group of (1) symptoms, (2) physical signs, and (3) abnormal findings on diagnostic studies that result from the failure of the kidneys to maintain adequate (1) excretory, (2) regulatory, and (3) endocrine function. It is considered the terminal clinical manifestation of kidney failure. At least 90 organic compounds have been shown to be retained in **uremia** (Box 35-2).

The classic signs of uremia (**azotemia**) include (1) progressive weakness and easy fatigue, (2) loss of appetite followed by (3) nausea and vomiting, (4) muscle wasting, (5) tremors, (6) abnormal mental function, (7) frequent but shallow respirations, and (8) metabolic acidosis. The syndrome evolves to produce (1) stupor, (2) coma, and (3) ultimately death unless support is provided by dialysis or successful kidney transplantation. The composition of plasma is abnormally labile in response to such factors as (1) diet, (2) state of hydration, (3) gastrointestinal bleeding, (4) vomiting, (5) diarrhea, and (6) intake of therapeutic drugs. Patients with stage 5 CKD (GFR of less than or equal to 15 mL/min/m^2) will generally exhibit signs and symptoms of uremia, or a need for RRT.

The most characteristic laboratory findings are increased concentrations of nitrogenous compounds in plasma, such as urea and creatinine, as a result of reduced GFR and decreased tubular function. Retention of these compounds and of metabolic acids is followed by progressive (1) hyperphosphatemia, (2) hypocalcemia, and potentially dangerous (3) hyperkalemia. Although most patients eventually exhibit acidemia, respiratory compensation by elimination of carbon dioxide is extremely important. In addition, reduced endocrine function is manifested by inadequate synthesis of EPO and calcitriol with resulting anemia and osteomalacia. Disordered regulation of blood pressure generally leads to hypertension. Biochemical characteristics of the uremic syndrome are summarized in Box 35-2.

In addition to the consequences of reduced (1) excretory, (2) regulatory, and (3) endocrine function of the kidneys, the uremic syndrome has several systemic manifestations—among them (1) pericarditis, (2) pleuritis, (3) disordered platelet and granulocyte function, and (4) encephalopathy.

Many retained metabolites have been implicated in the systemic toxicity of the uremic syndrome. Although urea was the

BOX 35-2 Biochemical Characteristics of the Uremic Syndrome

Retained Nitrogenous Metabolites
- Urea
- Cyanate
- Creatinine
- Guanidine compounds
- "Middle molecules"
- Uric acid

Fluid, Acid-Base, and Electrolyte Disturbances
- Fixed urine osmolality
- Metabolic acidosis (decreased blood pH, bicarbonate)
- Hyponatremia or hypernatremia or hyperkalemia
- Hyperchloremia
- Hypocalcemia
- Hyperphosphatemia
- Hypermagnesemia

Carbohydrate Intolerance
- Insulin resistance (hypoglycemia may also occur)
- Plasma insulin within reference interval or increased
- Delayed response to carbohydrate loading
- Hyperglucagonemia

Abnormal Lipid Metabolism
- Hypertriglyceridemia
- Decreased high-density lipoprotein cholesterol
- Hyperlipoproteinemia

Altered Endocrine Function
- Secondary hyperparathyroidism
- Osteomalacia (secondary to abnormal vitamin D metabolism)
- Hyperreninemia and hyperaldosteronism
- Hyporeninemia
- Hypoaldosteronism
- Decreased erythropoietin production
- Altered thyroxine metabolism
- Gonadal dysfunction (increased prolactin and luteinizing hormone, decreased testosterone)

first of these metabolites to be identified as being increased in uremia, it does not appear to be responsible for the systemic manifestations of uremia. Urea is a 60 Da water-soluble compound (see Chapter 21) that has the highest concentration of presently known uremic retention solutes in uremic plasma. Although its removal by dialysis is directly related to patient survival, the effects of urea on biological systems are not clear. Urea removal by dialysis is not necessarily representative of other molecules retained in the uremic syndrome, particularly protein bound solutes or middle molecules, such as PTH and cystatin C.

Other Diseases of the Kidney

Other kidney diseases discussed in this section include (1) diabetic nephropathy, (2) hypertensive nephropathy, (3) glomerular diseases, (4) interstitial **nephritis**, (5) polycystic kidney disease, (6) toxic nephropathy, (7) obstructive uropathy, (8) tubular diseases, (9) renal calculi, and (10) cystinuria. In addition, this section also includes discussions on prostaglandins and NSAIDs in kidney disease, and monoclonal light chains and kidney disease.

Diabetic Nephropathy

Diabetic nephropathy is a clinical diagnosis based on the finding of proteinuria in a patient with diabetes. Overt nephropathy is characterized by protein loss greater than 0.5 g/day. This is equivalent to albumin loss of around 300 mg/day. It is preferable to assess proteinuria as albuminuria, because it is a more sensitive marker for CKD due to diabetes. Consequently, there has been a uniform adoption of albumin as the "criterion standard" in evaluating diabetes-related kidney damage. Patients with a urinary albumin "excretion" rate exceeding 30 mg/day have pathologically increased albuminuria. Diabetic nephropathy is the most common cause of ESRD in the United States and accounts for approximately 40% of incident patients* in RRT programs. More than 100,000 people receiving HD in the United States have diabetes as the cause of their ESRD. Among patients who require dialysis, those with diabetes have a 22% higher mortality at 1 year and a 15% higher mortality at 5 years than patients without diabetes. Patients with type 1 diabetes and kidney failure with limited secondary complications of diabetes may be considered for simultaneous pancreas and kidney (SPK) transplantation. Tactics to reduce progression of CKD in patients with diabetes include (1) RAAS blockade, (2) attention to complications of CKD, and (3) reduction of cardiovascular risk. In addition, reaching optimal targets for glycemic control reduces the risk of progression.

Hypertension

Hypertension is second only to diabetes as a primary diagnosis of ESRD for incident patients commencing dialysis in the United States. From 2000-2009, there was an increase of approximately 9% in hypertension as the primary cause of ESRD accounting for around 33% of new ESRD patients. The incidence is higher in the elderly and especially among the black population in the United States. In addition, hypertension often develops as a consequence of CKD because of alterations in salt and water metabolism and activation of the sympathetic nervous and renin-angiotensin systems. Hypertension has been known to act as an accelerating force in the development of ESRD. Treatment of hypertension to predefined target blood pressure values is critical to preventing the progression to ESRD.

Glomerular Diseases

Clinically, there are a number of distinctive clinical syndromes that result from glomerular injury. Some of the more important are discussed below.

Individuals with primary glomerular disease present clinically with (1) abnormalities of the urine, including

*An incident patient is one who is receiving regular in-center hemodialysis or any type of peritoneal dialysis treatments for chronic renal failure at least once weekly for the first time. (http://www.usrds.org/download/1997/ch04.pdf/accessed September 16, 2013)

proteinuria and hematuria, (2) hypertension, (3) edema and, often, (4) reduced renal excretory function. Urinalysis should be ordered for patients presenting with hypertension or renal impairment or suspected of having kidney disease. Urinary casts are identified by microscopy, and red cell casts are indicative of glomerular bleeding and glomerular pathology. Laboratory tests performed to investigate glomerular disease and systemic disorders include (1) urinary protein, (2) plasma creatinine concentration and estimated GFR, (3) liver function tests, (4) plasma glucose concentration, (5) urinary examination for Bence Jones protein and, if myeloma is suspected, (6) serum protein electrophoresis. Serological testing for the presence of autoantibodies to (1) antinuclear antigens (ANAs), (2) double-stranded DNA (dsDNA), (3) extractable nuclear antigens (ENAs), and (4) antineutrophil cytoplasmic antibody (ANCA). The latter is measured if either SLE or systemic vasculitis is suspected. Antiglomerular basement membrane (anti-GBM) antibodies may be detected in rare cases of renal-limited anti-GBM disease (Goodpasture disease) and pulmonary-renal syndromes (Goodpasture syndrome). Components of the complement system sometimes are affected (e.g., reduced concentrations of complement C3 and C4) in several conditions, including (1) SLE, (2) infection, (3) cryoglobulinemia, and (4) mesangiocapillary (also referred to as membranoproliferative) glomerulonephritis. Blood cultures are taken for bacteriological examination in a case of suspected infection.

Immunoglobulin A Nephropathy

IgA nephropathy is the most common type of glomerulonephritis worldwide. The disease tends to be slowly progressive. For example, in 20 years 30% to 40% of affected patients will develop ESRD depending on the degree of (1) proteinuria and (2) GFR at the time of diagnosis and (3) interstitial fibrosis on biopsy. Biopsy findings are pathognomonic with deposition of polymeric IgA. Up to 50% of patients exhibit elevated concentrations of plasma IgA, although diagnosis depends on kidney biopsy findings. Current treatment strategies are unsatisfactory, but involve general measures to reduce proteinuria, and prednisolone therapy in selected cases.

Rapidly Progressive Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is a heterogeneous group of disorders characterized by a fulminating clinical course that leads to kidney failure in only weeks or a few months. These syndromes are often characterized by focal necrotizing glomerulonephritis and extracapillary crescent formation within the parietal layer of Bowman capsules. Proliferating epithelial cells and macrophages eventually compress the glomeruli and obstruct the proximal convoluted tubules, thus severely compromising nephron function.

Acute Nephritic Syndrome

The **acute nephritic syndrome** is characterized by the rapid onset of (1) hematuria, (2) proteinuria, (3) reduced GFR, and (4) sodium and water retention with resulting hypertension and localized peripheral edema. This is generally caused by a proliferative process causing marked glomerular inflammation. In contrast, nephrotic syndrome is characterized by heavy proteinuria but not typically hematuria.

Nephrotic Syndrome

Gross changes in glomerular permeability characterize the nephrotic syndrome. The diagnostic criteria for establishing nephrotic syndrome are the presence of (1) proteinuria (total protein >3 g/day or albumin >1.5 g/day), (2) hypoalbuminemia, (3) hypercholesterolemia, and finally (4) edema. Nephrotic syndrome results from a variety of causes, including (1) minimal change nephropathy (most common in children); (2) focal segmental glomerulosclerosis (FSGS); (3) membranous nephropathy, which may be idiopathic or associated with carcinoma, drugs, or infection; (4) SLE; and (5) diabetic nephropathy.

Interstitial Nephritis

A variety of chemical, bacterial, and immunological injuries to the kidney cause either generalized or localized changes that primarily affect the tubulointerstitium rather than the glomerulus. This group of disorders is characterized by alterations in tubular function that, in advanced cases, may cause secondary vascular and glomerular damage. **Interstitial nephritis**, including chronic pyelonephritis, is the primary diagnosis, accounting for 3.8% of patients admitted into dialysis programs in the United States. **Pyelonephritis** is the term associated with a bacterial infection that causes this kind of damage and is the most common of the interstitial nephritides. Acute allergic interstitial nephritis presents with AKI and marked inflammation of the interstitium. Blood cells that are prominent upon inspection include (1) lymphocytes, (2) polymorphonuclear cells, and (3) eosinophils. A drug hypersensitivity reaction is the most common form of acute interstitial nephritis. Urinary findings may be typical, or there may be blood and proteinuria. More than 100 different drugs have been implicated, but NSAIDs and β-lactam antibiotics are the drugs most commonly identified.

Polycystic Kidney Disease

Autosomal dominant **polycystic kidney disease** (ADPKD) is the second most common inherited monogenic disease (after familial hypercholesterolemia), and is the most common inherited kidney disease. Approximately 12.5 million people worldwide are affected. In the United Kingdom, ADPKD is responsible for 10% of new ESRD in patients younger than 65 years with approximately 50% of ADPKD patients developing kidney failure by age 55 years. An important clinical observation is the highly variable phenotype within families. The disease causes the development of multiple kidney cysts and extrarenal cysts occurring in the liver and pancreas. About 10% of ADPKD families have a strong family history of intracranial arterial aneurysm rupture. Hypertension is an early and frequent manifestation, and gross hematuria is a common presenting symptom. On the basis of its (1) effectiveness,

(2) cost, and (3) safety, ultrasound is the imaging modality most commonly used to make the diagnosis.

ADPKD is caused by mutations in the genes (PKD1 and PKD2) that encode polycystin 1 and 2, which are located in primary cilia. A definite diagnosis of ADPKD relies on imaging or molecular genetic testing. Genetic testing is not used routinely as a screening tool because current techniques identify only 70% of the hundreds of different PKD1 and PKD2 mutations. Specific treatments for ADPKD in clinical practice are currently lacking although generic therapy of CKD is used including treatment of hypertension with ACE inhibitors and/or ARBs and maintaining a fluid intake of 2 to 3 L/d to reduce risk of kidney stone disease. Specific therapies in development include vasopressin receptor antagonists and antiproliferative drugs that may reduce cyst progression.

Toxic Nephropathy

A wide variety of nephrotoxins exist in the environment that result in a condition known as **toxic nephropathy**. For example, a variety of metals (such as cadmium and lead) have long been known to be associated with kidney disease, often causing proximal tubular dysfunction and glomerular damage. A summary of the drugs and environmental toxins known to cause kidney damage is given in Table 35-6. Both glomerular and tubulointerstitial damage result from exposure to these toxins. Detection of both requires biochemical monitoring of GFR and tubular and glomerular proteinuria.

Obstructive Uropathy

Benign prostatic hypertrophy (BPH) is one of the most common types of **obstructive uropathy** and an almost universal finding in aging men. Among the most common symptoms are disorders of micturition, in particular increased frequency; and in many cases, this progresses to bladder outflow obstruction. There is a tendency to slower progression to ESRD in obstructive uropathy compared with other kidney diseases.

Tubular Diseases

Renal tubular acidoses (RTAs) and inherited tubulopathies are types of renal tubular disease.

Renal Tubular Acidoses

The **renal tubular acidoses (RTAs)** comprise a diverse group of both inherited and acquired disorders. They affect either the proximal or distal tubule. They are characterized by a (1) hyperchloremic, (2) normal-anion-gap, (3) metabolic acidosis, with (3) urinary bicarbonate or (4) hydrogen ion excretion inappropriate for the plasma pH. They are the result of either failure to retain bicarbonate or inability of the renal tubules to secrete hydrogen ion. Typically the GFR in RTA is normal, or slightly reduced, and there is no retention of anions, such as phosphate and sulfate (as occurs with the acidosis of renal failure).

The three categories of RTA are (1) distal (dRTA, type I); (2) proximal (pRTA, type II); and (3) type IV, which is secondary to aldosterone deficiency or resistance. Note: The term "type III RTA" (mixed proximal/distal defect) has been abandoned, because it is no longer considered a separate entity.

TABLE 35-6 Drugs and Environmental Toxins Associated with the Development of Nephropathy

Drug	Toxic Action
ACE inhibitors	Drastic drop in GFR in patients with bilateral renal artery stenosis
	High-dose captopril known to cause proteinuria
NSAIDs/COX-2 inhibitors	Drastic drop in GFR in patients with circulatory insufficiency (e.g., cardiac failure)
	Hypovolemia; known to cause acute and chronic interstitial nephritis
Antirheumatoid Drugs	
Calcineurin inhibitors	Vasoconstriction, glomerular vasculopathy, and interstitial fibrosis (cyclosporine and tacrolimus)
Gold salts	Membranous-type picture with nephrotic syndrome (mechanism unknown)
Mercury compounds	Membranous-type picture with nephrotic syndrome (mechanism unknown)
D-penicillamine	Membranous-type picture with nephrotic syndrome (mechanism unknown)
Antitumor Drugs	
Mitomycin	Hemolytic-uremic syndrome
Cisplatin	ATN
Methotrexate	Intraluminal precipitation and ATN
Antibiotics/Antifungals	
Aminoglycosides	ATN and interstitial nephritis
Cephalosporins	Interstitial nephritis
Penicillin G	Interstitial nephritis
Ampicillin	Interstitial nephritis
Amoxicillin	Interstitial nephritis
Amphotericin	Nephrotoxicity
Lithium	Distal tubular damage with nephrogenic DI
Allopurinol	Interstitial nephritis
Environmental Toxins	
Mercury	Glomerulonephritis
Cadmium	Chronic interstitial nephritis
Lead	Hypertension and tubulointerstitial nephritis
Chromium	Increased tubular proteins and enzymuria
Vanadium	Increased tubular proteins and enzymuria
Nickel	Increased tubular proteins and enzymuria
Paraquat	Free radical generator; acute tubular damage
Solvents	
Dry cleaning/paints	Glomerulonephritis

ACE, Angiotensin converting enzyme; ATN, acute tubular necrosis; COX, cyclooxygenase; DI, diabetes insipidus; GFR, glomerular filtration rate; NSAID, nonsteroidal anti-inflammatory drug.

The finding of a hyperchloremic metabolic acidosis in a patient without evidence of gastrointestinal bicarbonate losses and with no obvious pharmacological cause should prompt suspicion of an RTA. In addition to plasma electrolyte (including potassium) measurements, preliminary investigation should include measurement of urinary pH in a fresh, EMU sample. The finding of a urine pH greater than 5.5 in the presence of a systemic acidosis supports the diagnosis of dRTA.[19]

Inherited Tubulopathies

The inherited tubulopathies comprise a heterogeneous set of rare disorders, including (1) **Bartter syndrome**, (2) **Gitelman syndrome**, (3) **Liddle syndrome**, (4) **pseudohypoaldosteronism type I**, (5) **Dent disease**, and (6) **X-linked dominant hypophosphatemic** rickets (previously known as vitamin D–resistant rickets). Most are characterized by electrolyte disturbances. In addition to these, general reasons to suspect a tubulopathy include (1) a familial disease pattern, (2) renal impairment, (3) nephrocalcinosis, and (4) stone formation, especially if these should present at an early age. In cases in which a diuretic-sensitive channel is affected, these disorders will clearly mimic the effects of diuretic use, and exclusion of covert use of diuretics is important. Although they are individually uncommon or rare, an awareness of these disorders is critical for the clinical laboratorian when considering the potential differential diagnoses in patients having electrolyte imbalances.[20]

Diuretics

Diuretics are predominantly prescribed to treat hypertension and/or disorders associated with fluid overload. All diuretics act by interfering with tubular reabsorption of sodium and/or chloride and therefore have accompanying effects on water retention. Different classes of diuretics act at different sites along the nephron. Classes include (1) loop, (2) thiazide, and (3) "potassium-sparing" diuretics. Many diuretics will cause hypokalemia to some degree, depending on the (1) potency, (2) dose, (3) duration of treatment, and (4) patient's underlying potassium balance.[21]

Diabetes Insipidus

Diabetes insipidus (DI) is a disorder in which there is an abnormal increase in urine output, fluid intake, and often thirst. DI is due to the absence of an ADH effect, either because of impaired or failed secretion (cranial or central DI) or lack of end-organ response to ADH (nephrogenic DI). A further disorder, psychogenic polydipsia, or compulsive water drinking, has been known to present as DI. The investigation of DI involves firstly demonstrating that the patient is unable to form a concentrated urine by undertaking a water deprivation test (see Chapter 40). The patient is then given synthetic ADH to establish whether the defect in concentrating ability is at the renal or pituitary level.

Renal Calculi

Nephrolithiasis is a condition marked by the presence of renal calculi. Such calculi ("kidney stones") occur in the (1) renal pelvis, (2) ureter, and (3) bladder. Kidney stone formation is often considered to be a nutritional or environmental disease, linked to affluence, but genetic or anatomical abnormalities also play a role. Approximately 5% to 10% of the population of the western world are thought to have formed at least one kidney stone by the age of 70 years and the prevalence of kidney stones may be increasing. In both males and females, the average age of first stone formation is decreasing. For most stone types, there is a male preponderance. The passage of a stone is associated with severe pain called "renal colic", which may last for 15 minutes to several hours and is commonly associated with nausea and vomiting.

The majority of kidney stones found in the western world are composed of one or more of the following substances: (1) calcium oxalate with or without phosphate (frequency 67%); (2) magnesium ammonium phosphate (12%); (3) calcium phosphate (8%); (4) urate (8%); (5) cystine (1% to 2%); and (6) complex mixtures of the above (2% to 3%). These poorly soluble substances crystallize within an organic matrix, the nature of which is not well understood. Most kidney stones are treated by **lithotripsy** that entails crushing a calculus within the urinary system or gallbladder, followed at once by the washing out of the fragments.

Prostaglandins and Nonsteroidal Antiinflammatory Drugs in Kidney Disease

The prostaglandins are a series of twenty-carbon unsaturated fatty acid derivatives arachidonic acid synthesized by the cyclooxygenase (cox) enzyme system (see Chapter 23). The major renal vasodilatory prostaglandin is PGE_2, which is synthesized predominantly in the medulla of the kidney. The major vasoconstrictor prostaglandin is thromboxane A_2, which is produced primarily within the renal cortex. PGE_2 (1) increases renal blood flow rate, (2) inhibits sodium reabsorption in the distal nephron and collecting duct, and (3) stimulates renin release. These actions promote natriuresis (process of excretion of sodium in the urine) and diuresis. In patients with CKD, renal PGE_2 excretion rates are three to five times higher than those in healthy subjects, and therefore PGE_2 production represents a compensatory response to loss of nephron mass. Vasodilatory prostaglandins are synthesized following stimulation with renal sympathetic adrenergic and AII-dependent mechanisms to offset or modulate vasoconstriction. In the tubule, prostaglandins act as autocoids, exerting their effects locally, near the site of synthesis.

NSAIDs have (1) analgesic, (2) antipyretic, and (3) antiinflammatory effects. They block the synthesis of COX products of arachidonic acid, which have a critical role in (1) renal hemodynamics, (2) control of tubular function, and (3) renin release. Analgesic nephropathy is a common cause of ESRD in a number of countries, reaching 10% in Switzerland and Australia, but is essentially a preventable condition for which biochemical monitoring has proved useful. Older people demonstrate significant reduction of GFR within 1 week of ingestion of NSAIDs. Acute interstitial nephritis and nephrotic syndrome have been reported to occur with NSAIDs.

Monoclonal Light Chains and Kidney Disease

Immunoglobulin (Ig) molecules are formed in secretory B cells from polypeptide heavy (H) and light (L) chains. The molecular weight of light chains is around 22.5 kDa. In healthy individuals, the small quantity of circulating polyclonal light chains is filtered by the glomerulus with approximately 90%

reabsorbed in the proximal tubule. When the concentration of filtered light chains is increased, this leads to pathological alteration in the proximal tubule cells. For example, light chains have been known to deposit in the kidney as (1) casts, (2) fibrils, (3) precipitates and (4) crystals, giving rise to a spectrum of disease, including (1) cast nephropathy, (2) amyloid, (3) light chain deposition disease (LCDD), and (4) **Fanconi syndrome**. However, not all patients with a large excess production of monoclonal light chains develop disease. Other promoters include (1) dehydration, (2) hypercalcemia, and (3) contrast medium. NSAIDs also have been implicated.

Myeloma or multiple myeloma is a neoplastic proliferation of secretory B cells (plasma cells) that produce excess amounts of a monoclonal Ig (paraprotein), so-called M protein, because of the characteristic peaks obtained from serum protein electrophoresis on agarose gel. T is clonal production is associated with an excess of pure light chain production. In multiple myeloma complete monoclonal Igs (usually IgG or IgA) are accompanied in the plasma by variable concentrations of free light chains that appear in the urine as Bence Jones proteins. M proteins and light chains are identified in the blood and/or the urine in 98% of patients with myeloma using protein electrophoresis and immunofixation. Impairment of kidney function at presentation occurs in almost 50% of patients.

Light chains may cause tubular dysfunction, especially of the proximal tubular cells. Characteristically the light chain variable domain is resistant to degradation by proteases in lysosomes in the tubular cells. T e variable domain fragments accumulate in proximal tubular cells, and clinical features include RTA and phosphate wasting.

Treatment of cast nephropathy in myeloma includes (1) fluid resuscitation and (2) treatment of hypercalcemia and (3) infection as supportive measures. In addition chemotherapy is commenced to reduce the light chain load from the proliferating plasma cells.

Renal Replacement Therapy

ESRD is an administrative term in the United States that is related to (1) the conditions for payment for healthcare by the Medicare ESRD Program and specifically the level of GFR and (2) the occurrence of signs and symptoms of kidney failure necessitating initiation of treatment by RRT. No absolute recommendation of commencement of dialysis based on GFR alone is to be made, although commencement of dialysis is typically considered as GFR falls below 15 mL/min/1.73 m^2. T e USRDS reports the mean GFR on initiation of dialysis is 10 mL/min/1.73 m^2. RRT includes dialysis procedures and transplantation. Extensive laboratory support is required by an RRT program (Table 35-7).

TABLE 35-7 Clinical Laboratory Support for Dialysis Programs

Clinical Condition	Laboratory Tests
Acute Dialysis	
Dialysis disequilibrium	Urea and electrolyes, bicarbonate, calcium
Pyrexia	C-reactive protein, white cell count, blood cultures
Bleeding	Clotting screen, platelets
Chronic Dialysis Programs	
Anemia	Ferritin, TSAT, vitamin B12, folate Blood film, PTH, C-reactive protein
Sepsis	C-reactive protein, blood, urine specimens for microscopy, culture and sensitivity
Nutrition	Albumin, phosphate
Cardiovascular disease risk	Lipid profile
Dialysis-related amyloid	β2-Microglobulin (not routinely measured)
CKD-MBD	Predialysis plasma calcium, phosphate (monthly in HD patients; 3X monthly in PD patients)
	ALP
	PTH (at least every 3 months)
	Aluminum in patients receiving aluminum-based phosphate binders (3X-monthly)
Adequacy of HD as assessed by urea clearance	Predialysis and postdialysis urea
Sepsis, abdominal pain in PD	Microscopy and culture of peritoneal dialysate
Adequacy of PD as assessed by weekly small solute clearance	Dialysate creatinine, urea
Peritoneal membrane characteristics assessed by PET	Plasma and dialysate glucose and creatinine

ALP, alkaline phosphatase; CKD, chronic kidney disease; HD, hemodialysis; MBD, mineral and bone disorder; PD, peritoneal dialysis; PET, peritoneal equilibration test; PTH, parathyroid hormone; TSAT, transferrin saturation .

Dialysis

Dialysis is the process of separating macromolecules from ions and low molecular weight compounds in solution by the difference in their rates of diffusion through a semipermeable membrane. Crystalloids (aqueous solutions of mineral salt) pass readily through this membrane, but larger substances (colloids) pass very slowly or not at all. Two distinct physical processes are involved: diffusion and convection.

Dialysis procedures include (1) hemodialysis (HD), (2) **hemodiaf ltration** (HDF), and (3) **peritoneal dialysis (PD)**.

Hemodialysis

HD is the most common method used to treat advanced and permanent kidney failure. Operationally, it involves connecting the patient to a hemodialyzer into which their blood flows.

A concentration gradient is established between the blood side and the dialysate side of a semi-permanent membrane ("artificial kidney") to allow rapid diffusion of waste products from the blood. In addition, a hydrostatic pressure gradient is established across the membrane to facilitate fluid removal and further metabolite clearances by filtration. T e cleaned blood is returned to the patient. It

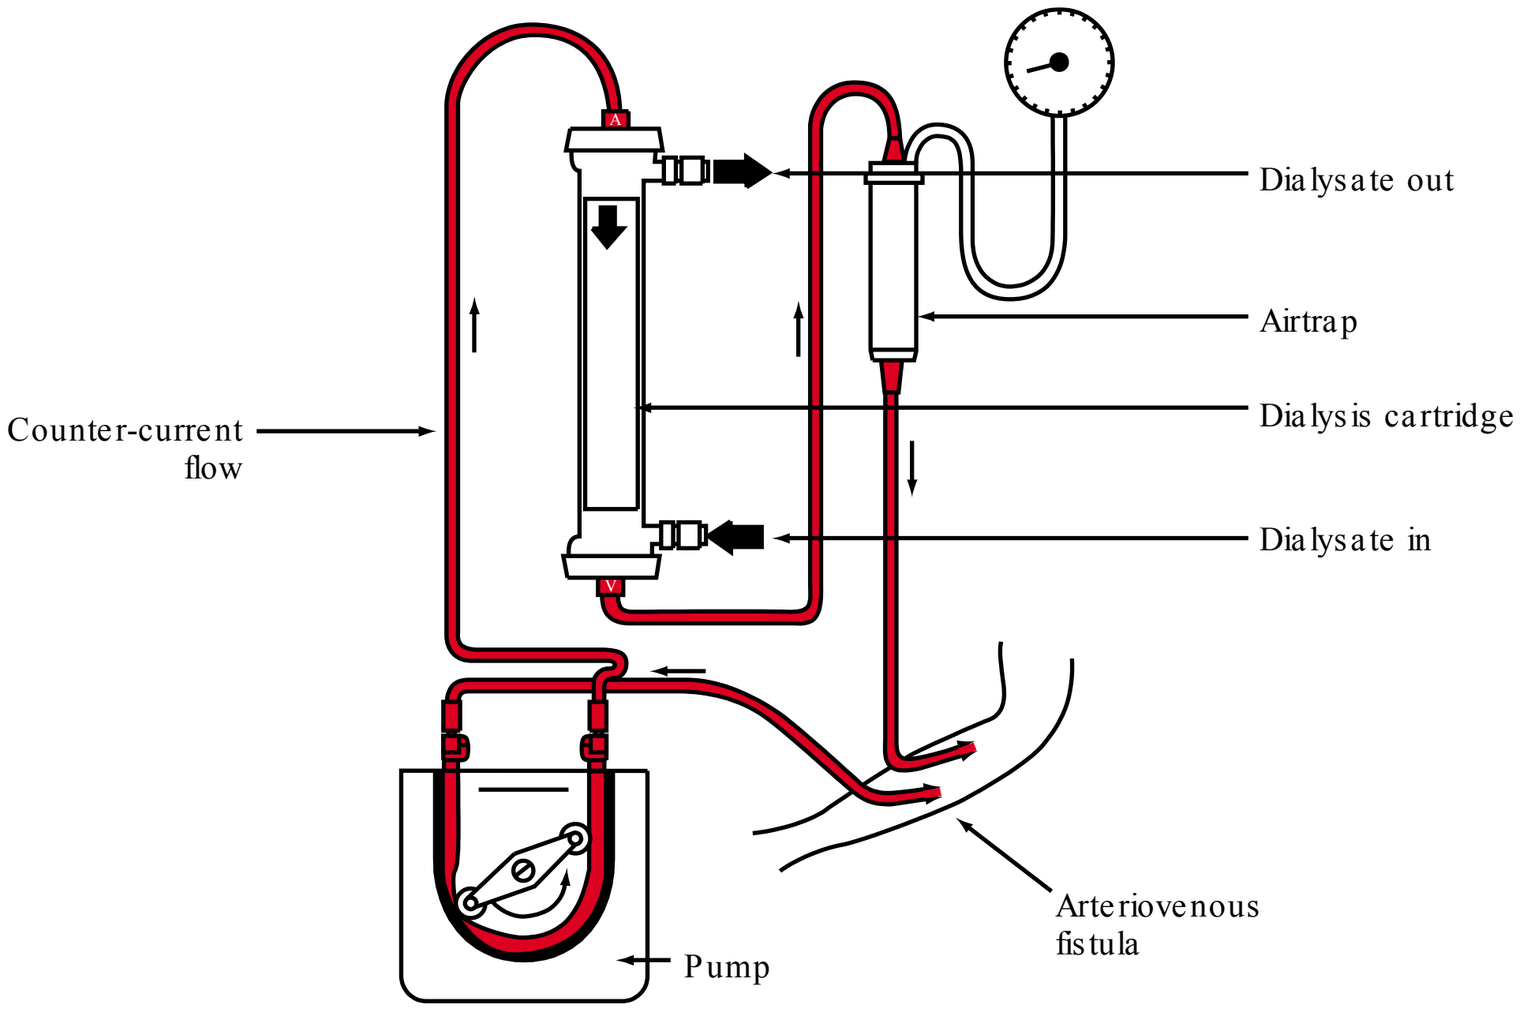

Figure 35-7 A hemodialyzer setup with inset fow diagram.

is a complicated and inconvenient therapy and requires a coordinated effort from a healthcare team and patient and care givers.

An example of a hemodialyzer is shown in Figure 35-7. The most important functional part is the dialyzer membrane. A variety of membranes are available with different surface areas and filtration characteristics. The oldest type of membrane was made from cuprophane and cellulose acetate; however, these have been replaced by more biocompatible synthetic membranes made from polysulfone and polyacrylonitrile. Patients are dialyzed in home-based or hospital-based units with dialysis usually performed three times a week for sessions lasting between 3 and 5 hours.

Hemodiafltration

HDF is a method of treatment that combines HD and hemofiltration. It offers the advantages of HD (predominantly diffusion based) and high filtration volumes in a single therapy. The result is that HDF provides a 10% to 15% increase in urea clearance compared with HD as well as increased middle molecule clearances from convection.

Peritoneal Dialysis

Peritoneal dialysis (PD) is a type of dialysis in which dialysate is introduced into the patient's peritoneal cavity and is the peritoneum employed as the dialysis membrane (Figure 35-8). **Continuous ambulatory peritoneal dialysis (CAPD)** is performed in ambulatory patients during normal activities.

Operationally, CAPD uses the patient's own peritoneal membrane (surface area approximately 2 m^2) across which fluid and solutes are exchanged between the peritoneal capillary blood and the dialysis solution placed in the peritoneal

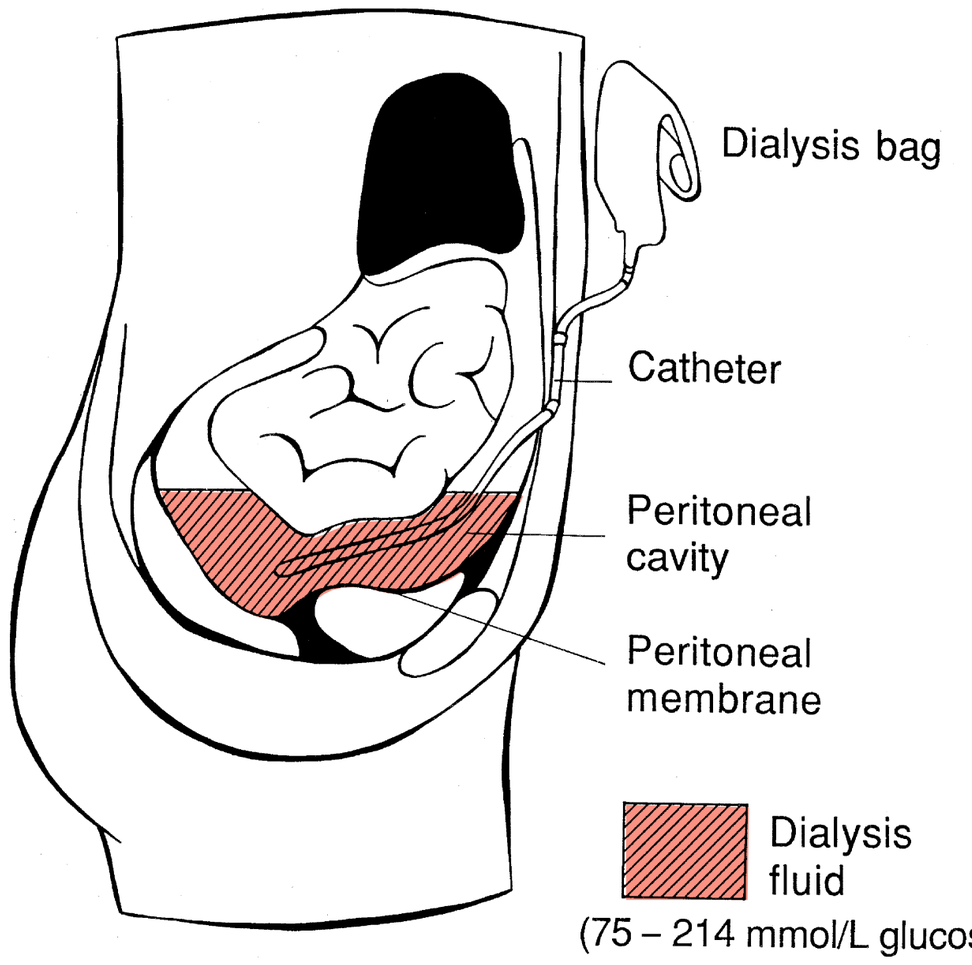

Figure 35-8 Diagrammatic sketch of peritoneal dialysis (PD). To convert glucose concentration in mmol/L to mg/dL, multiply by 18. (Redrawn from Nolph KD. Peritoneal anatomy and transport physiology. In: Maher JF, ed. Replacement of renal function by dialysis, 3rd edition. Dordrecht, The Netherlands: Kluwer Academic Publishers/Springer, 1989, Chapter 23. With kind permission of Springer Science and Business Media.)

cavity. Fluid removal or ultrafiltration is achieved by using dialysis fluids containing high concentrations of dextrose acting as an osmotic agent; as the dextrose passes across the peritoneal membrane, the rate of fluid removal decreases. Conventional therapies use four daily exchanges of approximately

2 L of fluid with approximately 10 L of spent dialysate generated, including UF.

Kidney Transplantation

Kidney transplantation is the most effective form of RRT, in terms of long-term survival and quality of life. Approximately 30% of patients on dialysis are selected to be placed on the waiting list for a transplant. Successful transplantation requires (1) preoperative assessment, (2) postoperative assessment, and (3) therapeutic drug management. In addition to cadaveric donation there has been increased utilization of live donors in many countries with excellent outcomes. All these advancements have led to increases in graft and patient survival with 1-year graft survival of approximately 90% being the norm. By contrast, long-term graft survival remains a major problem, with half of transplants failing within 14 years, usually as a result of chronic allograft injury or death with a functioning graft.

Preoperative Assessment

The criteria for acceptance into a transplant program differ slightly from center to center, and it is easier to consider reasons for exclusion. Candidates should not be obese (body mass index [BMI] less than 40 kg/m^2) and should not have (1) severe chronic lung disease, (2) inoperable ischemic heart disease, (3) active infective liver or immunological disease, (4) chronic infection (e.g., tuberculosis), (5) pre-existing malignancy, or (6) lower urinary tract dysfunction. There are also two important psychological issues to be considered: (1) the concept of organ receipt and (2) the potential difficulty in complying with immunosuppressive therapies. Age is no longer a primary issue in an otherwise healthy individual.

Laboratory assessment includes indicators of general operative health, such as (1) electrolytes, (2) acid-base status, (3) clotting profile, (4) full blood cell count, and (5) tissue cross-matching. Full human leukocyte antigen (HLA) tissue typing is also undertaken, in addition to a full screen for infectious diseases, particularly (1) cytomegalovirus (CMV), (2) hepatitis, (3) herpes, and (4) HIV, as these infections are sometimes activated by immunosuppressive therapy.

Postoperative Assessment

During the initial postoperative phase of 1 to 2 weeks, careful monitoring of plasma creatinine (Figure 35-9) and urine output is required to monitor graft function. Most grafts produce measurable amounts of urine within a matter of hours, and this is a clear sign of a functioning graft; however, in perhaps 5% to 10% of cases, there is apparently primary non-function. In this subgroup, continuing dialysis support is necessary. Since in nearly all cases the transplant has different tissue antigens to the recipient, it will be recognized as foreign by the recipient's immune system, which could result in rejection of the transplant.

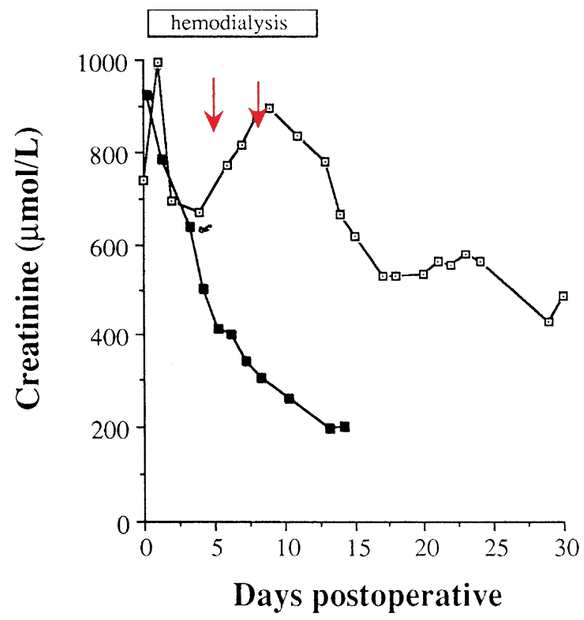

Figure 35-9 Posttransplantation biochemical profile. Open squares represent the course of a patient who experienced an early rejection episode (confirmed by biopsy, ⇩) and requiring initial hemodialysis (HD) support. Solid squares represent the typical profile of an uncomplicated transplant recipient. To convert creatinine concentration in µmol/L to mg/dL, multiply by 0.011.

Immunosuppression and Therapeutic Drug Management

The introduction of immunosuppressive drugs in the 1970s led to a vast improvement in the success rate of kidney transplantations. Despite their obvious benefits, immunosuppressive drugs have numerous and potentially serious side effects. Therefore, therapeutic drug management and monitoring are required, details of which are given in Chapter 30. In the very early postoperative phase, in addition to rejection, graft dysfunction may be a consequence of (1) delayed graft function, (2) immunosuppressive drug toxicity, and (3) acute tubular damage. Relative hypotension and dehydration may also contribute. Renal artery and vein thromboses are rare complications, and ureteric obstruction is readily diagnosed using ultrasonography. Histologic examination of a transplant biopsy is necessary to aid diagnosis and treatment adjustment. Regular monitoring of (1) kidney function, (2) drug concentrations, and (3) viral assay—particularly for CMV viremia and polyoma viruses, such as BK virus—is mandated following kidney transplantation in many centers. In addition vigilance for post-transplant lymphoproliferative disorders (PTLD), particularly driven by Epstein-Barr virus, is necessary. In the long-term, consideration is given to increased cardiovascular risk and regular assessment of bone mineral mass since osteoporosis is more prevalent in the transplanted population than in age- and sex-matched normal population. Non-infectious complications of immunosuppressive drugs are outlined in Table 35-8.

TABLE 35-8 Non-Infectious Complications of Immunosuppressant Drugs

Drug	Drug Dose	Target Therapeutic Range*	Selected Toxicity Profile
Corticosteroids (e.g., prednisone)	Dose depends on weight of patient and time since transplant.	Not appropriate	Increased risk of developing diabetes mellitus Osteoporosis Psychosis Hypertension Weight gain
Calcineurin Inhibitors			
Cyclosporine	Variable Depends on weight, time since transplant, and achieved drug concentration. Given in two divided doses and predose trough concentration measured in morning blood sample.	200-300 µg/L for first 3 to 12 months. Thereafter aim for 100 µg/L	Nephrotoxicity Hypertension Tubular electrolyte abnormalities (hypophosphatemia, hypomagnesemia, hyperkalemia) Hirsutism Gingival hyperplasia
Tacrolimus			As for cyclosporine, except no hirsutism or gingival hyperplasia Increased risk of diabetes mellitus Cardiomyopathy (children) Alopecia
Mycophenolate mofetil	Aim for 2 g daily in divided doses.	Not routinely measured although active compound, mycophenolic acid (MPA), measured in some institutions	Abdominal pain Diarrhea Myelosuppression
Sirolimus	Dose depends on weight and achieved drug concentration. The drug is administered once daily.	Concentration depends on time since transplant. Typical early (< 3 months) targets are 8-12 µg/L and thereafter 4-8 µg/L	Lymphocele (a fluid-filled collection near to transplanted kidney) Low platelets Hyperlipidemia
Azathioprine	Usual starting dose of 2 mg/kg body weight in a single daily dose.	Concentrations not measured. Because the enzyme TPMT metabolizes azathioprine, the risk of myelosuppression is increased in patients with low activity of the enzyme.	Myelosuppression Severe interaction if used with allopurinol (treatment for gout)
Biological Agents			
Anti-CD25 monoclonal antibodies Basiliximab and daclizumab	Given at time of transplant and once thereafter.		Very well tolerated
Polyclonal ATG and ALG, and monoclonal	Given in response to refractory rejection episodes in selected patients.		Increased risk of malignancy, post-transplant lymphoproliferative disease, hypersensitivity reactions

*These are not recommendations but are illustrative and will vary between centers.
ALG, Antilymphocyte globulin; ATG, antithymocyte globulin; TPMT, thiopurine methyltransferase.

Review Questions

1. It is difficult to directly measure the GFR of a kidney; therefore, which one of the following is assessed to determine GFR?
   a. Renal blood flow
   b. Renal threshold
   c. Serum creatinine
   d. Urine albumin
2. Which one of the following tests evaluates renal tubular (including loop of Henle) function?
   a. Urine osmolality
   b. Inulin clearance
   c. Urine albumin
   d. Urine protein
3. The structural and functional unit of the kidney is the nephron. What structures make up a nephron?
   a. Only the structures located in the kidney cortex
   b. The glomeruli, tubules, and associated blood vessels
   c. The ureters, bladder, and urethra
   d. Only the structures located in the kidney medulla
4. Pyelonephritis is:
   a. Caused by a lack of intrinsic factor
   b. The destruction of kidney glomeruli by immune complexes
   c. A tumor of the stomach
   d. A kidney tubule disease involving the renal pelvis

5. Which one of the following hormones synthesized in cells of the JGA is involved in control of blood pressure through its action on angiotensinogen?
   a. Erythropoietin
   b. Anti-diuretic hormone
   c. Renin
   d. Aldosterone
6. Regarding laboratory findings, uremia/azotemia specifically refers to:
   a. Reduced renal function
   b. Elevated nitrogenous compounds in blood
   c. Elevated serum proteins in blood
   d. Decreased urine albumin
7. T e most common glomerular disease caused by damage to the glomerular membrane from deposition of immune complexes is:
   a. IgA nephropathy
   b. Chronic glomerulonephritis
   c. Uremic syndrome
   d. Pyelonephritis
8. A disorder in which there is an abnormal increase in urine output, fluid intake, and often thirst and that is caused by the absence of anti-diuretic hormone is:
   a. Diabetes mellitus
   b. IgA nephropathy
   c. Diabetes insipidus
   d. Nephrolithiasis
9. Which one of the following hormones affects water reabsorption in the proximal tubule, the loop of Henle, the distal tubule, and the collecting duct of the kidney?
   a. Aldosterone
   b. Renin
   c. 1,25(OH_2) vitamin D_3
   d. Anti-diuretic hormone
10. A drug prescribed to an individual to treat hypertension and/or disorders associated with fluid overload is referred to as a(n):
    a. ACE inhibitor
    b. Diuretic
    c. Cystatin C
    d. Exogenous marker

CHAPTER

36

Physiology and Disorders of Water, Electrolyte, and Acid-Base Metabolism

Emily I. Schindler, M.D., Ph.D., and Mitchell G. Scott, Ph.D.

Objectives

1. Define the following:
   - Acid-base balance
   - Aldosterone
   - Anion gap
   - Anti-diuretic hormone
   - Compensation
   - Depletional hyponatremia
   - Dilutional hyponatremia
   - Hyper- and hypovolemia
   - Interstitial fluid
   - Respiration, internal and external
2. State the significance of and describe the total body water (TBW) distribution between compartments, including approximate volume and composition of each compartment, electrolyte distribution and active/passive transport for ion exchange; list the hormonal regulators of water and sodium.
3. For each of the following electrolytes, state and describe regulatory mechanisms, disorders and causes/effects of these disorders:
   - Chloride
   - Potassium
   - Sodium
4. State the Henderson-Hasselbalch equation, and explain each of its components; explain its relation to compensatory mechanisms in acid-base disturbances.
5. Categorize the physiological buffer systems relative to their specific roles in the regulation of blood pH.
6. Explain the specific respiratory and renal mechanisms important in the regulation of acid-base balance.
7. For each of the acid-base imbalances listed below, list the causes, state the primary deficit, compensatory mechanisms and laboratory values obtained with each:
   - Metabolic acidosis
   - Metabolic alkalosis
   - Respiratory acidosis
   - Respiratory alkalosis
8. State the formula for and calculate anion gap; discuss the clinical usefulness of anion gap, including eight causes of an increased anion gap and four causes of normal anion gap acidosis.
9. Compare chloride responsive, chloride resistant, and exogenous base metabolic alkalosis, including causes and lab values.
10. Assess and solve case studies related to electrolyte disturbances and acid-base balance disorders.

Key Words and Definitions

Acid-base balance The homeostatic maintenance of acids and bases within the body to achieve a physiological pH (approximately 7.40).

Acidemia An arterial blood pH<7.35.

Alkalemia An arterial blood pH>7.45.

Anion gap (AG) The difference between the serum sodium concentration and the sum of the serum chloride and bicarbonate concentrations; the anion gap is high in some forms of metabolic acidosis.

Antiporter A membrane transport protein that mediates the cotransport of substances in opposite directions.

Chronic obstructive pulmonary disease (COPD) Any disorder characterized by persistent or recurring obstruction of bronchial air flow, such as chronic bronchitis, asthma, or pulmonary emphysema.

Compensated metabolic acidosis A state of acidosis in which the pH of the blood has been returned toward normal by respiratory compensation.

Depletional hyponatremia A condition characterized by low plasma concentration of sodium associated with low total body sodium and normal blood volume; called also euvolemic hyponatremia.

Diabetes insipidus Any of several types of polyuria in which the volume of urine exceeds 3 liters per day, causing dehydration and great thirst, as well as sometimes emaciation and great hunger.

Dilutional hyponatremia A condition characterized by low plasma concentration of sodium resulting from loss of sodium from the body with nonosmotic retention of water.

Extracellular fluid (ECF) A general term for all the body fluids outside the cells, including the interstitial fluid, plasma, lymph, and cerebrospinal fluid (CSF); this fluid provides a constant external environment for the cells.

Henderson-Hasselbalch equation An equation that defines the relationship between pH, bicarbonate, and the partial pressure of dissolved carbon dioxide gas.

Key Words and Definitions—cont'd

Hyperkalemia A concentration of serum potassium above the reference interval limit of 5.0 mmol/L.

Hypernatremia A concentration of serum sodium above the reference interval limit of 150 mmol/L.

Hypervolemia Abnormal increase in the volume of circulating fluid (plasma) in the body.

Hypokalemia A concentration of serum potassium below the reference interval limit of 3.5 mmol/L.

Hyponatremia A concentration of serum sodium below the reference interval limit of 136 mmol/L.

Hypovolemia Abnormally decreased volume of circulating fluid (plasma) in the body.

Intracellular fluid (ICF) The portion of the total body water (TBW) with its dissolved solutes that is within the cell membranes.

Ketoacidosis A condition characterized as acidosis accompanied by the accumulation of ketone bodies (ketosis) in the body tissues and fluids.

Metabolic acidosis A pathological process that leads to the accumulation of acid that lowers the bicarbonate concentration and decreases the pH; also known as primary bicarbonate deficit.

Metabolic alkalosis A pathological process that leads to the accumulation of base that raises the bicarbonate concentration and increases the pH; also known as primary bicarbonate excess.

Mixed acid-base disturbance The occurrence of more than one acid-base disorder simultaneously; the blood pH may be low, high, or within the reference interval.

Respiratory acidosis A pathological process that leads to the accumulation of carbon dioxide that raises the PCO_2 and decreases the pH; usually caused by emphysema or hypoventilation.

Respiratory alkalosis A pathological process that leads to the excessive elimination of carbon dioxide which lowers the PCO_2 and increases the pH; caused by hyperventilation.

Sodium–hydrogen exchanger (NHE) A membrane protein that is primarily responsible for maintaining the balance of sodium; also called the sodium–hydrogen antiporter.

Total body water (TBW) Any of various estimates of the water content of the human body, taking into consideration the person's height, weight, and age.

Adaptation to terrestrial life led to the evolution of physiological systems to maintain the composition of the internal milieu of animals, including humans. These systems include a variety of chemical buffers and highly specialized mechanisms of the lungs and kidneys that work in concert to regulate (1) water, (2) electrolytes, and (3) pH between intracellular and extracellular compartments. Small changes (perturbations) in the dynamic equilibria that exist for (1) water, (2) electrolytes, and (3) pH may arise from external sources, such as (1) trauma, (2) changes in altitude, (3) ingestion of toxic substances, or (4) internal sources, such as healthy metabolism and disease state. Endogenous correction of these imbalances may not always be adequate; at these times, the clinical laboratory provides valuable information for guiding therapy.

Total Body Water—Volume and Distribution

Approximately two thirds of **total body water (TBW)** is distributed into the **intracellular fluid (ICF)** compartment, and one third exists in the **extracellular fluid (ECF)** compartment. These compartments are physically separated by the cellular plasma membrane. The ECF may be subdivided into interstitial (≈75% of ECF) and intravascular (≈25% of ECF) fluid compartments, which are separated by the capillary endothelium. The average adult has ≈5 L blood volume (intravascular compartment) and a plasma volume of ≈3.0 L when the hematocrit is ≈40%.

Factors that influence daily water and electrolyte requirements include (1) activity of the individual, (2) environmental conditions, and (3) disease. However, on average, an adult must take in ≈1.5 to 2.0 L of water daily to maintain fluid balance. Because primary regulatory mechanisms are designed to first maintain intracellular hydration status, imbalances in TBW are initially reflected in the ECF compartment. Table 36-1 lists common causes and clinical manifestations of expansion and contraction of the ECF compartment.

Water and Electrolytes—Composition of Body Fluids

The primary cationic (positively charged) electrolytes are (1) sodium (Na^+), (2) potassium (K^+), (3) calcium (Ca^{2+}), and (4) magnesium (Mg^{2+}). The primary anionic (negatively

TABLE 36-1 Causes and Clinical Manifestations of Changes in Extracellular Fluid Volume

	Clinical Manifestations	Causes
ECF Loss	Thirst, anorexia, nausea, lightheadedness, orthostatic hypotension, syncope, tachycardia, oliguria, decreased skin turgor and "sunken eyes," shock, coma, death	Trauma (and other causes of acute blood loss), "third-spacing" of fluid (e.g., burns, pancreatitis, peritonitis), vomiting, diarrhea, diuretics, renal or adrenal (sodium wasting) disease
ECF Gain	Weight gain, edema, dyspnea (due to pulmonary edema), tachycardia, jugular venous distention, portal hypertension (ascites), esophageal varices	Heart failure, cirrhosis, nephrotic syndrome, iatrogenic (intravenous fluid overload)

ECF, Extracellular fluid.

charged) electrolytes include (1) chloride (Cl^-), (2) bicarbonate (HCO_3^-), (3) phosphate (HPO_4^{2-}, HPO_4^-), (4) sulfate (SO_4^{2-}), (5) organic ions (such as, lactate), and (6) negatively charged proteins. Electrolyte concentrations of the body fluid compartments are shown in Table 36-2. Na^+, K^+, and Cl^- in the plasma or serum are commonly analyzed in an electrolyte profile, because their concentrations provide the most relevant information about the (1) osmotic, (2) hydration, and (3) acid-base status of the body.[3] Although hydrogen ion (H^+) is a cation, its concentration is approximately 1 million–fold lower in plasma than the major electrolytes listed in Table 36-2 (10^{-9} mol/L vs. 10^{-3} mol/L) and thus is negligible in terms of osmotic activity.

Extracellular and Intracellular Compartments

The compartments of fluid found in the human body are (1) plasma, (2) interstitial fluid, and (3) ICF.

Plasma

Plasma generally has a volume of 1300 to 1800 mL/m^2 of body surface and constitutes approximately 5% of the body volume (≈3.5 L for a 66 kg subject). Table 36-2 describes the electrolyte composition of plasma. The mass concentration of water in normal plasma is about 0.933 kg/L, depending on the protein and lipid content (see "Electrolyte Exclusion Effect" in Chapter 24). Thus a concentration of sodium in the plasma of 140 mmol/L would correspond to a molality of sodium in plasma water of 150 mmol/kg H_2O (140 mmol/L divided by 0.933 kg/L). The concentration of net protein ions in plasma is ≈12 mmol/L with the charge mainly caused by albumin.

TABLE 36-2 Electrolyte and Water Composition of Body Fluid Compartments*

Component	Plasma	Interstitial Fluid	Intracellular Fluid†
Volume, H_2O (TBW = 42 L)	3.5 L	10.5 L	28 L
Na^+	142	145	12
K^+	4	4	156
Ca^{2+}	2.4	2-3	0.3
Mg^{2+}	2	1-2	26
Trace elements	1	—	—
Total cations	155	—	—
Cl^-	103	114	4
HCO_3^-	27	31	12
$Protein^-$	16	—	55
$Organic\ acids^-$	5	—	—
HPO_4^{2-}	2	—	—
SO_4^{2-}	1	—	—
Total anions	154	—	—

TBW, Total body water.
*All electrolyte values are expressed in mEq/L of fuid. Because the H_2O content of plasma is ≈93% by volume, the corresponding electrolyte concentrations in plasma water are ≈10% higher. Note that the molar concentration of divalent ions is one half the depicted value.
†These values are derived from skeletal muscle.

Interstitial Fluid

Interstitial fluid is essentially an ultrafiltrate of blood plasma. When all extracellular spaces except plasma are included, the volume accounts for about 26% (10.5 L) of the total body volume. Plasma is separated from the interstitial fluid by the endothelial lining of the capillaries, which acts as a semipermeable membrane and allows passage of water and diffusible solutes but not compounds of high molecular mass, such as proteins.

Intracellular Fluid

The exact composition of ICF is extremely difficult to measure because of the relative unavailability of cells free of contamination. Data for ICF (see Table 36-2), therefore, are considered only approximations. As indicated in the table, the ICF constitutes ≈66% of the total body volume. The composition of ICF differs markedly from that of ECF because of separation of these compartments by the cell membrane. The composition differences are primarily a consequence of active and passive transport of ions.

Distribution of Ions by Active and Passive Transport

Examination of Table 36-2 reveals that the electrolyte compositions of blood plasma and interstitial fluid (both ECFs) are similar, but their compositions differ markedly from that of ICF. The major ECF ions are Na^+, Cl^-, and HCO_3^-, but in ICF, the main ions are (1) K^+, (2) Mg^{2+}, (3) organic phosphates, and (4) protein. This unequal distribution of ions is due to active transport of Na^+ from inside to outside the cell against an electrochemical gradient. This process requires energy supplied by metabolic processes in the cell such as glycolysis. An active sodium pump deriving its energy from adenosine triphosphate (ATP) is present in most cell membranes and frequently is coupled with transport of K^+ into the cell.

In addition to the Na^+/K^+-ATPase, a ubiquitous Na^+-H^+ exchanger (often referred to as an **antiporter**) actively pumps H^+ out of the ICF in exchange for Na^+. This exchanger is critical for maintaining intracellular pH homeostasis.

Electrolytes

Individual electrolytes having a strong influence on electrolyte disorders and maintenance of water homeostasis include (1) Na^+, (2) K^+, (3) Cl^-, and (4) HCO_3^-

Sodium

Disorders of Na^+ homeostasis occur because of (1) excessive loss, (2) excessive gain, (3) and/or retention of Na^+ or H_2O. As described in detail in Chapter 35, the kidney is the primary organ for regulating body water and extracellular Na^+.

Kidney Function

In the proximal tubules, 70% to 80% of filtered Na^+ is actively reabsorbed, with H_2O and Cl^- following passively to maintain electrical neutrality and osmotic equivalence. In the descending loop of Henle, H_2O, but not electrolytes, is passively reabsorbed because of the high osmotic strength of interstitial fluid

in the renal medulla. In the ascending loop of Henle, Cl^- is reabsorbed actively with Na^+ following. At the distal tubule, the first of the two primary Na^+/H_2O regulating processes occurs. Here, aldosterone stimulates the cortical collecting ducts to reabsorb Na^+ (with water following passively) and secrete K^+ (and to a lesser extent, H^+) to maintain electrical neutrality. Aldosterone is produced by the adrenal cortex in response to angiotensin II derived via the action of renin. The secretion of renin by renal juxtaglomerular cells is stimulated by low chloride, by β-adrenergic activity, and by low arteriolar pressure.[12] Thus, when the kidneys are hypoperfused (as occurs when blood volume decreases, or when the renal arteries are obstructed), the distal tubules, under the influence of aldosterone, reclaim Na^+.

Further water regulation in the kidney occurs from the distal tubule through the collecting duct, where tubular permeability to H_2O is under the influence of antidiuretic hormone (ADH) (see Chapters 35 and 40). ADH (also called vasopressin) is released by the posterior pituitary under the influence of baroreceptors in the aortic arch and of hypothalamic chemoreceptors responsive to circulating osmolality. When blood volume is decreased, or when plasma osmolality is increased, (1) ADH is secreted, (2) tubular permeability to H_2O increases, and (3) H_2O is reabsorbed in an attempt to restore blood volume or to decrease osmolality. In contrast, when blood volume is increased or osmolality decreased, ADH secretion is inhibited, and more H_2O is excreted in the urine (diuresis).

Besides the kidney, the body's other mechanism for restoring Na^+/H_2O homeostasis is ingestion of H_2O. Thirst is stimulated by decreased blood volume or by a hyperosmotic condition. It is important to remember that receptors that influence renal handling of Na^+ and H_2O, and thirst, sense changes only in the intravascular blood volume and not the total ECF. Furthermore, laboratory assessment of water and electrolyte disorders is made primarily from the blood volume (plasma). As discussed in subsequent sections, the clinician must assess the status of TBW and blood volume before interpreting laboratory values in the diagnosis of water and electrolyte disorders (see Table 36-1).

Hyponatremia

Hyponatremia is defined as a decreased plasma Na^+ concentration (<130 to 135 mmol/L). Hyponatremia typically manifests clinically as (1) nausea, (2) generalized weakness, and (3) mental confusion. For example, Na^+ values are typically (1) <120 mmol/L for mental confusion, (2) <110 mmol/L for ocular palsy, and (3) between 90 and 105 mmol/L for severe mental impairment.[11]

It is important to note, however, that symptoms are due to changes in osmolality rather than to the Na^+ concentration per se. For example, hyponatremia is categorized as (1) hypo-osmotic, (2) hyperosmotic, or (3) isosmotic. Thus, measurement of plasma osmolality is an important initial step in the assessment of hyponatremia. Of these, the most common form is hypo-osmotic hyponatremia. Figure 36-1 describes an algorithm for laboratory measurements and physical examination findings in the differential diagnosis of plasma Na^+ <135mmol/L.

Hypo-Osmotic Hyponatremia

Typically, when plasma Na^+ concentration is low, calculated or measured osmolality will also be low. This type of hyponatremia is due to excess loss of Na^+ (**depletional hyponatremia**) or increased ECF volume (**dilutional hyponatremia**). Differentiating these initially requires clinical assessment of TBW and ECF volume by history and physical examination.

Depletional hyponatremia (excess loss of Na^+) is almost always accompanied by loss of ECF water, but to a lesser extent than Na^+ loss. This occurs because thirst leads to ingestion of water, which obviously is more hypotonic than the lost fluids. **Hypovolemia** is apparent in the physical examination with the observation of (1) orthostatic hypotension, (2) tachycardia, and (3) decreased skin turgor. If urine Na^+ is low (generally <10 mmol/L), the loss is extrarenal (see Figure 36-1), because the kidneys are retaining filtered Na^+ in response to aldosterone, which is stimulated by hypovolemia. Causes of extrarenal loss of Na^+ in excess of H_2O include losses from the gastrointestinal tract or skin (see Figure 36-1).

Alternatively, if urine Na^+ is elevated in this setting (generally >20 mmol/L), renal loss of Na^+ is likely. Renal loss of Na^+ occurs with (1) osmotic diuresis, (2) use of diuretics that inhibit reabsorption of Cl^- and Na^+ in the ascending loop, (3) adrenal insufficiency (no aldosterone or cortisone prevents distal tubule reabsorption of Na^+), and (4) salt wasting nephropathies that occurs after acute tubular necrosis or obstructive nephropathy. Renal loss of Na^+ in excess of H_2O has been known to occur in **metabolic alkalosis** from prolonged vomiting, because increased renal HCO_3^- excretion is accompanied by Na^+ ions.

Dilutional hyponatremia is a result of excess H_2O retention and often is detected during the physical examination as edema. In advanced renal failure, water is retained because of decreased filtration and H_2O excretion. When ECF is increased but the blood volume is decreased, as occurs in (1) congestive heart failure (CHF), (2) hepatic cirrhosis, or (3) nephrotic syndrome, a vicious cycle is established. For example, the decreased blood volume is sensed by baroreceptors and results in increased aldosterone and ADH, even though ECF volume is excessive. The kidneys reabsorb Na^+ and H_2O in response to increased aldosterone and ADH in an attempt to restore the blood volume, but this simply results in further increases in ECF and further dilution of Na^+.

In hypo-osmotic hyponatremia with a normal volume status, the most common causes are the (1) syndrome of inappropriate ADH (SIADH), (2) primary polydipsia, and (3) hypothyroidism (see Figure 36-1). SIADH is usually a result of ectopic or otherwise "inappropriate" ADH production arising from a variety of conditions[6] (see Chapters 35 and 40) and results in excessive H_2O retention.

Hyperosmotic Hyponatremia

Hyponatremia that occurs in the presence of increased quantities of other solutes in the ECF is the result of an extracellular shift of water or an intracellular shift of Na^+ to maintain osmotic balance between ECF and ICF compartments. The

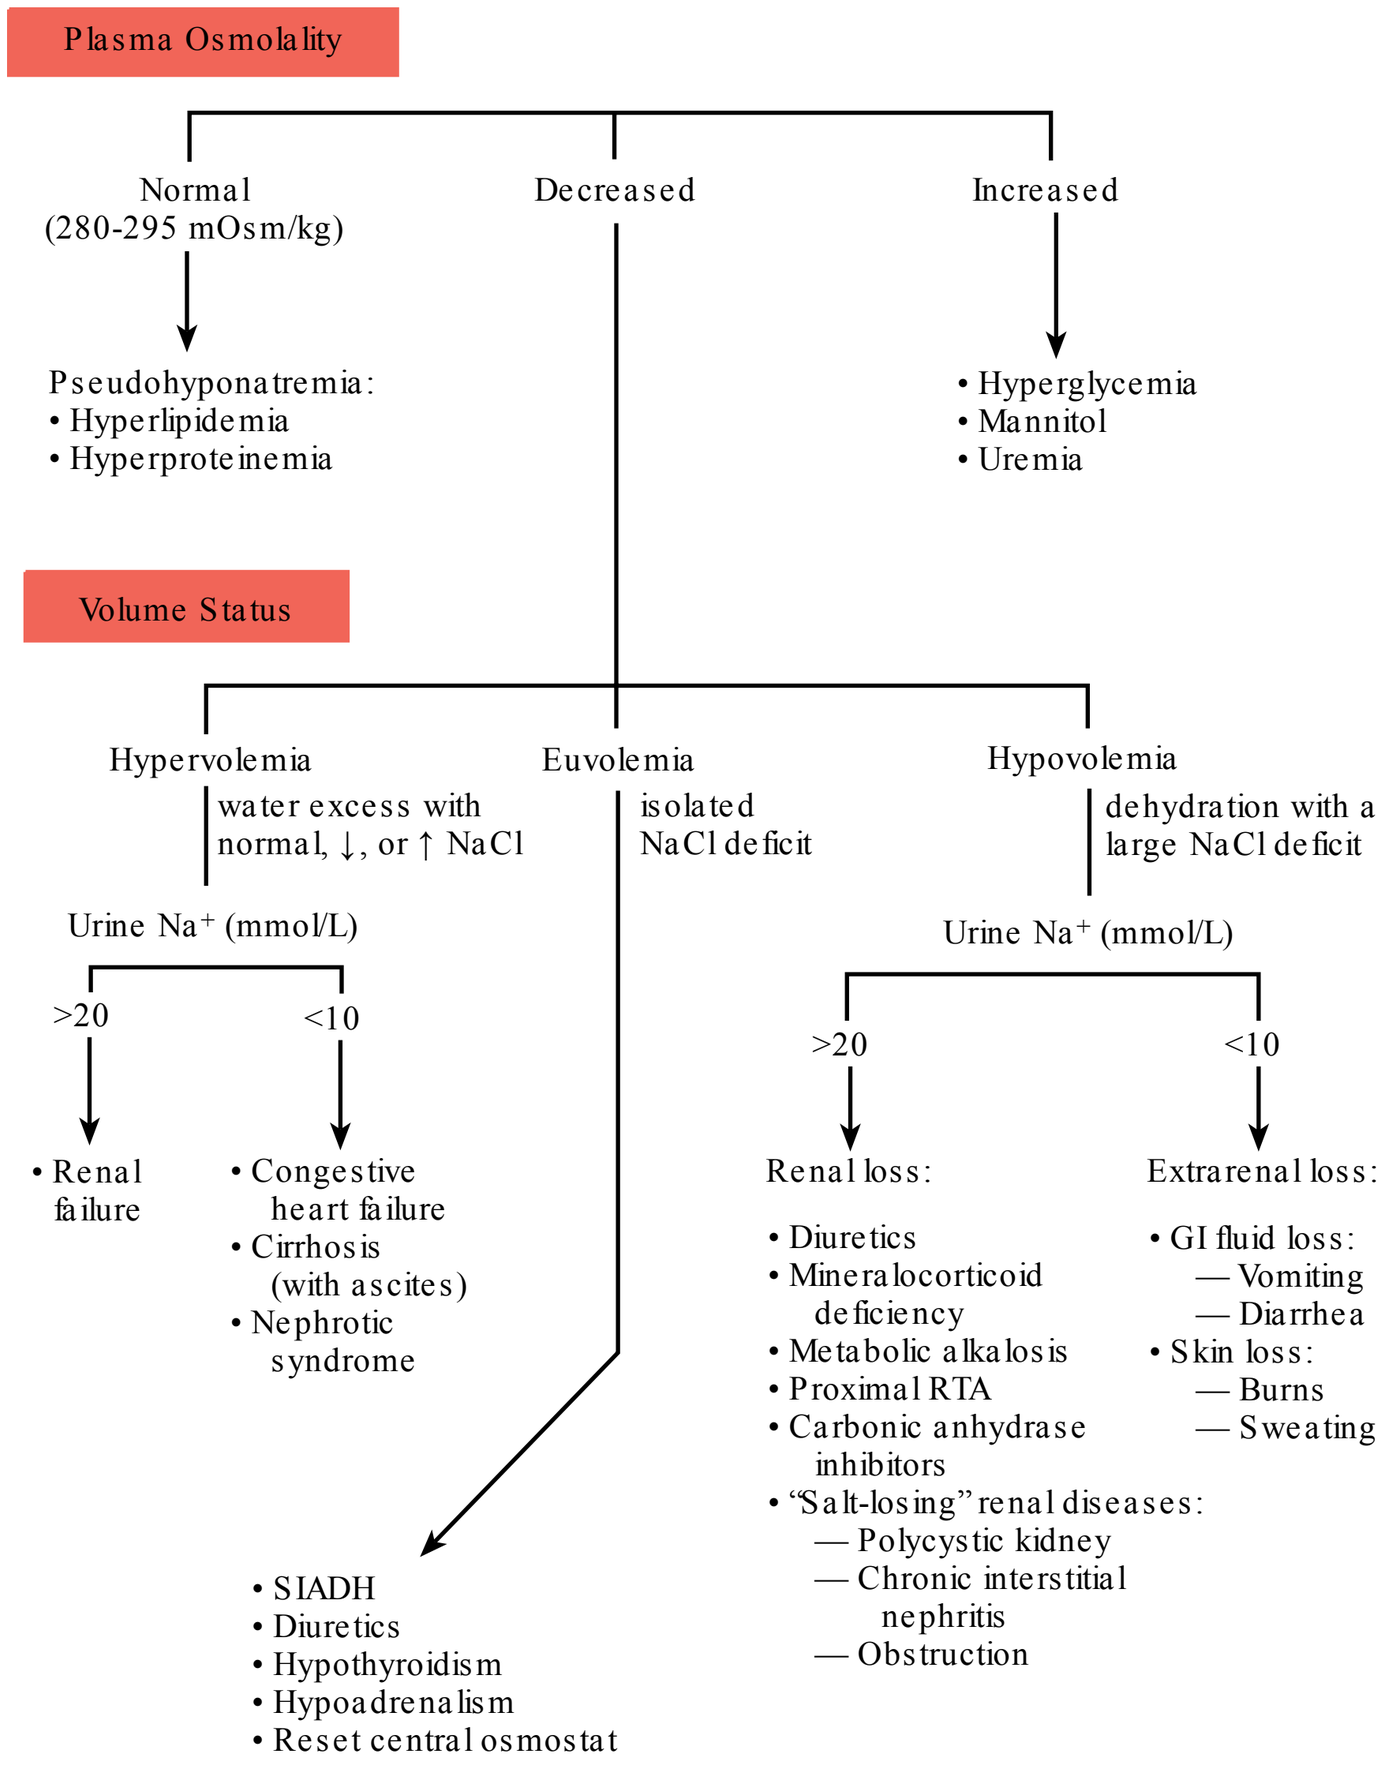

Figure 36-1 Algorithm for the differential diagnosis of hyponatremia. (Modifed from Kirkpatrick W, Kreisberg R. Acid-base and electrolyte disorders. In: Liu P, ed. Blue book of diagnostic tests. Philadelphia: WB Saunders, 1986:239-54.)

most common cause of this type of hyponatremia is severe hyperglycemia (see Figure 36-1). As a general rule, Na^+ is decreased by ≈1.6 to 2.4 mmol/L for every 100 mg/dL increase in glucose above 100 mg/dL.[13]

Isosmotic Hyponatremia

If the measured Na^+ concentration in plasma is decreased, but measured (1) plasma osmolality, (2) glucose, and (3) urea are within their reference interval, the most likely explanation is pseudohyponatremia caused by the electrolyte exclusion effect (see Chapter 24).

Hypernatremia[1]

Hypernatremia (plasma Na^+ >150 mmol/L) is always hyperosmolar. Symptoms of hypernatremia are primarily neurologic (because of neuronal cell loss of H_2O to the ECF) and include (1) tremors, (2) irritability, (3) ataxia, (4) confusion, and (5) coma. Most cases of hypernatremia occur in patients with altered mental status or in infants, both of whom may have difficulty in rehydrating themselves despite a normal thirst reflex.

Hypernatremia arises in the setting of (1) hypovolemia (excessive water loss or failure to replace normal water losses), (2) **hypervolemia** (a net Na^+ gain in excess of water gain), or (3) normovolemia. Again, assessment of TBW status by physical examination and measurement of urine Na^+ and osmolality are important steps in establishing a diagnosis (Figure 36-2).

Hypovolemic Hypernatremia

Hypernatremia in the setting of decreased ECF is caused by renal or extrarenal loss of hypo-osmotic fluid, leading to dehydration. Thus, once hypovolemia is established by physical examination, measurement of urine Na^+ and osmolality is used to determine the source of fluid loss. Patients who have large extrarenal losses will have concentrated urine (often >800 mOsmol/L) with low urine Na^+ (<20 mmol/L), reflecting a proper renal response to conserve Na^+ and water to restore ECF volume.

Hypervolemic Hypernatremia

The presence of excess TBW and hypernatremia indicates a net gain of water and Na^+ with Na^+ gain in excess of water

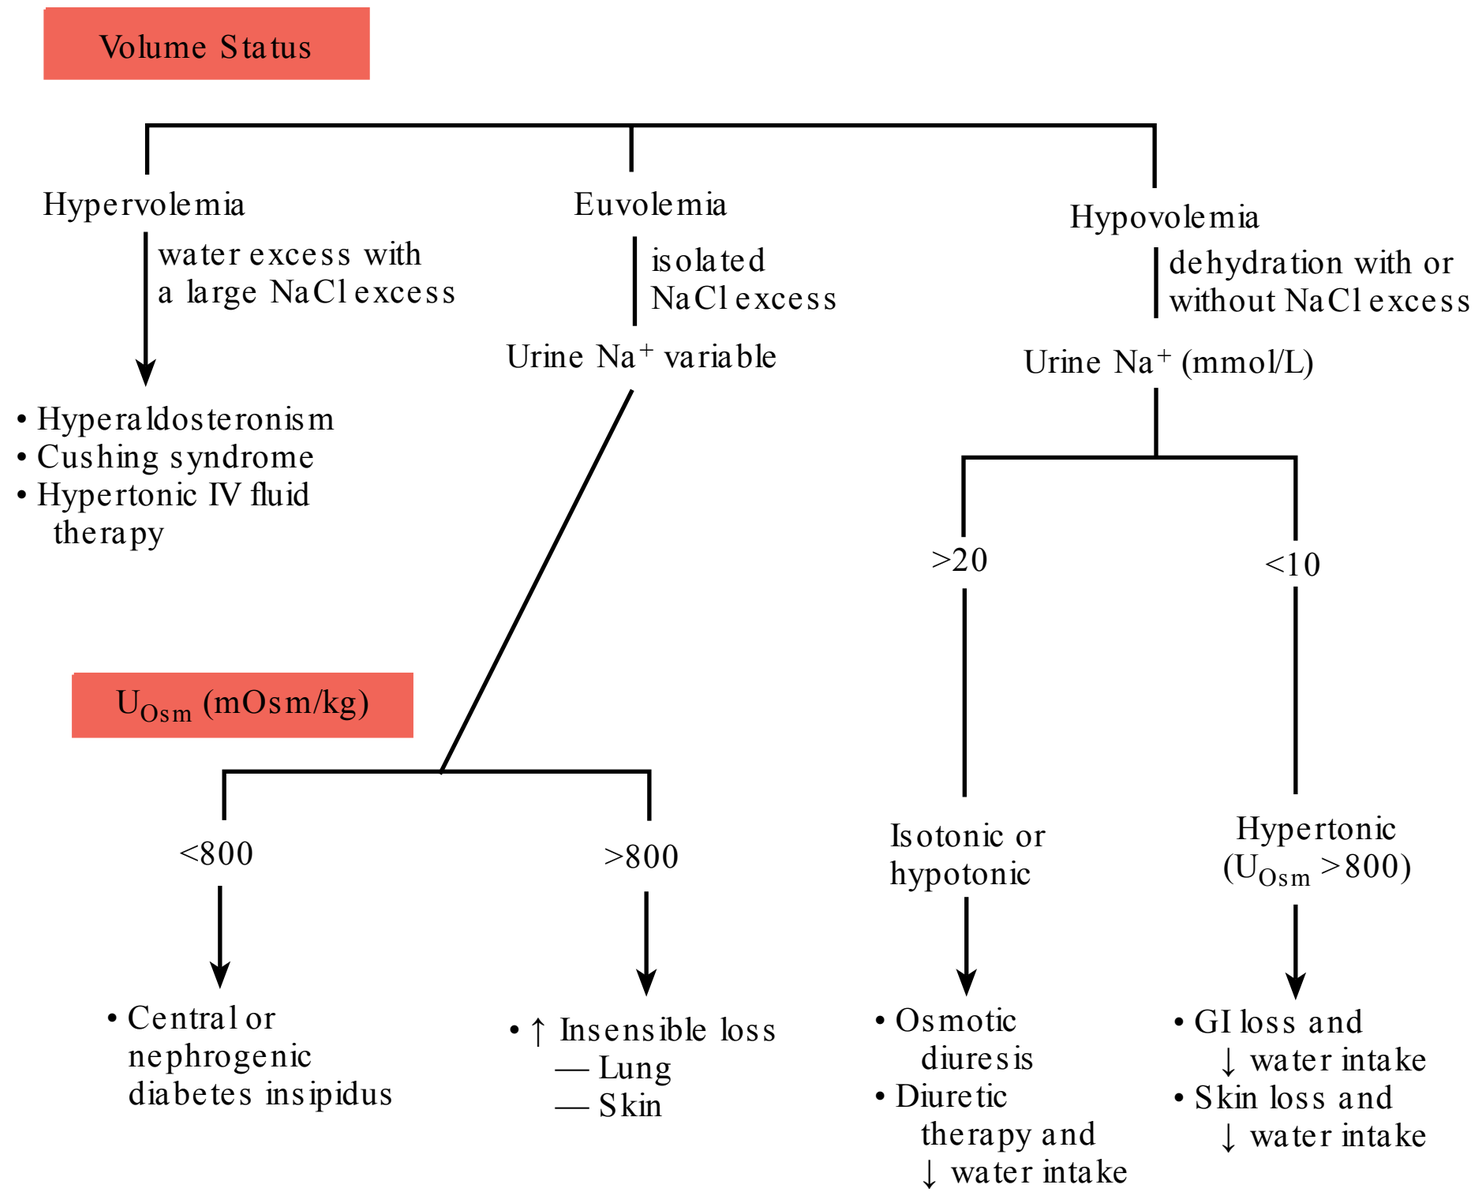

Figure 36-2 Algorithm for the differential diagnosis of hypernatremia. (Modified from Kirkpatrick W, Kreisberg R. Acid-base and electrolyte disorders. In: Liu P, ed. Blue book of diagnostic tests. Philadelphia: WB Saunders, 1986:239-54.)

(see Figure 36-2). This rare condition is observed most commonly in hospital patients receiving hypertonic saline or sodium bicarbonate.

Normovolemic Hypernatremia

Hypernatremia in the presence of normal ECF volume is often a prelude to hypovolemic hypernatremia. Insensible losses through the lung or skin again must be suspected and are characterized by concentrated urine as the kidneys conserve water. Another cause of normovolemic hypernatremia is water diuresis, which is manifested by polyuria (see Figure 36-2). The differential for polyuria (generally defined as >3 L urine output/d) is a water or solute diuresis. Solute diuresis is exemplified by the osmotic diuresis of diabetes mellitus and generally is characterized by urine osmolality >300 mOsmol/L and hyponatremia. Water diuresis, a manifestation of **diabetes insipidus** (DI), is characterized by dilute urine (osmolality <250 mOsmol/L) and slight hypernatremia. DI is either central or nephrogenic. Central DI is due to decreased or absent ADH secretion resulting from (1) head trauma, (2) hypophysectomy, (3) pituitary tumor, or (4) granulomatous disease. Nephrogenic DI is due to renal resistance to ADH as a result of drugs, such as (1) lithium, (2) demeclocycline, (3) amphotericin, or (4) propoxyphene. Nephrogenic DI also results from sickle cell anemia and Sjögren syndrome as they affect collecting duct responsiveness to ADH; or, more rarely, mutant ADH receptors.[2]

Potassium

The total body potassium of a 70 kg subject is ≈3.5 mol (40 to 59 mmol/kg) of which only 1.5% to 2% is present in the ECF. Nevertheless, plasma K^+ is often a good indicator of total K^+ stores, unless abnormal K^+ is due to abnormal cellular shifts. Disturbance of K^+ homeostasis has serious consequences. For example, a decrease in extracellular K^+ (**hypokalemia**) is characterized by (1) muscle weakness, (2) irritability, and (3) paralysis. Plasma K^+ concentrations less than 3.0 mmol/L are often associated with marked neuromuscular symptoms. At lower concentrations, tachycardia and cardiac conduction defects are apparent by electrocardiogram (flattened T waves) and has been known to lead to cardiac arrest.[11]

High extracellular K^+ (**hyperkalemia**) concentrations may produce symptoms of (1) mental confusion, (2) weakness, (3) tingling, (4) flaccid paralysis of the extremities, and (5) weakness of the respiratory muscles.[11] Cardiac effects of hyperkalemia include bradycardia and conduction defects. Prolonged severe hyperkalemia >7.0 mmol/L can lead to peripheral vascular collapse and cardiac arrest. Symptoms are almost always present at K^+ concentrations >6.5 mmol/L. Concentrations >10.0 mmol/L in most cases are fatal.

Hypokalemia

Causes of hypokalemia (plasma K^+ <3.5 mmol/L) are classified as redistribution of extracellular K^+ into ICF, or true K^+ deficits, caused by decreased intake or loss of potassium-rich body fluids (Figure 36-3).

Redistribution

Intracellular redistribution of K^+ is illustrated by the fall in plasma K^+ that occurs following insulin therapy for diabetic hyperglycemia when cells take up K^+ as a consequence of glucose transport. Redistribution hypokalemia is also a feature of

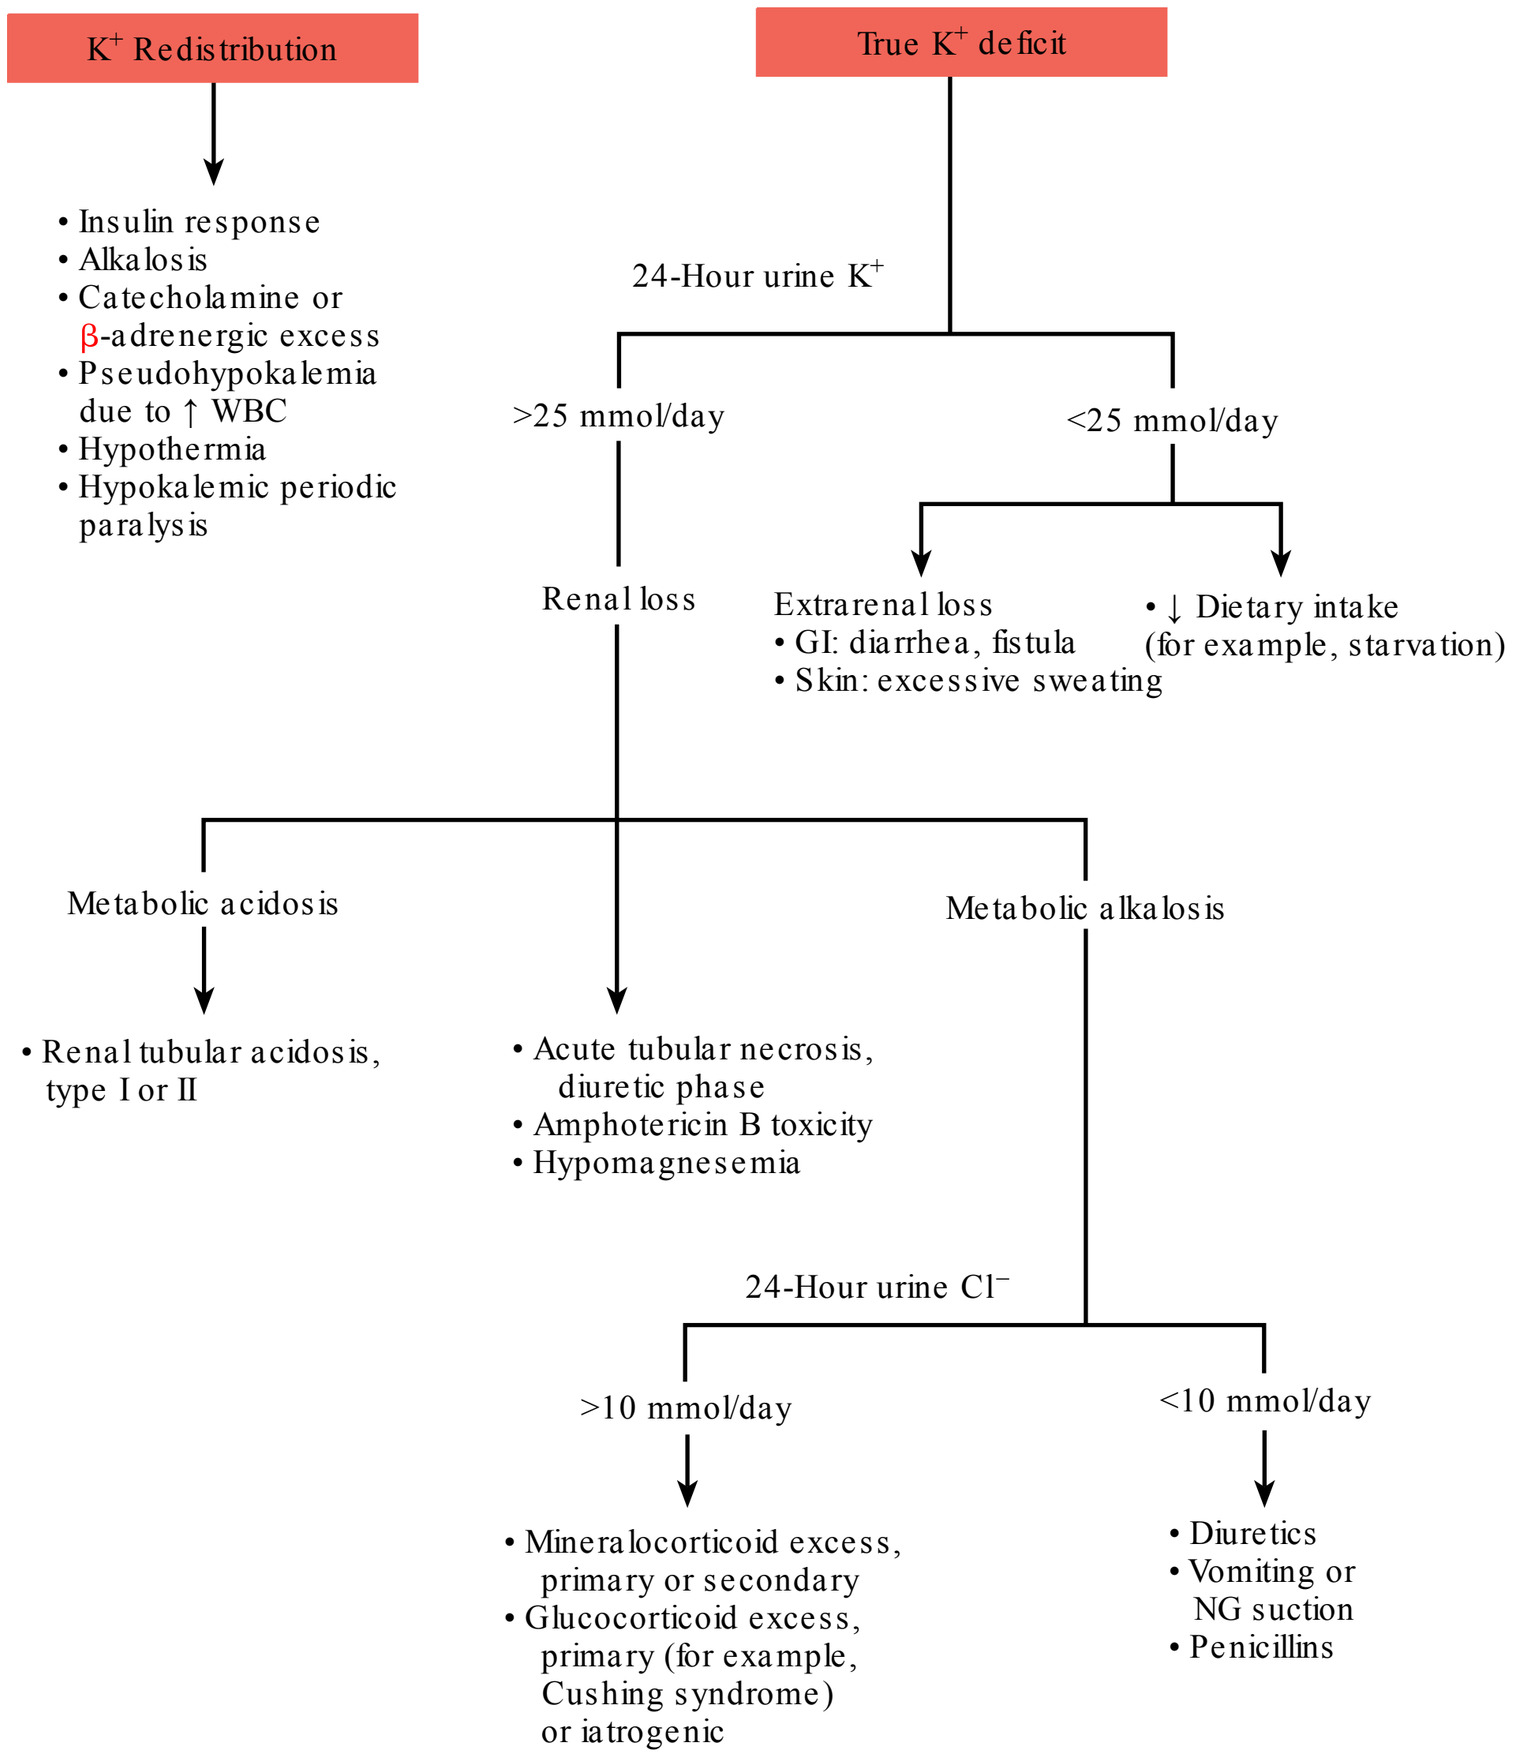

Figure 36-3 Algorithm for the differential diagnosis of hypokalemia. (Modifed from Kirkpatrick W, Kreisberg R. Acid-base and electrolyte disorders. In: Liu P, ed. Blue book of diagnostic tests. Philadelphia: WB Saunders, 1986:239-54.)

alkalosis, in which K^+ moves from ECF into cells as increased H^+ alters activity of the Na^+/K^+-ATPase. In addition, renal conservation of H^+ in the distal tubule occurs at the expense of K^+. Causes of intracellular redistribution are listed in Figure 36-3.

True Potassium Deficit

Hypokalemia reflecting true total body deficits of K^+ is classified into renal and nonrenal losses, based on daily excretion of K^+ in the urine (see Figure 36-3). If urine excretion of K^+ is <30 mmol/d, it is judged that the kidneys are properly functioning and are attempting to reabsorb K^+ as appropriate in a hypokalemic setting. The cause may be decreased K^+ intake or extrarenal loss of K^+-rich fluid. Situations of decreased intake include chronic starvation and postoperative intravenous fluid therapy with K^+-poor solutions. Gastrointestinal loss of K^+ occurs most commonly with diarrhea.

Urine excretion exceeding 25 to 30 mmol/d in a hypokalemic setting indicates that the kidneys are the primary source of lost amounts of K^+. Renal losses of K^+ may occur during the diuretic (recovery) phase of acute tubular necrosis and during states of excess mineralocorticoid (primary or secondary aldosteronism) or glucocorticoid (Cushing syndrome) production. When this occurs the distal tubules increase Na^+ reabsorption and K^+ excretion. Renal loss of K^+ is also caused by thiazide and loop diuretics.[9] In addition to redistribution of K^+ into cells in an alkalotic setting, K^+ is lost from the kidneys in exchange for reclaimed H^+ ions.

Hyperkalemia

Hyperkalemia (plasma K^+ >5.0 mmol/L) is a result of singly or in combination: (1) redistribution, (2) increased intake, or (3) increased retention. In addition, preanalytical conditions—such as, (1) hemolysis, (2) thrombocytosis (>10^6/μL), and (3) leukocytosis (>10^5/μL)—have been known to cause marked pseudohyperkalemia (Figure 36-4), as described in detail in Chapter 24.

Redistribution

The transfer of intracellular K^+ into ECF invariably occurs in acidosis as K^+ shifts outward as the result of pH-induced

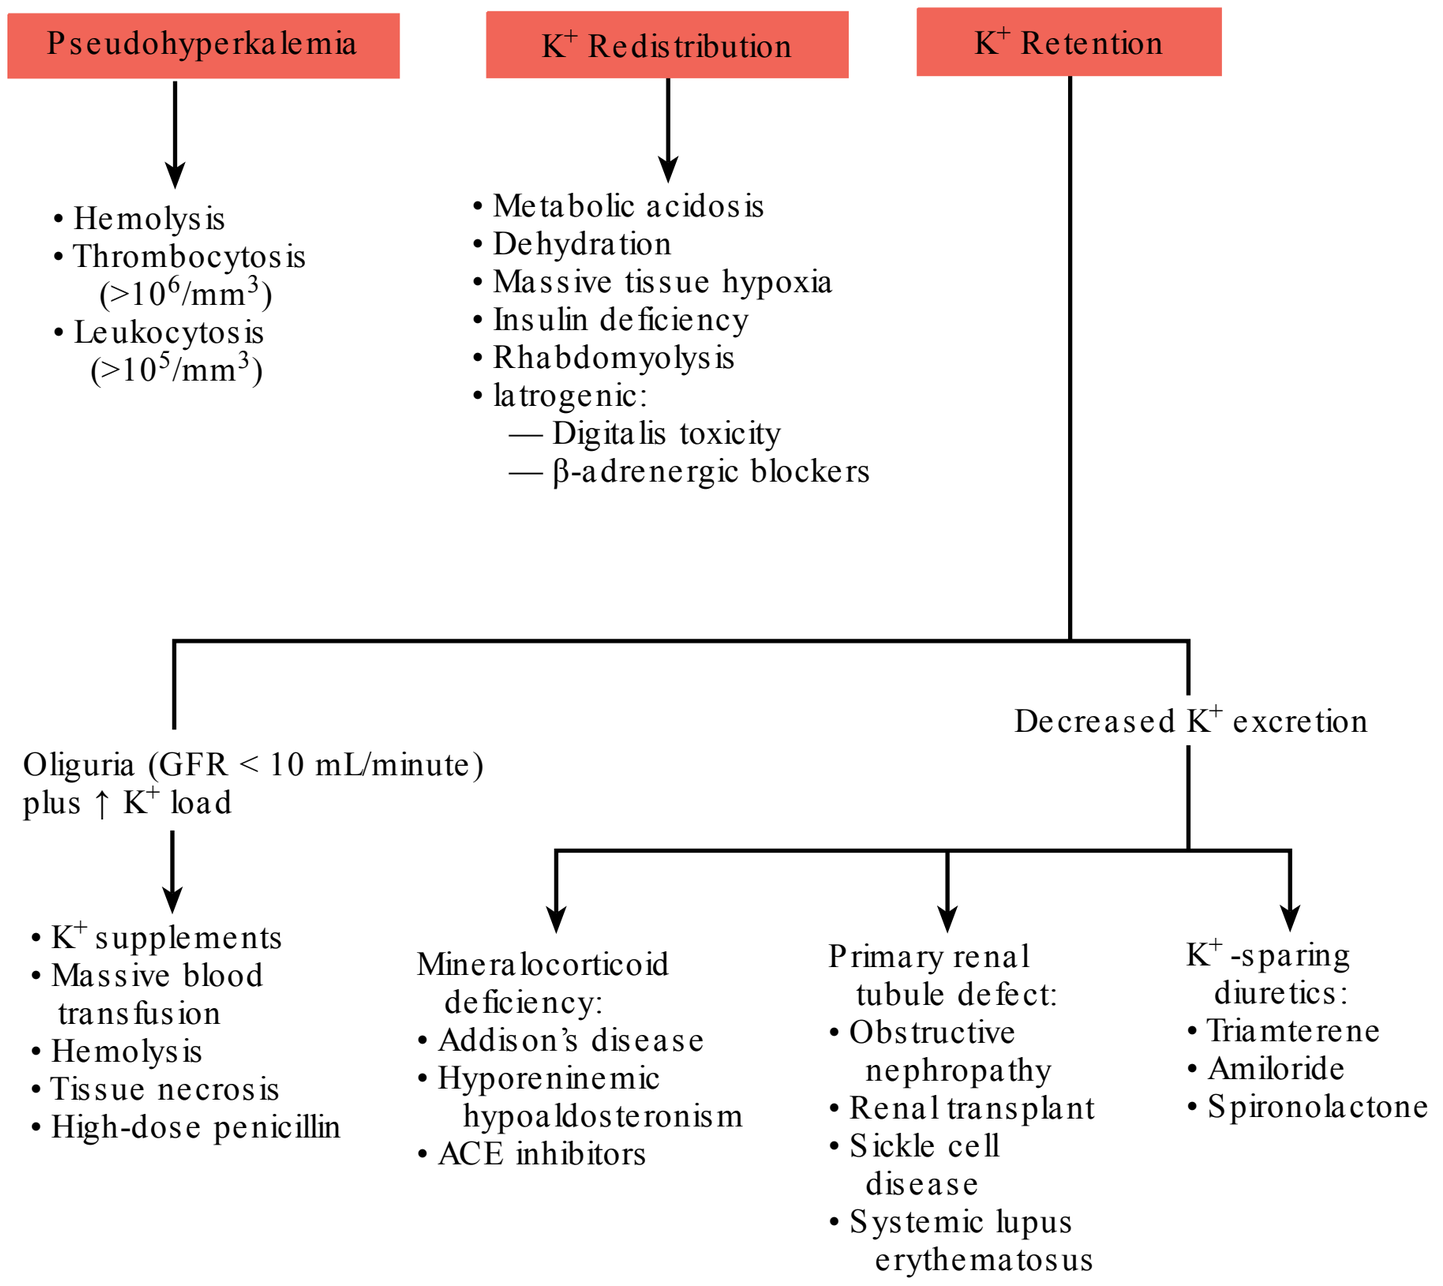

Figure 36-4 Algorithm for the differential diagnosis of hyperkalemia. (Modified from Kirkpatrick W, Kreisberg R. Acid-base and electrolyte disorders. In: Liu P, ed. Blue book of diagnostic tests. Philadelphia: WB Saunders, 1986:239-54.)

changes in Na^+/K^+-ATPase activity. When acidosis is corrected, normokalemia will be restored rapidly. Extracellular redistribution of K^+ may also occur in (1) tissue hypoxia; (2) insulin deficiency (e.g., diabetic ketoacidosis); (3) massive intravascular hemolysis; (4) severe burns; (5) violent muscular activity, as in status epilepticus; (6) rhabdomyolysis; and (7) tumor lysis syndrome. Finally, important iatrogenic causes of redistribution hyperkalemia include digoxin toxicity and β-adrenergic blockade, especially in patients with diabetes or on dialysis.[11]

Potassium Retention

When glomerular filtration or renal tubular function is decreased, hyperkalemia may be precipitated by intravenous infusion of K^+. When renal function is natural , overtreatment with K^+ solutions is unlikely to produce hyperkalemia, because renal capacity is more than adequate to excrete the excess K^+. Decreased excretion of K^+ in moderate and acute renal disease and end-stage renal failure (with oliguria or anuria) are the most common causes of prolonged hyperkalemia (see Figure 36-4). Hyperkalemia occurs along with Na^+ depletion in adrenocortical insufficiency (e.g., Addison disease) because diminished Na^+ reabsorption results in decreased tubular K^+ secretion. Drugs that block the production of aldosterone, such as (1) inhibitors of angiotensin-converting enzyme (ACE inhibitors; e.g., lisinopril), (2) nonsteroidal antiinflammatory drugs, and (3) angiotensin II receptor blockers, may also cause hyperkalemia.

Chloride

In the absence of acid-base disturbances, Cl^- concentrations in plasma generally will follow those of Na^+. However, determination of plasma Cl^- concentration is useful in the differential diagnosis of acid-base disturbances and is essential for calculating the **anion gap (AG)**. Fluctuations in serum or plasma Cl^- have little clinical consequence.

Hypochloremia

In general, causes of hypochloremia will parallel causes of hyponatremia. **Respiratory acidosis**, which is accompanied by increased HCO_3^-, is another common cause of decreased Cl^- with normal Na^+.

Hyperchloremia

Increased plasma Cl^- concentration, similar to increased Na^+ concentration, occurs with (1) dehydration, (2) prolonged diarrhea with loss of sodium bicarbonate, (3) DI, and (4) overtreatment with normal saline solutions, which have a Cl^- content of 154 mmol/L. A rise in Cl^- concentration may also be seen in **respiratory alkalosis** because of renal compensation for excreting HCO_3^-.

Bicarbonate

T e total carbon dioxide (CO_2) content of plasma consists of carbon dioxide dissolved in an aqueous solution (dCO_2), CO_3 loosely bound to amine groups in proteins (carbamino compounds), HCO_3^-, and very small quantities of CO_3^{2-} ions and

carbonic acid (H_2CO_3). Bicarbonate ions make up all but ≈2 mmol/L of the total carbon dioxide of plasma. Alterations in HCO_3^- and CO_2 dissolved in plasma are characteristic of acid-base imbalances.

Acid-Base Physiology

Normal metabolic processes result in the production of large amounts of (1) carbonic acid and lesser amounts of (2) sulfuric, (3) phosphoric, and (4) other acids. For example, during a 24-hour period, a person weighing 70 kg respires approximately 20 mol of carbon dioxide (the volatile form of carbonic acid) through the lungs, and about 70 to 100 mmol (or ≈1 mmol/kg) of nonvolatile acids (mainly sulfuric and phosphoric acids) through the kidneys. These products of metabolism are transported to the lungs and kidneys via the ECF and blood with no appreciable change in the ECF pH, and with only a minimal difference between arterial (pH 7.35 to 7.45) and venous (pH 7.32 to 7.38) blood. This is accomplished by the buffering capacity of blood and by respiratory and renal regulatory mechanisms.

Acid-Base Balance and Acid-Base Status

The bicarbonate/carbonic acid system is the most important mammalian buffering system. The acid-base status of body fluids is typically assessed by measurements of (1) total CO_2, (2) plasma pH, and (3) PCO_2.

The following clinical terms are used to describe acid-base status. **Acidemia** is defined as an arterial blood pH <7.35, and **alkalemia** indicates an arterial blood pH >7.45. Acidosis and alkalosis refer to pathological states that often lead to acidemia or alkalemia. It should be noted that more than one type of pathological process can occur simultaneously, giving rise to a **mixed acid-base disturbance**, in which the blood pH may be (1) low, (2) high, or (3) within the reference interval. To understand how these and other perturbations of acid-base metabolism affect human physiology, it will be necessary to examine briefly the concepts of (1) acids, (2) bases, (3) pH, and (4) buffers in relation to the relevant systems that function to maintain normal **acid-base balance** in the human body.

Acid-Base Parameters—Definitions and Abbreviations

Acids are chemical substances that donate protons (H^+ ions) in solution, and bases are substances that accept protons. Strong acids readily give up H^+, whereas strong bases readily accept H^+. Thus the conjugate base of a strong acid is a weak base and vice versa.

pH and pK

The pH of a solution is defined as the negative logarithm of the hydrogen ion activity ($pH = -\log aH^+$). Thus pH is a dimensionless quantity, and a decrease in one pH unit represents a tenfold increase in H^+ activity (see Chapter 8 for a more detailed discussion of this topic). Potentiometric determinations of blood pH measure H^+ activity and not H^+ concentration, although the activity is assumed to equal the concentration. The average pH of blood (7.40) corresponds to a hydrogen ion concentration of 40 nmol/L, but this assumes an activity coefficient of 1 (see Figure 36-5). This is relationship is inverse and is obviously nonlinear.

The pK is the pH at which an acid is half dissociated, existing as equal proportions of acid and conjugate base. Thus acids have pK values <7.0, whereas bases have pK values >7.0. The lower the pK, the stronger the acid is, and the higher the pK, the stronger the conjugate base is. For example, the pK of lactic acid is 3.86, and that of ammonium ion NH_{4+} is 9.5.

The pH of plasma may be considered to be a function of two independent variables: (1) the PCO_2, which is regulated by the lungs and represents the acid component of the carbonic acid/bicarbonate buffer system, and (2) the concentration of titratable base (base excess or deficit, which is defined later), which is regulated by the kidneys. The plasma total CO_2 (bicarbonate) concentration generally is taken as a measure of the base excess or deficit in plasma and ECF, although conditions exist in which it may not accurately reflect the true base excess or deficit.

Bicarbonate and Dissolved CO_2

Bicarbonate is the second largest fraction (behind Cl^-) of plasma anions (≈26 mmol/L). Conventionally, it is defined to include (1) plasma bicarbonate ion (HCO_3^-), (2) carbonate ion (CO_3^{2-}), and (3) CO_2 bound in plasma carbamino compounds. At the pH of blood, the plasma carbonate concentration is ≈26 μmol/L, which is ≈1/700 to 1/1000 of the total bicarbonate fraction. CO_2-bound carbamino compounds (RCNHCOOH) are 0.2 mmol/L in plasma and 1.5 mmol/L in erythrocytes. Actual bicarbonate ion concentration is not measured, but rather is calculated from the **Henderson-Hasselbalch equation** as described later (and discussed in detail in

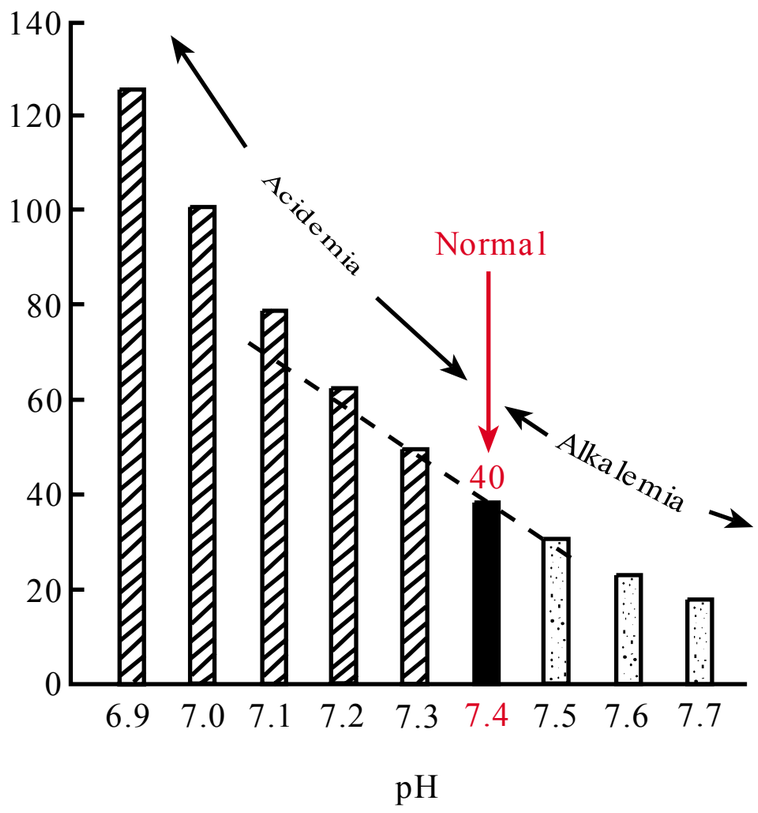

Figure 36-5 Relationship of pH to hydrogen ion concentration. A broken line is drawn to emphasize the (approximate) linear relationship between hydrogen ion concentration and pH over the pH range of 7.2 to 7.5. (From Narins RG, Emmett M. Simple and mixed acid-base disorders: a practical approach. Medicine 1980;59:161-87.)

Chapter 24). Also as described in Chapter 24, the analyte usually measured in plasma is total CO_2, which includes bicarbonate and dissolved CO_2 (dCO_2). At the pH of the blood, the amount of dissolved CO_2 is 700 to 1000 times greater than the amount of carbonic acid (H_2CO_3); therefore $cdCO_2$ is the term used to express their combined concentration. It is calculated from the solubility coefficient of CO_2 in blood at 37 °C (α = 0.031 mmol/L per mm Hg) multiplied by the measured PCO_2 in mm Hg. Thus at a PCO_2 of 40 mm Hg, $cdCO_2$ is 1.224 mmol/L (0.031 mmol/L × 40 mm Hg). This $cdCO_2$ value is then used, in the Henderson-Hasselbalch equation, to calculate the total bicarbonate concentration.

Henderson-Hasselbalch Equation

The Henderson-Hasselbalch equation is described in detail in Chapter 24. However, it is important to review this equation here, because it enhances understanding of pH regulation of body fluids as it relates to compensatory mechanisms of the body in acid-base disturbances. The equation derived in Chapter 24 is also written as follows:

$$pH = 6.1 + \frac{c\,HCO_3^-}{c\,dCO_2}$$

where $cdCO_2$ is equal to α (0.031 mmol/L per mm Hg) PCO_2, and 6.1 is the pK for the carbonic acid/bicarbonate system.

The average typical ratio of the concentrations of bicarbonate and dissolved carbon dioxide in plasma is 26 (mmol/L)/1.25 (mmol/L) ≈ 20/1. Thus, any change in the concentration of bicarbonate or dissolved CO_2 relative to each other is accompanied by a change in pH. Such changes in this important ratio also occurs through a change in $cHCO_3^-$ (the renal component) or in PCO_2 (the respiratory component). Clinical conditions characterized as metabolic disturbances of acid-base balance are classified as primary disturbances in $cHCO_3^-$. Those characterized as respiratory disturbances are classified as primary disturbances in $cdCO_2$ (PCO_2). Various compensatory mechanisms attempting to re-establish the normal ratio of $cHCO_3^-/cdCO_2$ may result in changes in bicarbonate concentration, dissolved CO_2 concentration, or both. Application of the Henderson-Hasselbalch equation to human acid-base physiology is illustrated with the use of a lever-fulcrum (teeter-totter) diagram (Figure 36-6).

Buffer Systems and Their Role in Regulating the pH of Body Fluids

A buffer is a mixture of a weak acid and a salt of its conjugate base that resists changes in pH when a strong acid or base is added to the solution (see Chapter 8). If concentrations of the acid and base components of a buffer are equal, the pH will equal the pK. Generally, buffers work best at resisting pH changes in the interval ±1 pH unit of its pK, (buffers work best when the ratio of acid/base is within the range of 10:1 to 1:10). Buffers are also more effective at higher concentrations, so that a 10 mmol/L buffer solution is more effective than a 1.0 mmol/L solution.

The action of buffers in the regulation of body pH is explained by using the bicarbonate buffer system as an example. If a strong acid is added to a solution containing HCO_3^- and H_2CO_3, the H^+ will react with HCO_3^- to form more H_2CO_3, and subsequently CO_2 and H_2O. The hydrogen ions are thereby bound, and the increase in the H^+ concentration will be minimal.

$$H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \rightleftharpoons CO_2 + H_2O$$

Bicarbonate/Carbonic Acid Buffer System

The most important buffer of plasma is the bicarbonate/carbonic acid pair. Upon inspection, it is not initially apparent

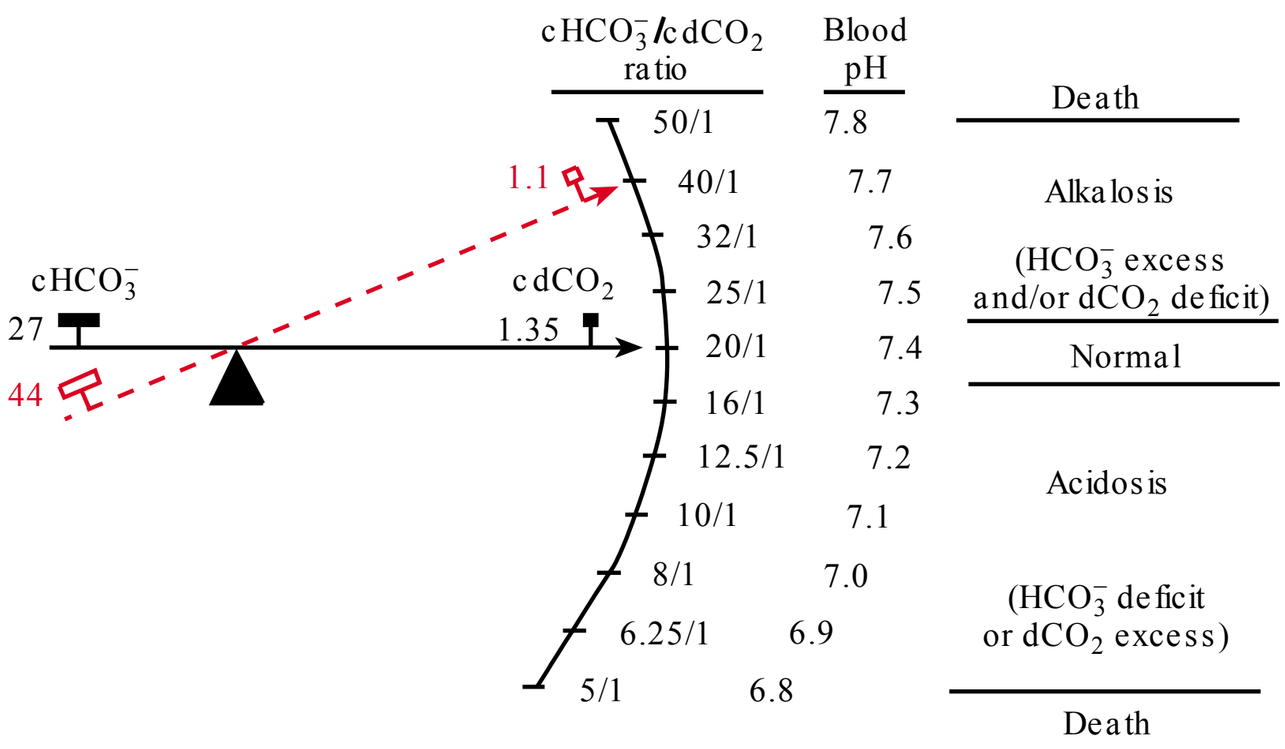

Figure 36-6 Scheme demonstrating the relation between pH and the ratio of bicarbonate concentration to the concentration of dissolved CO_2. If the ratio in blood is 20:1 ($cHCO_3^-$ = 27 mmol/ $cdCO_2$ = 1.35 mmol/L), the resultant pH will be 7.4, as demonstrated by the solid beam. The dotted line shows a case of uncompensated alkalosis (bicarbonate excess) with a bicarbonate concentration of 44 mmol/L and a $cdCO_2$ of 1.1 mmol/L. The ratio therefore is 40:1, and the resultant pH is 7.7. In a case of uncompensated acidosis, the pointer of the balance would point to a pH between 6.8 and 7.35, depending on the $cHCO_3^-/cdCO_2$ ratio. (From Weisberg HF. A better understanding of anion-cation ("acid-base") balance. Surg Clin North Am 1959;39:93-120.)

that this buffer would be very effective because its pK is 6.1, whereas normal plasma pH is 7.4. Also note that the normal bicarbonate/dCO_2 ratio is 20:1, which is outside the 10:1 or 1:10 ratio at which buffers are most effective. However, the effectiveness of the bicarbonate buffer is based on the fact that the lungs are able to readily dispose of or retain CO_2. In addition, the renal tubules are able to increase or decrease the rate of reclamation of bicarbonate from the glomerular filtrate (see Chapter 35).

Phosphate Buffer System

At a plasma pH of 7.4, the ratio $`cHPO_4^{2-}/cH_2PO_4^{-}´$ is 4:1 (pK = 6.8). T e total concentration of this buffer in both erythrocytes and plasma accounts for about 5% of the nonbicarbonate buffer value of plasma. Organic phosphate, however, in the form of 2,3-diphosphoglycerate (present in erythrocytes in a concentration of about 4.5 mmol/L), accounts for about 16% of the nonbicarbonate buffer value of erythrocytes.

Plasma Protein and Hemoglobin Buffer System

Proteins, especially albumin, account for the greatest portion (>90%) of the nonbicarbonate buffer value of plasma. T e most important buffer groups of proteins in the physiological pH range are the imidazole groups of histidines (pK ≈7.3). Each albumin molecule contains 16 histidines. In addition, hemoglobin accounts for the major part of nonbicarbonate buffers of erythrocyte fluid.

Respiratory Mechanism in the Regulation of Acid-Base Balance

In addition to supplying O_2 to tissue cells for normal metabolism, the respiratory mechanism contributes to maintenance of typical body pH through elimination or retention of CO_2 in **metabolic acidosis** and alkalosis, respectively.

Respiration

Exchange of O_2 and CO_2 in the lungs between alveolar air and blood is called external respiration, in contrast to internal respiration, which occurs at the cellular level. At inspiration, muscular contraction expands intrathoracic volume and creates a fall in intrapulmonary pressure. Atmospheric air is drawn into the bronchial tree, which terminates at the alveoli, where the exchange of gases between alveolar air and pulmonary blood occurs. Expiration takes place passively as the elastic tissues of the lungs and chest wall rebound and the intrathoracic volume is decreased.

Peripheral venous blood reaches the pulmonary circulation from the right ventricle of the heart and is arterialized in the capillaries of the lungs by uptake of O_2 and loss of CO_2. Pulmonary venous blood then returns to the left ventricle by way of the left atrium and is pumped through the aorta to the peripheral tissues. In the capillaries of peripheral tissues, the arterial blood releases O_2 to the tissue cells and takes up CO_2.

In a resting state, the respiration rate is normally 12 to 15 breaths/min. Involuntary increases in rate and depth of respiration are regulated by the medullary respiratory center in the brainstem, which is (1) stimulated by central chemoreceptors located on the anterior surface of the medulla oblongata and (2) by peripheral chemoreceptors located in the carotid arteries and aorta. Peripheral chemoreceptors are stimulated by a fall in pH caused by accumulation of CO_2 or by a decrease in PO_2. Central chemoreceptors are stimulated only by a decrease in pH of the cerebrospinal fluid (CSF). Pathologically, the response of these receptors is perturbed by adverse conditions in the circulatory or respiratory system. When this occurs, the patient may require assisted ventilation that uses a mechanical device to provide gas mixtures via an endotracheal tube. Adjustments of gas mixtures and rates of mechanical ventilation depend greatly on the results of laboratory blood gas and pH determinations.

Exchange of Gases in the Lungs and Peripheral Tissues

Diffusion of O_2 and CO_2 across alveolar and cell membranes is governed by gradients in the partial pressure of each gas (Figure 36-7). Dry air inspired at a pressure of 1 atm (760 mm Hg) consists of 21% O_2 (PO_2 ≈160 mm Hg), 0.03% CO_2 (PCO_2 ≈0.25 mm Hg), 78% nitrogen, and ≈0.1% other inert gases. As inspired air passes over the moist mucous membranes of the upper respiratory tract, it is (1) warmed to 37 °C, (2) becomes saturated with water vapor, and (3) mixes with air in the respiratory tree. T is results in partial pressures of ≈150 mm Hg for O_2, ≈0.3 mm Hg for CO_2, ≈47 mm Hg for H_2O, and ≈563 mm Hg for nitrogen. Further mixing with alveolar air results leads to partial pressures at the alveolar membrane of ≈105 mm Hg for O_2, ≈40 mm Hg for CO_2, and ≈47 mm Hg for H_2O. Venous blood on the opposite side of the alveolar membrane has PO_2 ≈40 mm Hg and PCO_2 ≈46 mm Hg. T us the gradient for O_2 is inward, toward the blood; and for CO_2, it is outward, toward the alveoli. CO_2 removal is so efficient that the PCO_2 in expired air is more than 100 times the PCO_2 in inspired air (see Figure 36-7). In arterial blood, the PO_2 is slightly lower than in alveolar air (90 to 100 vs. 105 mm Hg).

At the arterial end of capillaries of peripheral tissues, the PO_2 at 95 mm Hg is substantially higher than the average PO_2 at the surface of tissue cells (20 mm Hg). T e PCO_2 at 40 mm Hg is substantially lower than that in the cells (50 to 70 mm Hg). T us, in the tissue capillary, the gradient for O_2 is inward to the cell; for CO_2, it is outward to the capillary blood. T e arteriovenous difference in partial pressures is approximately 60 mm Hg for O_2 and 6 mm Hg or less for CO_2. T is difference in arteriovenous (affecting an artery and a vein) PO_2 is one indicator of the efficiency of O_2 extraction in the passage of blood through the capillaries.

Respiratory Response to Acid-Base Perturbations

The respiratory system responds immediately to a change in acid-base status. However, several hours may be required for the response to become maximal and is not attained until both central and peripheral chemoreceptors are fully stimulated. For example, in the early stages of metabolic acidosis, plasma pH decreases, but because H^+ ions equilibrate

rather slowly across the blood-brain barrier, the pH in CSF remains nearly normal. However, because peripheral chemoreceptors are stimulated by decreased plasma pH, hyperventilation occurs, and plasma PCO_2 is decreased. Consequently, the PCO_2 of the CSF decreases immediately because CO_2 equilibrates rapidly across the blood-brain barrier, leading to a rise in pH of the CSF that inhibits the central chemoreceptors. As plasma bicarbonate gradually falls because of acidosis, bicarbonate concentration and pH in the CSF will also eventually fall. At this point, stimulation of respiration becomes maximal from both central and peripheral chemoreceptors.

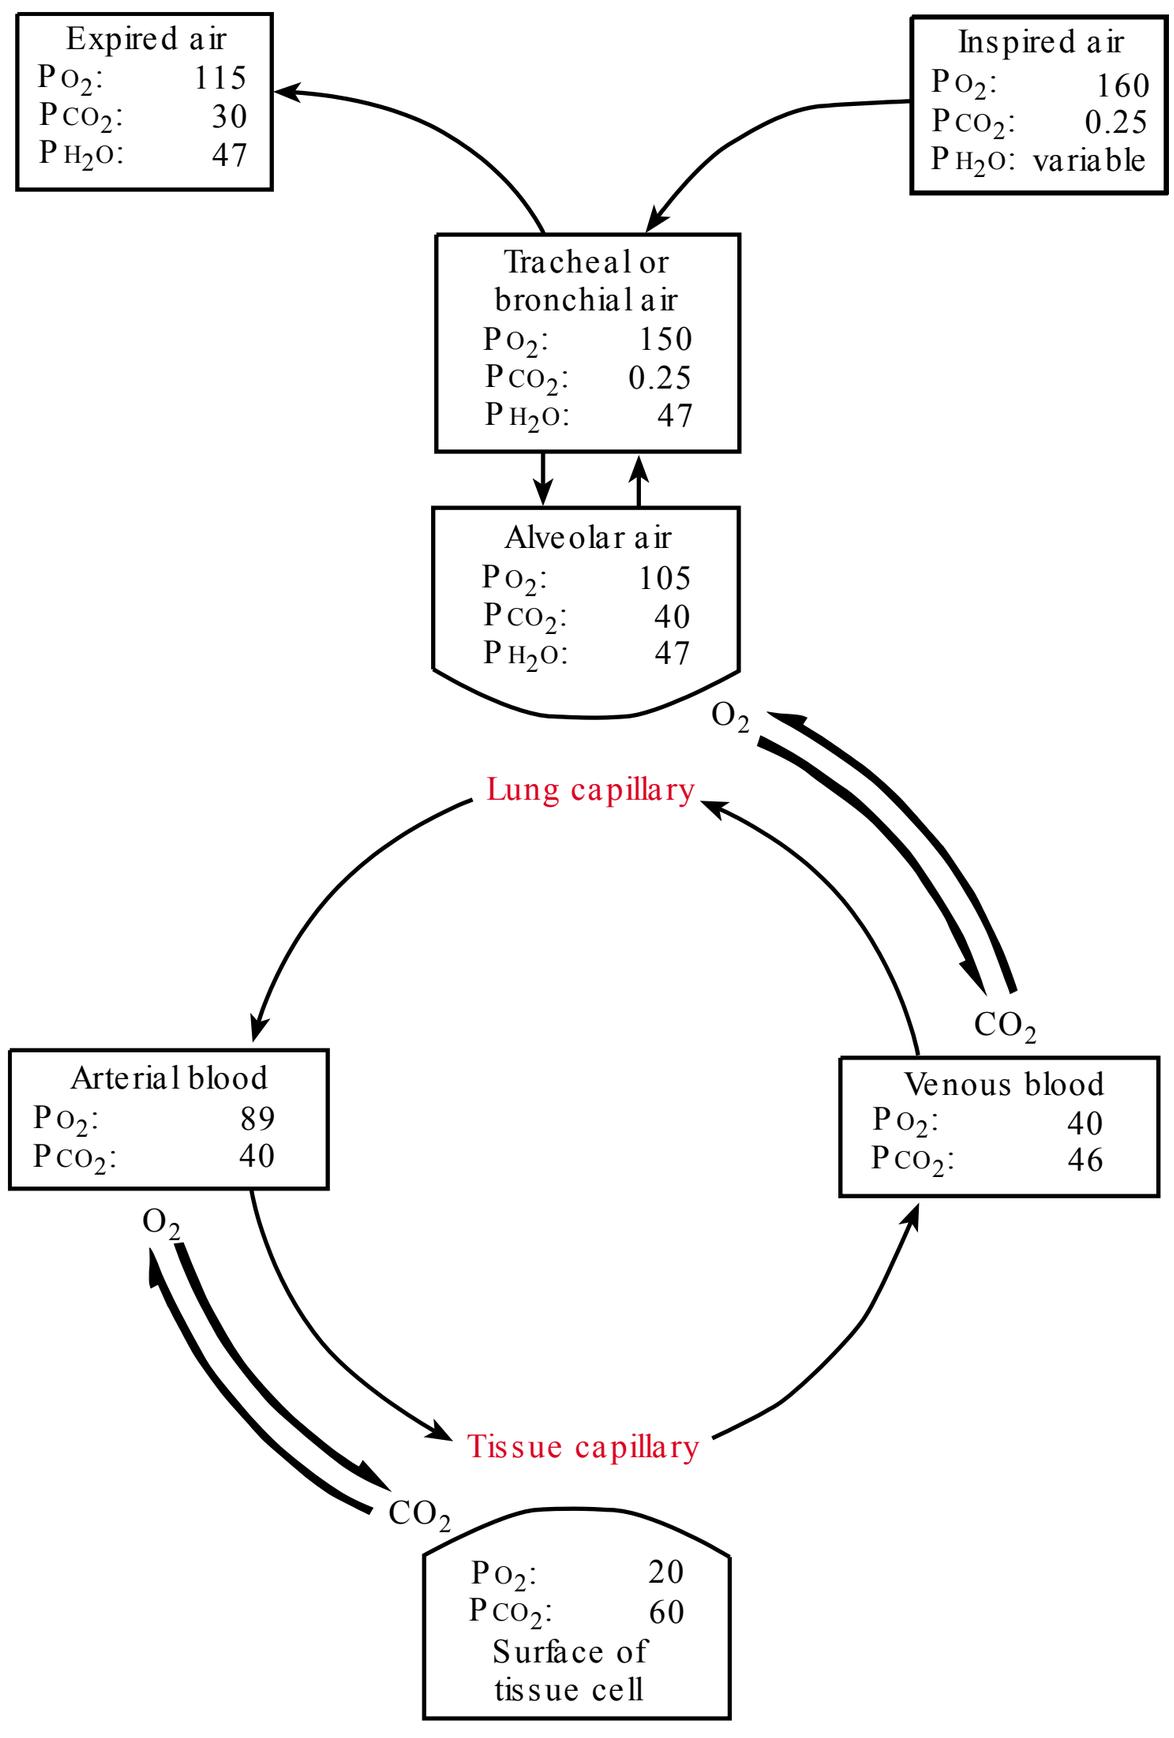
The reverse is true when a patient with metabolic acidosis is treated with HCO_3^-. When the pH in plasma increases as the result of HCO_3^- administration, stimulation of the peripheral chemoreceptors returns to normal. However, because of slow equilibration of HCO_3^- between plasma and CSF, the central chemoreceptors continue to be stimulated and the patient continues to hyperventilate. Respiration does not return to normal until normal acid-base balance in the CSF is restored.

Renal Mechanisms in the Regulation of Acid-Base Balance

The average pH of plasma and of the glomerular filtrate is ≈7.4, whereas the average urinary pH is ≈6.0, reflecting the renal excretion of nonvolatile acids. Various functions of the kidneys respond to different alterations in acid-base status. In the case of acidosis, excretion of acids is increased and that of base is conserved. In alkalosis, the opposite occurs. The pH of the urine changes correspondingly and may vary in random specimens from pH 4.5 to 8.0. Renal excretion of acid and conservation of HCO_3^- occur through several mechanisms, including (1) Na^+-H^+ exchange, (2) production of ammonia and excretion of NH_4, and (3) reclamation of HCO_3^-.

Na^+-H^+ Exchange

Nearly all mammalian cells contain a plasma membrane ATP-hydrolyzing protein capable of exchanging sodium ions for protons—the so-called **sodium hydrogen exchanger (NHE)**. In the renal tubules, Na^+-H^+ exchangers extrude H^+ ions into the tubular fluid in exchange for Na^+ ions. Na^+-H^+ exchange is enhanced in states of acidosis and is inhibited in alkalosis.



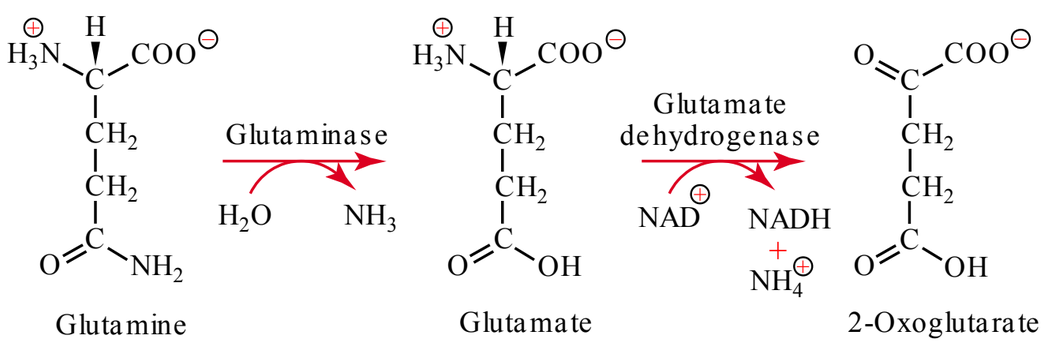


Figure 36-7 Partial pressures of oxygen and carbon dioxide in air, blood, and tissue. Values shown are approximations in mm Hg and are calculated assuming a 5% shunt. Red arrows show directions of gradients. (Modifed *f*rom Tietz NW. Fundamentals o*f* clinical chemistry, 3rd edition. Philadelphia: WB Saunders, 1987.)

The proximal tubules cannot maintain an H^+ gradient of more than ≈1 pH unit, whereas the distal tubules cannot maintain one of more than ≈3 pH units. Thus maximum urine acidity is reached at ≈pH 4.4. In type I and type IV renal tubular acidosis (RTA), this exchange process is defective and may lead to a decrease in blood pH.

Potassium ions compete with H^+ in the renal tubular Na^+-H^+ exchanger. If the concentration of intracellular K^+ in renal tubular cells is high, more K^+ and less H^+ are exchanged for Na^+. As a result, the urine becomes less acidic, thereby increasing the acidity of body fluids. If K^+ is depleted, more H^+ ions are exchanged for Na^+; the urine becomes more acidic and the body fluids more alkaline. Thus hyperkalemia contributes to acidosis and hypokalemia to alkalosis.

Renal Production of Ammonia and Excretion of Ammonium Ions

Renal tubular cells are able to generate ammonia from glutamine and other amino acids derived from muscle and liver cells according to the following reaction:

$$NH_4^+ \rightleftharpoons NH_3 + H^+$$

The ammonium ion produced dissociates into ammonia and hydrogen ions to a degree dependent on the pH. At physiological blood pH, the ratio of NH_4 to NH_3 is about 100 to 1. Ammonia is a gas that diffuses readily across the cell membrane into the tubular lumen, where it combines with hydrogen ions to form ammonium ions. At the acid pH of urine, the equilibrium between NH_4 and NH_3 shifts markedly to the left (≈10,000 to 1), strongly favoring formation of NH_4. The NH_4 formed in the tubular lumen will not easily cross cell membranes and thus is trapped in the tubular urine and excreted with anions, such as (1) phosphate, (2) chloride, and (3) sulfate. In healthy individuals, NH_4 production in the tubular lumen accounts for the excretion of ≈60% (30 to 60 mmol) of the hydrogen ions.

Excretion of H^+ as $H_2PO_4^-$

H^+ secreted into the tubular lumen by the Na^+-H^+ exchanger may also react with HPO_4^{2-} to form $H_2PO_4^-$. This process depends on the amount of phosphate filtered by the glomeruli and the pH of urine. Under normal physiological conditions, ≈30 mmol of H^+ is excreted per day as $H_2PO_4^-$. Acidemia increases phosphate excretion and thus provides additional buffer for reaction with H^+. A decrease in the glomerular filtration rate (GFR), as observed in renal disease, results in a decrease in $H_2PO_4^-$ excretion.

Reclamation of Filtered Bicarbonate

The unmodified glomerular filtrate has the same concentration of HCO_3^- as does plasma; however, with increasing acidification of proximal tubular urine, the HCO_3^- concentration is decreased. Excreted H^+ reacts with HCO_3^- catalyzed by carbonic anhydrase in the proximal tubular cells) to form H_2CO_3 and subsequently CO_2 and H_2O.

This increase in urinary CO_2 causes carbon dioxide to diffuse across the tubular cell membrane into the tubular cell, where it reacts with H_2O in the presence of cytoplasmic carbonic anhydrase to form H_2CO_3 and subsequently H^+ and HCO_3^-. Thus reclamation of bicarbonate consists of diffusion of CO_2 into tubular cells and its subsequent conversion to HCO_3^-. The increase in HCO_3^- helps to maintain or restore a normal pH in the circulation. Typically in a healthy individual, ≈90% of filtered HCO_3^- (or about 4500 mmol/d) is reclaimed in the proximal tubule, which parallels Na^+ reabsorption. Thus for each mmol H^+ secreted into the tubular fluid, 1 mmol Na^+ and 1 mmol HCO_3^- enter the tubular cell and return to the general circulation. When plasma HCO_3^- concentration is above ≈28 mmol/L, the capacity of the proximal and distal tubules to reclaim HCO_3^- is exceeded, and HCO_3^- is excreted in the urine.

Conditions Associated with Abnormal Acid-Base Status and Abnormal Electrolyte Composition of the Blood[5,10,11]

Many pathological conditions are accompanied by acid-base and electrolyte disturbances in the blood. Abnormalities in acid-base status of the blood are always accompanied by characteristic changes in electrolyte concentrations in the plasma. Hydrogen ions cannot accumulate without concomitant accumulation of anions (such as, Cl^- or lactate), or without exchange for cations (such as, K^+ or Na^+). Consequently, the electrolyte composition of blood serum or plasma is often determined along with measurements of blood gases and pH to assess acid-base disturbances.

Acid-base disturbances are traditionally classified as (1) metabolic acidosis, (2) metabolic alkalosis, (3) respiratory acidosis, or (4) respiratory alkalosis. For simple acid-base disorders, the laboratory parameters observed for these groups are shown in Table 36-2. However, interpretation of laboratory values to classify these disorders is rarely straightforward because of compensatory responses by the respiratory and renal systems in attempting to correct the imbalance.

Causes of acid-base disorders, resultant laboratory values, and compensatory responses are discussed here in the traditional categorization of these disorders. However, it is often difficult to remember which disorders fall into which categories, and so it is common for mnemonic devices or tables to be used to facilitate description of these disorders. A useful and more logical approach is to realize that an acidosis only occurs as the result of one (or a combination) of three mechanisms: (1) increased addition of acid, (2) decreased elimination of acid, and (3) increased loss of base. Similarly, alkalosis occurs only by (1) increased addition of base, (2) decreased

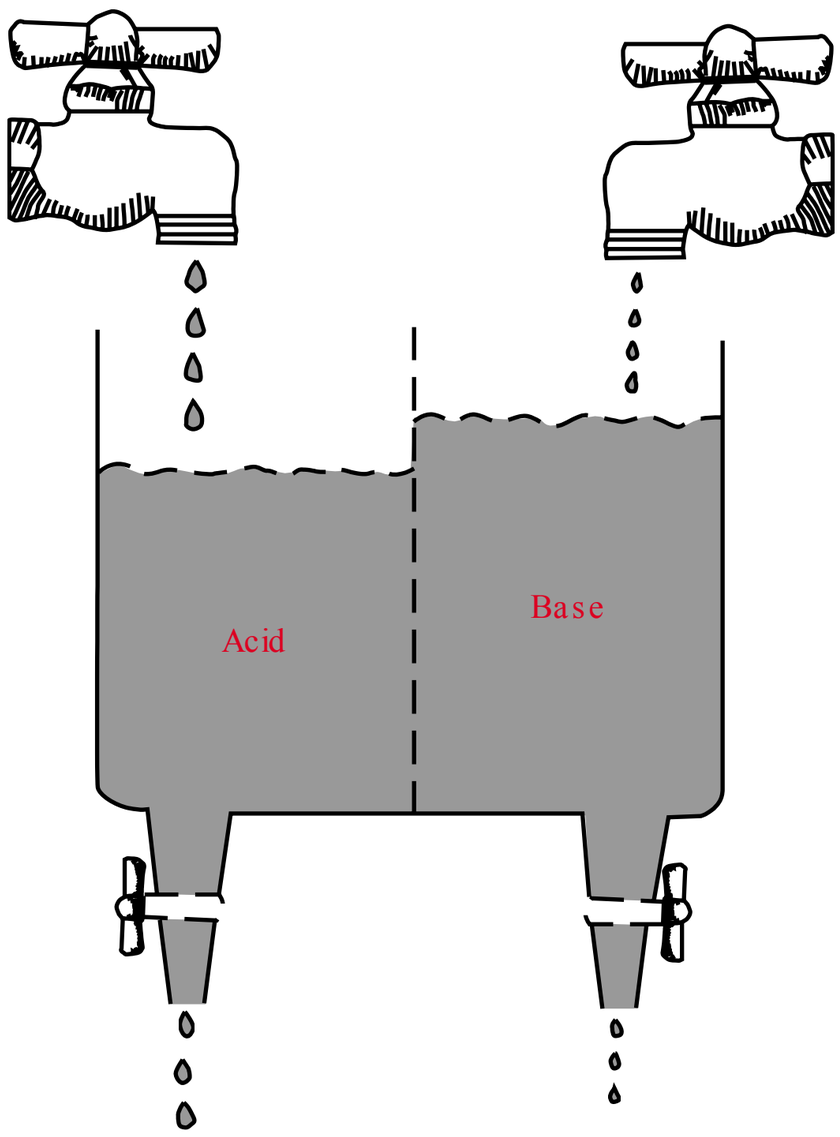

Figure 36-8 Simple depiction of the body as a two-vat system of acid and base. At equilibrium, input and output from each "vat" are equal. (From Dufour DR. Acid-base disorders. In: Dufour DR, Christenson RH, eds: Professional practice in clinical chemistry: a review. Washington, DC: AACC Press, 1995:604-35.)

elimination of base, and (3) increased loss of acid. Dufour has illustrated this simple concept by depicting the body as a two-tank vat, one of acid and one of base with inputs and outputs for each vat (Figure 36-8).[5] In the normal setting, these inputs and outputs are balanced. An acid-base disorder then involves a perturbation in the input or output of these body reservoirs, as is discussed in the next section.

Metabolic Acidosis (Primary Bicarbonate Deficit)

Metabolic acidosis is readily detected by decreased plasma bicarbonate (or a negative base excess). Causes include the following:

1. Production of organic acids that exceeds the rate of elimination (e.g., production of acetoacetic acid and β-hydroxybutyric acid in diabetic **ketoacidosis** and of lactic acid in lactic acidosis). Bicarbonate is "lost" in the buffering of excess acid.
2. Reduced excretion of acids (H^+) as occurs in renal failure and some RTAs, resulting in an accumulation of acid that consumes bicarbonate.
3. Excessive loss of bicarbonate due to increased renal excretion (decreased tubular reclamation) or excessive loss of duodenal fluid (as in diarrhea). Plasma $cHCO_3^-$ decreases with the fall associated with a rise in the concentration of inorganic anions (mostly chloride) or, rarely, a concomitant fall in the sodium concentration.

When any of these conditions exists, the ratio of $cHCO_3^-/cCO_2$ is decreased because of the primary decrease in bicarbonate. The resulting drop in pH stimulates respiratory compensation via hyperventilation, which lowers PCO2 and thereby raises the pH.

Increased Anion Gap Acidosis (Organic Acidosis)

Metabolic acidoses are classified as those associated with an increased anion gap or a normal anion gap (Table 36-3). The concept of the anion gap was originally devised as a quality control rule when it was noted that if the sum of Cl^- and HCO_3^- values was subtracted from the Na^+ value [$Na^+ - (Cl^- + HCO_3^-)$], the difference, or "gap," averaged 12 mmol/L in healthy subjects.[7] This apparent gap is due to unmeasured anions (e.g., proteins, SO_4^{2-}, $H_2PO_4^{2-}$) that are present in plasma. It is important to note that infrequently, low serum anion gaps (<2 mEq/L) occur. Laboratory error is the most common cause, but (1) bromide, (2) lithium, or (3) iodide intoxication also leads to a low anion gap, as does (4) low albumin/increased immunoglobulin in cirrhosis and (5) monoclonal gammopathies.[7] The anion gap is increased in many patients with a metabolic acidosis, and the presence of an elevated anion gap is often the first indication of a metabolic acidosis and should be assessed in the electrolyte profiles of all patients (Figure 36-9).[7]

All anion gap metabolic acidoses, besides inborn errors of metabolism, are able to be explained by one (or a combination) of eight underlying mechanisms listed here according to the common mnemonic device, MUDPILES. The physiologic basis for the anion gap in these conditions is the consumption of bicarbonate in buffering excess acid. Cl^- values remain normal when the excess acid is any other than HCl, because lost bicarbonate is replaced by the unmeasured anions.

Methanol

Although nontoxic itself, methanol is metabolized by the liver to formaldehyde and formic acid (see Chapter 31). Accumulation of this acid leads to metabolic acidosis with a high anion gap and to clinical symptoms of optic papillitis ("snowfield" blindness), and ultimately blindness as well as neurologic defects that may lead to coma. Methanol and other ingested alcohols, such as (1) ethylene glycol, (2) ethanol, and (3) isopropanol will increase the osmolality of plasma. Thus in the presence of a high anion gap acidosis, determination of the osmolal gap (see Chapter 24) will help determine the source of the unmeasured anion and will suggest specific toxicologic analyses.[4]

Uremia of Renal Failure

Loss of functional renal tubular mass results in (1) decreased ammonia formation, (2) decreased Na^+-H^+ exchange, and (3) decreased GFR. All result in decreased acid excretion (see Chapter 35). Acidosis usually develops if GFR falls below 20 mL/min.

Diabetes or Ketoacidosis

The pathogenesis of ketoacidosis is discussed in detail in Chapter 22. Ketoacids (such as, β-hydroxybutyrate and 2-oxoglutarate accumulate) represent the unmeasured anions. Accumulation

TABLE 36-3 Conditions of Metabolic Acidoses with High and Normal Anion Gaps

Etiology	Retained Acids	Other Laboratory Findings
High Anion Gap*		
Methanol toxicity	Formate	↑Osmolal gap (>15 mOsmol/kg)
Uremia of renal failure	Sulfuric, phosphoric, organic	↑BUN† and serum creatinine
Ketoacidoses		
Diabetes mellitus	Acetoacetate and β-hydroxybutyrate	↑Plasma and urine glucose
Ethyl alcohol toxicity		†Osmolal gap (>15 mOsmol/kg)
Starvation		
Paraldehyde toxicity		
Isoniazid or iron toxicity, also ischemia	Organic, mainly lactate	Isoniazid and iron act as mitochondrial poisons
Lactic acidosis	Lactate	
Ethylene glycol toxicity	Hippurate, glycolate, oxalate	↑Osmolal gap (>15 mOsmol/kg), urine oxalate crystals
Salicylate toxicity	Salicylate, organic	Respiratory alkalosis
Normal Anion Gap		
Gastrointestinal fluid loss	Primary loss of bicarbonate	
Severe diarrhea		Hypokalemia
Pancreatitis		K^+ variable
Intestinal fistula		
Renal tubular acidoses		
Proximal (type II) RTA		Urine pH<5.5, with K^+ normal or low
Distal (type I) RTA		Urine pH>5.5 with hypokalemia (usually)
Type IV RTA		Urine pH<5.5 with hyperkalemia

*Although there is considerable variability, the anion gap is often >25 mmol/L in these conditions with the exception of uremic renal failure.
†Blood urea nitrogen (reference interval: 8 to 25 mg/dL, or ≈3.0 to 9.0 mmol/L).
RTA, Renal tubular acidosis.

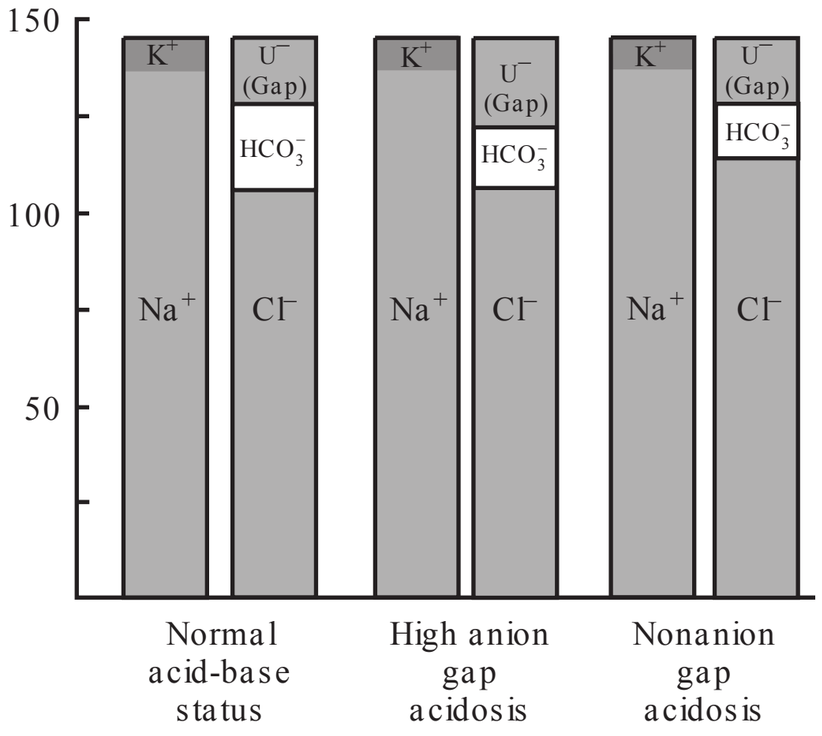

Figure 36-9 Simple "Gambelgram" depiction of normal gap, anion gap acidosis, and nonanion gap acidosis. Cations, Na^+ and K^+, are in left bar for each condition, whereas measured (Cl^- and HCO_3^-) and unmeasured (U^-) anions are in right bar for each condition.

of these "ketone bodies" causes a decrease in HCO_3^- and a high anion gap. Ketoacids also accumulate in states of starvation and alcoholic malnutrition.

Paraldehyde Toxicity

Paraldehyde toxicity may develop after chronic paraldehyde ingestion. The pathogenesis is poorly defined, but the acidosis includes β-hydroxybutyric acid. Patients with paraldehyde toxicity have a pungent, apple-like odor to their breath.

Isoniazid, Iron, or Ischemia ("Three I's")

These causes of high anion gap acidosis share the common feature of accumulating organic acids with a predominance of lactic acid. Thus the "three I's" actually represent special cases in the general category of lactic acidosis, which is described later. Both isoniazid, an antimycobacterial agent commonly used in the treatment of tuberculosis, and iron toxicity involve the production of toxic peroxides that act as mitochondrial poisons and interfere with normal cellular respiration.

Tissue ischemia results from many causes; one of which is hypoperfusion that leads to hypoxia of cells. This results in anaerobic metabolism with accumulation of organic (mainly lactic) acids.

Lactic Acid Acidosis

Lactic acid, present in blood entirely as the lactate ion (pK = 3.86), is an intermediate of carbohydrate metabolism that is derived mainly from muscle cells and erythrocytes (see Chapter 22). It represents the end product of anaerobic metabolism and is normally metabolized by the liver. Therefore, the blood lactate concentration is affected by its rate of production and rate of metabolism, both of which are dependent on adequate tissue perfusion. An increase in the concentration of lactate to >3 mmol/L with the associated increase in H^+ is considered lactic acidosis.

Lactic acidosis caused by severe tissue hypoxia is seen in (1) severe anemia, (2) shock, (3) cardiac arrest, and (4) pulmonary insufficiency. If the origin of lactate (e.g., seizure, hypoxic tissue) is rectified, it is rapidly metabolized to CO_2, which then is eliminated by an intact respiratory system.

Lactic acidosis is also caused by (1) drugs and toxins, (2) acquired and hereditary defects in enzymes involved in gluconeogenesis, (3) uremia, (4) liver failure, (5) tumors, (6) seizures, (7) anesthesia, and (8) abnormal intestinal bacteria producing d-lactate.

Ethylene Glycol

Ingested ethylene glycol is metabolized primarily to glycolic and oxalic acids. Its metabolism leads to an acidosis with high anion and osmolal gaps. Accumulation of toxic metabolites may also contribute to lactic acid production that further contributes to the acidosis. Precipitation of calcium oxalate and hippurate crystals in the urinary tract may lead to acute renal failure. Clinically, patients develop a variety of neurologic symptoms that may lead to coma. The minimal lethal dose of ethylene glycol is ≈100 mL for an average 70 kg adult.

Salicylate Intoxication

Acidosis generally occurs with blood salicylate concentrations above 30 mg/dL. Salicylate, itself an unmeasured anion, alters peripheral metabolism, leading to the production of various organic acids without dominance of any specific acid. These processes eventually result in a metabolic acidosis with a high anion gap. Salicylate also stimulates the respiratory center to increase the rate and depth of respiration, resulting in a low PCO_2 and thus a mixed respiratory alkalosis and metabolic acidosis.

Normal Anion Gap Acidosis (Inorganic Acidosis)

In contrast to high anion gap acidoses, in which bicarbonate is consumed from buffering excess H^+, the cause of acidosis in the presence of a normal anion gap is the loss of bicarbonate-rich fluid from the kidney or the gastrointestinal tract. As bicarbonate is lost, more Cl^- ions are reabsorbed with Na^+ or K^+ to maintain electrical neutrality so that hyperchloremia ensues (see Figure 36-9). Normal anion gap acidosis is divided into (1) hypokalemic, (2) normokalemic, and (3) hyperkalemic acidoses, which is helpful in the differential diagnosis of this type of disorder (see Table 36-3).

Gastrointestinal Losses

Diarrhea may cause acidosis as a result of loss of (1) Na^+, (2) K^+, and (3)HCO_3^-. One of the primary exocrine functions of the pancreas is production of HCO_3^- to neutralize gastric contents on entry into the duodenum. If the water, K^+, and HCO_3^- in the intestine are not reabsorbed, a hypokalemic, normal anion gap metabolic acidosis develops. The resulting hyperchloremia is due to replacement of lost bicarbonate with Cl^- to maintain electrical balance.

Renal Tubular Acidoses, Types I and II

These syndromes are characterized predominantly by loss of bicarbonate due to decreased tubular secretion of H^+ (distal or type I RTA) or decreased reabsorption of HCO_3^- (proximal or type II RTA).[8] Because the major urine-acidifying power of the kidneys rests in the distal tubules, proximal and distal RTAs may be differentiated by measurement of urine pH after administration of acid. In proximal RTA, urine pH becomes <5.5, whereas in distal RTA, the distal tubules are compromised and urine pH is >5.5.[8]

Carbonic Anhydrase Inhibitors

Acetazolamide is the most commonly used drug in this class of therapeutic agents. It is rarely used as a mild diuretic. More often, it is used for urine alkalinization and in patients suffering from open-angle glaucoma or acute mountain (altitude) sickness. Inhibition of carbonic anhydrase causes wasting of (1) Na^+, (2) K^+, and (3) HCO_3^- in the proximal tubules and represents a pharmacologically-induced proximal RTA.

Hyperkalemic Normal Anion Gap Acidosis (RTA Type IV)

Common causes of hyperkalemic normal anion gap acidosis—often called RTA type IV—include (1) failure of the kidneys to synthesize renin, (2) failure of the adrenal cortex to secrete aldosterone, and (3) renal tubular resistance to aldosterone. This type of acidosis inhibits Na^+ reabsorption, and both K^+ and H^+ are thus abnormally retained. The result is decreased renal ammonia formation and therefore decreased elimination of H^+. Hyperkalemia is also usually present.

Compensatory Mechanisms in Metabolic Acidosis

The buffer systems of the blood (mainly the bicarbonate/carbonic acid buffer) minimize changes in pH. In acidoses, the bicarbonate concentration decreases to yield a ratio of $cHCO_3^-/cdCO_2$ of less than 20:1. The respiratory compensatory mechanism responds to correct the ratio with increased rate and depth of respiration to eliminate CO_2. Table 36-4 depicts expected compensation in acidoses and alkaloses and corresponding laboratory values.

Respiratory Compensatory Mechanism

The decrease in pH in metabolic acidosis stimulates hyperventilation (Kussmaul respiration), which results in (1) the elimination of carbonic acid as CO_2, (2) a decrease in PCO_2 (hypocapnia), and (3) ultimately a decrease in $cdCO_2$. There is also a decrease in $cHCO_3^-$ that is smaller than that in $cdCO_2$. For example, the ratio of $cHCO_3^-/cdCO_2$ might be 16:1.28 (12.5:1) for a pH of 7.2 before compensation, and 14.5:0.9 (16:1) for a pH of 7.30 after compensation (see Figure 36-6).

TABLE 36-4 Classification and Characteristics of Simple Acid-Base Disorders

	Primary Change	Compensatory Response	Expected Compensation
Metabolic			
Acidosis	$\downarrow cHCO_3^-$	$\downarrow PCO_2$	$PCO_2 = 1.5\ (cHCO_3^-) + 8 \pm 2$ PCO_2 falls by 1 to 1.3 mm Hg for each mmol/L fall in $cHCO_3^-$ Last 2 digits of pH = PCO_2 (e.g., if PCO_2 = 28, pH = 7.28) $cHCO_3^-$ + 15 = last two digits of pH ($cHCO_3^-$ = 15, pH = 7.30)
Alkalosis	$\uparrow cHCO_3^-$	$\uparrow PCO_2$	PCO_2 increases 6 mm Hg for each 10 mmol/L rise in HCO_3^- $cHCO_3^-$ + 15 = last two digits of pH $cHCO_3^-$ = 35, pH = 7.50)
Respiratory			
Acidosis			
Acute	$\uparrow PCO_2$	$\uparrow cHCO_3^-$	$cHCO_3^-$ increases by 1 mmol/L for each 10 mm Hg rise in PCO_2
Chronic	$\uparrow PCO_2$	$\uparrow cHCO_3^-$	$cHCO_3^-$ increases by 3.5 mmol/L for each 10 mm Hg rise in PCO_2
Alkalosis			
Acute	$\downarrow PCO_2$	$\downarrow cHCO_3^-$	$cHCO_3^-$ falls by 2 mmol/L for each 10 mm Hg fall in PCO_2
Chronic	$\downarrow PCO_2$	$\downarrow cHCO_3^-$	$cHCO_3^-$ falls by 5 mmol/L for each 10 mm Hg fall in PCO_2

Modified from Narins RG, Gardner LB. Simple acid-base disturbances. Med Clin North Am 1981;65:321-46.

Renal Compensatory Mechanism

Functional kidneys respond to restore the normal pH through increased excretion of acid and preservation of base by an increased (1) rate of Na^+-H^+ exchange, (2) ammonia formation, and (3) reabsorption of bicarbonate. When the renal compensating mechanisms are functioning, urine acidity and ammonia are increased.

Metabolic Alkalosis (Primary Bicarbonate Excess)

Alkalosis occurs when (1) excess base is added to the system, (2) base elimination is decreased, or (3) acid-rich fluids are lost (Box 36-1). All lead to a primary bicarbonate excess, such that the ratio of $cHCO_3^-/cdCO_2$ becomes greater than 20:1. For instance, a primary increase in bicarbonate to 48 mmol/L will alter the $cHCO_3^-/cdCO_2$ to 48:1.5 (32:1) for a pH of 7.6 (see Figure 36-9). The patient will hypoventilate to raise PCO_2, thereby lowering the pH toward normal. However, hypoxia usually prevents the patient from achieving a PCO_2 greater than 55 mm Hg. Above pH 7.55, tetany may develop, even in the presence of a normal serum total calcium concentration. The cause of the tetany is a decreased concentration of ionized calcium due to increased binding of calcium ions by albumin as H^+ ions decrease. Measurement of urine Cl^- is often helpful, as causes of metabolic alkalosis fall into (1) Cl^- responsive, (2) Cl^- resistant, and (3) exogenous base categories (see Box 36-1 and Figure 36-3).

BOX 36-1 Conditions Leading to Metabolic Alkalosis

- **Chloride-Responsive (Urine Cl^- <10 mmol/L)**
- Contraction alkaloses
  - Prolonged vomiting or nasogastric suction
  - Pyloric or upper duodenal obstruction
  - Prolonged or abusive diuretic therapy (loop diuretics)
  - Dehydration
- Posthypercapnic state
- Cystic fibrosis (systemic ineffective reabsorption of Cl^-)
- **Chloride-Resistant (Urine Cl^- >20 mmol/L)**
- Mineralocorticoid excess
  - Primary hyperaldosteronism (adrenal adenoma or, rarely, carcinoma)
  - Bilateral adrenal hyperplasia
  - Secondary hyperaldosteronism
  - Congenital adrenal hyperplasia (due to adrenal enzyme deficiencies in cortisol production [11β- or 17α-hydroxylase])
- Glucocorticoid excess
  - Primary adrenal adenoma (Cushing syndrome)
  - Pituitary adenoma secreting ACTH (Cushing disease)
  - Exogenous cortisol therapy
  - Excessive licorice ingestion
- Bartter syndrome (defective renal Cl^- reabsorption)
- **Exogenous Base**
- Iatrogenic
  - Bicarbonate-containing intravenous fluid therapy
  - Massive blood transfusion (sodium citrate overload)
  - Antacids and cation-exchange resins in dialysis patients
  - High-dose carbenicillin or penicillin (associated with hypokalemia)
- Milk-alkali syndrome

ACTH, Adrenocorticotropic hormone.

Cl^- Responsive Metabolic Alkalosis

Most causes of Cl^- responsive metabolic alkalosis occur as a result of hypovolemia (see Box 36-1). When the ECF is severely depleted, the resulting acid-base disorder is often referred to as contraction alkalosis. Hypovolemia will result in (1) increased reabsorption of Na^+, (2) increased HCO_3^- absorption and (3) excretion of K^+ and H^+. Urine Cl^- will be less than 10 mmol/L, as both the available Cl^- and HCO_3^- are reabsorbed with Na^+. Urine Na^+ is not useful for classifying metabolic alkalosis because an obligatory loss of Na^+ will occur when filtered HCO_3^- exceeds reclamation. Common causes of contraction alkalosis include prolonged vomiting or nasogastric suction and the use of certain diuretics. Treatment consists of replacing TBW with (1) water, (2) NaCl tablets, or (3) saline infusion.

Cl^- Resistant Metabolic Alkalosis

This condition is far less common than Cl^- responsive metabolic alkalosis and is almost always associated with an underlying disease, such as (1) primary hyperaldosteronism, (2) Cushing syndrome, or (3) Bartter syndrome, or with excess addition of exogenous base. In these conditions, urine Cl^- will usually be greater than 20 mmol/L.

In states of adrenocortical excess (endogenous or pharmacologic, primary or secondary), K^+ and H^+ are "wasted" by the kidneys as a consequence of increased Na^+ reabsorption stimulated by elevated aldosterone or cortisol. The attendant hypokalemia often further contributes to the alkalosis and should be treated with K^+ replacement therapy. The decreased tubular K^+ concentration stimulates NH_3 production and thus renal H^+ excretion as NH_4^+. Diseases in which endogenous mineralocorticoids, glucocorticoids, or both are elevated include (1) primary and secondary hyperaldosteronism, (2) bilateral adrenal hyperplasia, (3) pituitary adrenocorticotropic hormone (ACTH)-producing adenoma (Cushing disease), and (4) primary adrenal adenomas producing glucocorticoids (Cushing syndrome) or aldosterone.

Exogenous Base

Examples in this category include (1) citrate toxicity following massive blood transfusion, (2) aggressive intravenous therapy with bicarbonate solutions, and (3) ingestion of large quantities of antacids in the treatment of gastritis or peptic ulcer (milk-alkali syndrome). The latter is far less commonly seen since the introduction and now widespread use of H_2-receptor antagonists (drugs used to block the action of histamine on parietal cells) and proton pump inhibitors (drugs that reduce gastric acid production).

Compensatory Mechanisms in Metabolic Alkalosis

The compensatory mechanisms for metabolic alkalosis include both respiratory compensation and, if physiologically possible, renal compensation. The increase in pH depresses the respiratory center, causing retention of carbon dioxide (hypercapnia), which in turn causes an increase in cH_2CO_3 and $cdCO_2$. Thus the ratio of $cHCO_3^-/cdCO_2$, which was originally increased, approaches its normal value, although the actual concentrations of both $cHCO_3^-$ and $cdCO_2$ remain increased. The kidneys respond to the state of alkalosis by decreased (1) Na^+-H^+ exchange, (2) formation of ammonia, and (3) reclamation of bicarbonate. This response is blunted, however, in conditions of hypokalemia and hypovolemia.

Respiratory Acidosis

Any condition that decreases elimination of carbon dioxide through the lungs results in an increase in PCO_2 (hypercapnia) and dCO_2 (respiratory acidosis). Thus respiratory acidosis occurs only through decreased elimination of CO_2. Causes of decreased CO_2 elimination (Box 36-2) are classified as acute or chronic. Alternatively, these conditions may be separated into those caused by factors that directly depress the respiratory center, such as (1) centrally acting drugs, (2) CNS trauma, or (3) infection, and (4) those that affect the respiratory apparatus or cause mechanical obstruction of the airways. **Chronic obstructive pulmonary disease (COPD)** is the most common cause. Rebreathing, or breathing air high in CO_2 content, may also cause a high PCO_2. An increase in PCO_2 results in an increase in $cdCO_2$ (and thus H_2CO_3, which dissociates to H^+ and HCO_3^-), which in turn causes a decrease in the $cHCO_3^-/cdCO_2$ ratio (e.g., the ratio may be 28:1.7 [16:1] for a pH of ≈7.30; see Figure 36-6). Doubling of PCO_2 will cause a fall in pH of about 0.23 when other factors remain constant.

BOX 36-2 Conditions Leading to Respiratory Acidosis

Factors That Directly Depress the Respiratory Center
- Drugs, such as narcotics and barbiturates
- CNS trauma, tumors, and degenerative disorders
- Infections of the CNS, such as encephalitis and meningitis
- Comatose states, such as cerebrovascular accident due to intracranial hemorrhage
- Primary central hypoventilation

Conditions That Affect the Respiratory Apparatus
- COPD (most common cause)
- Severe pulmonary fibrosis
- Status asthmaticus (severe)
- Disease of the upper airways, such as laryngospasm or tumor
- Pulmonary infection (severe)
- Impaired lung motion due to pleural effusion or pneumothorax
- Adult respiratory distress syndrome
- Chest wall disease and chest wall deformity
- Neurologic disorders affecting the muscles of respiration

Others
- Abdominal distention, as in peritonitis and ascites
- Extreme obesity (pickwickian syndrome)
- Sleep disorders, such as sleep apnea

CNS, Central nervous system; COPD, chronic obstructive pulmonary disease.

Compensatory Mechanisms in Respiratory Acidosis

Compensation for respiratory acidosis occurs immediately via buffers, and over time via the kidneys and, if possible, the lungs. Excess carbonic acid present in blood is buffered to a great extent by the hemoglobin and protein buffer systems. Buffering of CO_2 causes a slight rise in $cHCO_3^-$. Thus in the immediate posthypercapnic state, this compensation may appear as a metabolic alkalosis (see Box 36-2). The kidneys respond to respiratory acidosis similarly to the way that they respond to metabolic acidosis, namely, with increased (1) Na^+-H^+ exchange, (2) ammonia formation, and (3) reclamation of bicarbonate. In a partially chronic compensated respiratory acidosis at steady state, the plasma pH is returned about halfway toward normal as compared with the acute (uncompensated) situation. Renal compensation is not effective before 6 to 12 hours and is not optimal until 2 to 3 days. In chronic respiratory acidosis, such as occurs in patients with COPD, full renal compensation may be seen even in those patients with very high PCO_2 (>50 mm Hg). However, patients with severe COPD often present with a superimposed metabolic alkalosis arising

from a variety of causes, such as prolonged administration of diuretics.

The increase in PCO_2 stimulates the respiratory center, resulting in an increased pulmonary rate and depth of respiration, provided that the primary defect is not in the respiratory center. Elimination of carbon dioxide through the lungs results in a decrease in $cdCO_2$; thus the ratio of $cHCO_3^-/cdCO_2$ and pH approach normal.

Respiratory Alkalosis

A decrease in PCO_2 (hypocapnia) and the resulting primary deficit in $cdCO_2$ (respiratory alkalosis) are caused by an increased rate and/or depth of respiration. Therefore, the basic cause of respiratory alkalosis is excess elimination of acid via the respiratory route. Excessive elimination of carbon dioxide reduces the PCO_2 and causes an increase in the $cHCO_3^-/cdCO_2$ ratio. The latter shifts the normal equilibrium of the bicarbonate/carbonic acid buffer system, reducing the hydrogen ion concentration and increasing the pH. This shift also results in a decrease in $cHCO_3^-$, which somewhat improves the change in pH. Analogous to causes of respiratory acidosis, causes of respiratory alkalosis have been classified as those with a direct stimulatory effect on the respiratory center and those due to effects on the pulmonary system. These and some additional conditions underlying respiratory alkaloses are listed in Box 36-3.

Compensatory mechanisms for respiratory alkalosis respond in two stages. In the first stage, erythrocyte and tissue buffers provide H^+ ions that consume a small amount of HCO_3^-. The second stage becomes operational in prolonged respiratory alkalosis and depends on renal compensation as described for metabolic alkalosis (decreased reclamation of bicarbonate).

BOX 36-3 Factors Causing Respiratory Alkalosis

Nonpulmonary Stimulation of Respiratory Center
Anxiety, hysteria
Febrile state
Gram-negative septicemia
Metabolic encephalopathy (e.g., from liver disease)
CNS infection, such as meningitis, encephalitis
Cerebrovascular accident
Intracranial surgery
Hypoxia (e.g., severe anemia, high altitudes [acute condition])
Drugs and agents, such as salicylates, catecholamines, and progesterone
Pregnancy, mainly third trimester (↑ progesterone?)
Hyperthyroidism
Pulmonary Disorders*
Pneumonia
Pulmonary emboli
Interstitial lung disease
Large right-to-left shunt (PCO_2 <50 mm Hg)
CHF
Respiratory compensation after correction of metabolic acidosis
Others
Ventilator-induced hyperventilation

*The severe stages of some of these disorders may be associated with respiratory acidosis if elimination of CO_2 is severely impaired.
CHF, Congestive heart failure; CNS, central nervous system.

Review Questions

1. External respiration is defined as:
   a. the exchange of oxygen (O_2) and carbon dioxide (CO_2) at the tissue level.
   b. decreased O_2 due to the decreased availability of O_2 as in suffocation.
   c. the exchange of O_2 and CO_2 in the lungs between alveoli and blood.
   d. the number of breaths an individual takes in one minute.
2. Total body water (TBW) makes up approximately 60% of body weight. The majority of TBW is located in which one of the following compartments?
   a. Extracellular fluid (ECF)
   b. Intracellular fluid (ICF)
   c. Interstitial fluid
   d. Plasma
3. The anion gap, an estimate of anions not directly measured in serum, is correctly calculated by which one of the following formulae?
   a. $(Na) + (Cl + HCO_3)$
   b. $(Na) - (Cl + HCO_3)$
   c. $(Cl) + (HCO_3 + Na)$
   d. $(HCO_3 - Na) - (Cl)$
4. Hypernatremia commonly occurs in:
   a. decreased production of antidiuretic hormone (ADH).
   b. decreased aldosterone.
   c. the syndrome of inappropriate ADH (SIADH) secretion.
   d. all of the above.
5. A decrease in PCO_2 and a resulting primary deficit in $cdCO_2$ is referred to as:
   a. metabolic acidosis.
   b. metabolic alkalosis.
   c. respiratory acidosis.
   d. respiratory alkalosis.
6. Low blood volume will cause synthesis of this hormone by the kidneys, which in turn causes production of aldosterone, which will increase kidney reabsorption of sodium and retention of water.
   a. Insulin
   b. Renin
   c. Antidiuretic hormone (ADH)
   d. Erythropoietin
7. Because of increased dietary intake of this particular electrolyte, an individual with this disorder will demonstrate mental confusion, bradycardia, and possible eventual cardiac arrest.
   a. Sodium; hypernatremia
   b. Sodium; hyponatremia
   c. Potassium; hyperkalemia
   d. Potassium; hypokalemia

8. Which one of the following is the primary cause of respiratory acidosis?
   a. Hyperventilation
   b. Overdose of antacids
   c. Chronic obstructive pulmonary disease (COPD)
   d. Uncontrolled diabetes mellitus
9. The metabolic component of acid-base balance is the:
   a. hepatic system.
   b. respiratory system.
   c. gastrointestinal tract.
   d. renal system.
10. In whole blood, the normal ratio of bicarbonate to dissolved carbon dioxide is approximately:
   a. 10:1
   b. 1:20
   c. 20:1
   d. 1:10

CHAPTER

37 Liver Disease*

D. Robert Dufour, M.D.

Objectives

1. Define the following:
   - Acinus
   - Ascites
   - Bilirubin
   - Cholestasis
   - Cirrhosis
   - Gallbladder
   - Hepatic lobule
   - Hepatitis
   - Hepcidin
   - Jaundice
   - Model for end-stage liver disease (MELD) score
   - Portal hypertension
   - Portal triad
   - Xenobiotics
2. Describe the microscopic and macroscopic anatomy of the hepatic system, including functional units, lobules, hepatobiliary ducts, blood supply, intrinsic cell types, and functional organization.
3. Detail the major functions of the liver, including the mechanisms of bilirubin excretion, substances synthesized and their functions, and substances metabolized and their sources.
4. List the causes and consequences of each of the following clinical manifestations of liver disease:
   - Disordered hemostasis
   - Jaundice
   - Liver enzyme release
   - Portal hypertension
5. List the enzymes synthesized in the liver, their subcellular location, tissue specificity, and mechanisms of enzyme release and clearance.
6. Compare and contrast acute liver injury with chronic liver injury, including manifestations of injury, target cells involved, specific means of cell death, and laboratory analyses used to distinguish between them.
7. List and describe five types of viral hepatitis, including type of virus, mode of transmission, involvement in liver cancer, methods of prevention, and laboratory tests used to diagnose the presence of the virus.
8. Describe the following types of liver disease, including causes, clinical presentation, and laboratory findings:
   - Acute alcoholic hepatitis
   - Alcoholic liver disease
   - Autoimmune hepatitis
   - Cholestatic hepatitis
   - Cholestatic liver diseases
   - Cirrhosis
   - Drug-induced liver injury (DILI)
   - Ischemic hepatitis
   - Primary biliary cirrhosis (PBC)
   - Primary sclerosing cholangitis (PSC)
   - Toxic hepatitis
9. State the formula for calculating a MELD score; calculate a MELD score given appropriate values and determine prognosis in cirrhosis.
10. Describe hepatocellular carcinoma (HCC) including prevalence, risk factors, screening tests, and laboratory findings.
11. Assess and solve case studies related to liver disease.

Key Words and Definitions

Alcoholic hepatitis An acute or chronic degenerative and inflammatory lesion of the liver in the alcoholic that is potentially progressive though sometimes reversible.

Alcoholic liver disease Liver injury caused by excessive ethanol (alcohol) ingestion.

Apoptosis Programmed cell death as signaled by the nuclei in normally functioning human and animal cells when age or state of cell health and condition dictates

Ascites Serous fluid that accumulates in the abdominal cavity.

Autoimmune hepatitis (AIH) A form of hepatitis, usually with hypergammaglobulinemia and serum autoantibodies.

Bile A greenish-yellow fluid secreted by the liver and stored in the gallbladder.

Biliprotein The conjugated bilirubin-protein complex (also known as delta-bilirubin).

Biotransformation The series of chemical alterations of a compound (for example, a drug) that occurs within the body, as by enzymatic activity.

Cholestasis Suppression of the normal flow of bile.

*The author gratefully acknowledges the original contributions by Drs. Keith G. Tolman and Robert Rej, on which portions of this chapter are based.

Key Words and Definitions—cont'd

Chronic hepatitis A collective term for a clinical and pathological syndrome that has several causes and is characterized by varying degrees of hepatocellular necrosis and inflammation for at least 6 months.

Cirrhosis Liver disease characterized pathologically by loss of the normal microscopic lobular architecture with fibrosis and nodular regeneration.

Drug-induced liver injury (DILI) A diseases of the liver that is caused by prescribed medications, over-the-counter medications, vitamins, hormones, herbs, illicit ("recreational") drugs, and environmental toxins.

Fulminant hepatitis A rare and frequently fatal form of acute hepatitis B in which the patient's condition rapidly deteriorates with hepatic encephalopathy, necrosis of the hepatic parenchyma, coagulopathy, renal failure, and coma.

Fulminant hepatic failure A condition characterized by the development of severe liver injury with impaired synthetic capacity and encephalopathy in patients with previous normal liver or at least well-compensated liver disease.

Gallstone A solid formation in the gallbladder, most commonly composed of cholesterol and bile salts.

Hemochromatosis A rare genetic disorder, due to abnormalities in genes that regulate iron metabolism.

Hepatic encephalopathy A condition used to describe the deleterious effects of liver failure on the central nervous system. Features include confusion ranging to unresponsiveness (coma).

Hepatic failure A condition of severe liver dysfunction that is accompanied by a loss of normal liver functions.

Hepatitis Inflammation of the liver. Typically divided into acute (duration of weeks to months) and chronic (lasting for more than 6 months).

Hepatocellular carcinoma (HCC) A cancer arising from hepatocytes.

Hepatocyte An epithelial liver cell that performs most of the synthetic and metabolic functions of the liver.

Hepcidin A hormone produced by liver cells, in response to signals from a complex pathway, that decreases iron mobilization across intestinal and macrophage membranes, preventing excess iron in the blood.

Jaundice A clinical finding characterized by hyperbilirubinemia and deposition of pigment in the skin, mucous membranes, and sclera with resulting yellow appearance; also called icterus.

Model for End-Stage Liver Disease (MELD) Score A scoring system for assessing the severity of chronic liver disease.

Necrosis The sum of the morphological changes indicative of cell death and caused by the progressive degradative action of enzymes; it may affect groups of cells or part of a structure or an organ.

Non alcoholic fatty liver disease (NAFLD) A condition characterized by the buildup of extra fat in liver cells that is not caused by alcohol.

Non alcoholic steatohepatitis (NASH) An inflammatory disease of the liver of uncertain pathogenesis.

Portal hypertension Any increase in the pressure in the portal vein (which carries venous blood from the intestines and spleen to the liver) due to anatomical or functional obstruction (for example, cirrhosis) to blood flow in the portal venous system.

Primary biliary cirrhosis (PBC) A rare form of liver disease that results in the irreversible destruction of the small bile ducts within the liver.

Primary sclerosing cholangitis (PSC) A chronic, nonbacterial inflammatory narrowing of the bile ducts (usually the larger ducts outside of the liver.

Reye syndrome A sudden, sometimes fatal, disease of the brain (encephalopathy) caused by specific forms of acute injury to the liver.

Seroconversion Development of antibodies in blood serum as a result of infection or immunization.

Sjögren syndrome A systemic autoimmune disease in which immune cells attack and destroy the glands that produce tears and saliva.

Varices Enlarged and tortuous veins, most commonly found in the esophagus (termed esophageal varices).

Viral hepatitis Liver inflammation caused by viruses. Specific hepatitis viruses have been labeled A, B, C, D, and E.

Viral load The measurement of the amount of virus in the blood. It is expressed as the copies of virus per milliliter of body fluid and used to guide treatment decisions and monitor response to treatment.

Wilson disease An autosomal recessive disorder associated with excessive quantities of copper in the tissue, particularly the liver and central nervous system.

Xenobiotics Chemical substances foreign to the biological system. They include naturally occurring compounds, drugs, environmental agents, carcinogens, insecticides, etc.

The liver has a central and critical biochemical role in (1) metabolism, (2) digestion, (3) detoxification, and (4) the elimination of substances from the body. All blood from the intestinal tract initially passes through the portal vein to the liver, where products derived from digestion of food are (1) processed, (2) transformed, and (3) stored. The liver also has a central role in (1) protein, (2) carbohydrate, (3) lipid metabolism, (4) synthesizing bile acids from cholesterol to facilitate dietary fat, and (5) vitamin absorption. The liver metabolizes both endogenous and exogenous compounds (such as, drugs and toxins) by **biotransformation**, allowing their elimination.[15] The liver performs endocrine functions as it catabolizes (1) thyroid hormone, (2) cortisol, and (3) vitamin D, and synthesizes (4) insulin-like growth factor I, (5) angiotensinogen,(6) **hepcidin**, (7) thrombopoietin, and (8) small amounts of erythropoietin. Many of these hepatic functions may be assessed by laboratory procedures to gain insight into the integrity of the liver.[4]

As a large organ, the liver performs its functions with extensive reserve capacity. In many cases, individuals with liver disease maintain normal function despite extensive liver damage. In such cases, liver disease may only be recognized by using tests that detect liver injury. Most commonly, this is accomplished by measurement of plasma activities of enzymes found within liver cells released in somewhat specific patterns with different forms of injury. Chronic liver injury often involves fibrosis in the liver. Consequently, detection of markers of the fibrotic process might be indicators of degree of liver injury.

The chapter begins with a discussion of the anatomy and biochemical functions of the liver. The various disease states that involve the liver are then discussed. The chapter concludes with a discussion of use of laboratory test results in recognizing and characterizing patterns of liver injury.

Anatomy of the Liver

The adult liver weighs approximately 1.2 to 1.5 kg. It is located beneath the diaphragm in the right upper quadrant of the abdomen and is protected by the ribs and held in place by ligamentous attachments (Figure 37-1).

Blood Supply

The liver has a dual blood supply. The first is the portal vein, which carries blood from the spleen and nutrient-enriched blood from the gastrointestinal (GI) tract. It supplies approximately 70% of the blood flow to the liver. The second blood supply is the hepatic artery, which is a branch of the celiac axis. It carries oxygen-enriched arterial blood from the central circulation to the liver. Ultimately, these two blood supplies

Figure 37-1 Structure of the liver. (From Dorland's illustrated medical dictionary, 30th edition. Philadelphia: WB Saunders, 2003, plate 26.)

merge and flow into the sinusoids that course between individual hepatocytes. The venous drainage from the liver converges into the hepatic veins, which join the inferior vena cava near its entry into the right atrium.

Biliary Drainage

Biliary drainage originates at the bile canaliculi, grooves between adjacent hepatocytes, which form ductules that merge to form the intrahepatic bile ducts. These ultimately join to form the right and left hepatic ducts, which exit from the liver at the porta hepatis and unite to form the common hepatic duct. The hepatic duct is joined by the cystic duct from the gallbladder, creating the common bile duct (see Figure 37-1), which enters the duodenum (usually with the pancreatic duct) at the ampulla of Vater. The gallbladder, located on the undersurface of the right lobe of the liver, stores and concentrates **bile**, which is a mixture of bile salts and waste products. Hormonal stimuli initiated by food ingestion cause contraction of the muscular wall of the gallbladder, releasing bile salts into the intestine to facilitate digestion of fat.

Microscopic Anatomy

The functional anatomical unit of the liver is the acinus, adjacent to the portal triad, which consists of a branch of the (1) portal vein, (2) hepatic artery, and (3) bile duct. Each acinus is a diamond-shaped mass of liver parenchyma that is supplied by a terminal branch of the portal vein and of the hepatic artery and drained by a terminal branch of the bile duct. At the periphery of the portal triad, the hepatic artery and portal vein branches fuse to formsinusoids, which perfuse the liver and ultimately drain into the central (terminal) hepatic vein (see Figure 37-1). The sinusoids are lined by fenestrated endothelial cells that contain pores that allow free filtration of blood and phagocytic Kupffer cells (see Figure 37-1). The fenestrations (pores) allow passage of (1) nutrients into hepatocytes, (2) larger blood proteins into the space surrounding the hepatocyts, and (3) the liver's synthetic products into the systemic circulation. The Kupffer cells, derived from monocytes, contain lysosomes that break down phagocytized bacteria, and are the main site for clearance of antigen-antibody complexes from blood.

The major functioning cells in the liver are the hepatocytes, responsible for most of its metabolic and synthetic functions. Stellate cells (formerly referred to as Ito cells) are located between the endothelial lining of sinusoids and the hepatocytes. In their normal, quiescent state, stellate cells store vitamin A, and synthesize nitric oxide (among other bioactive substances), which helps to regulate intrahepatic blood flow. When stimulated, stellate cells are transformed to collagen producing cells, and are responsible for fibrosis and, eventually, **cirrhosis**. Oval cells are located within periportal bile ductules; these are believed to be liver progenitor cells, which proliferate following liver injury and regenerate both bile ducts and hepatocytes.

The blood supply to each acinus passes hepatocytes loosely arranged in three zones (Figure 37-2). Zone 1 is the area immediately adjacent to the portal tract, and these hepatocytes are enriched with lysosomes and mitochondria. The periphery of the acinus, zone 3, has (1) hepatocytes enriched with endoplasmic reticulum, (2) is very active metabolically, and (3) has relatively low oxygen tension. This area is most susceptible to injury, although zone 1 appears to be involved with protecting the liver from external injury and providing a base for hepatic regeneration.

Ultrastructure of the Hepatocyte

Hepatocytes contain a well-developed organelle substructure (Figure 37-3). Mitochondria are the site of oxidative phosphorylation and energy production. The rough endoplasmic reticulum is the site of protein synthesis, while the smooth endoplasmic reticulum contains microsomes involved in drug and toxin metabolism and cholesterol and bile acid synthesis. Peroxisomes catalyze the β-oxidation of medium-chain fatty acids with chain lengths from 7 to 18 carbons and enzymes that participate in ethanol metabolism. Lysosomes contain hydrolytic enzymes that act as scavengers. Deposition of (1) iron, (2) lipofuscin (an iron-negative lipid pigment), (3) bile pigments, and (4) copper occurs in the lysosomes. The Golgi

apparatus is involved with secretion of various substances, including bile acids and albumin.

Biochemical Functions of the Liver

The liver is involved in a number of (1) excretory, (2) synthetic, and (3) metabolic functions.

Hepatic Excretory Function

Organic anions of both endogenous and exogenous origin are (1) extracted from the sinusoidal blood, (2) biotransformed, and (3) excreted into the bile or urine. Assessment of this excretory function provides valuable clinical information. The most frequently used tests involve the (1) measurement of plasma concentrations of endogenously produced compounds, such as bilirubin and (less commonly used) bile acids, and (2) determination of the rate of clearance of exogenous compounds, such as aminopyrine, lidocaine, and caffeine. Drug metabolic tests also are used as markers of function in liver transplants and in advanced liver disease.

Bilirubin is a pigment derived from heme turnover. It is extracted and biotransformed in the liver and excreted in bile and urine. The (1) chemistry, (2) biochemistry, and (3) analytical methodology for bilirubin and related compounds are discussed in Chapter 28. Only a brief overview of factors relevant to understanding of liver disease is included here.

Bilirubin is carried to the liver, loosely bound to albumin, in its native, unconjugated form. Bilirubin is transported across the hepatocyte membrane and rapidly conjugated to produce bilirubin glucuronides, which are then excreted into bile by an energy-dependent process. This process is highly efficient, and bilirubin conjugates are detectable in normal plasma only using highly sensitive techniques. In the presence of bilirubin monoglucuronide, albumin (and other proteins) is modified by covalent attachment of bilirubin to lysine residues, producing **biliprotein** or δ-bilirubin. Increases in conjugated bilirubin or δ-bilirubin are highly specific markers of hepatic dysfunction (except in rare inherited disorders, such as Dubin-Johnson syndrome). In the intestinal tract, bilirubin glucuronides are hydrolyzed and reduced by bacteria to urobilinogens, which undergo an enterohepatic circulation, and then to stool pigments stercobilin, mesobilin, and urobilin.

Increased plasma bilirubin is typically classified as unconjugated (indirect: an approximation of unconjugated bilirubin) or conjugated (direct: an approximation of the sum of conjugated bilirubin and biliprotein). Increased unconjugated bilirubin indicates either overproduction of bilirubin, usually caused by (1) hemolysis, (2) decreased delivery of bilirubin to

the liver (in **portal hypertension**), or (3) decreased metabolism by the liver (primarily because of congenital defects involving uridine 5'-phosphate [UDP]-glucuronyl transferase). With severe liver injury, liver disease may cause primarily unconjugated hyperbilirubinemia. Increased conjugated bilirubin generally results from acute hepatitis or **cholestasis** (stoppage or suppression of the flow of bile); the percentage of conjugated bilirubin is similar in both types of liver disease. Conjugated bilirubin is often mildly elevated in advanced forms of chronic **hepatitis** or chronic cholestasis, and it is often the only evidence of dysfunction of the liver. Urine bilirubin is typically elevated in the presence of increased conjugated bilirubin. With resolution of liver disease, conjugated bilirubin is rapidly cleared, and biliprotein may become the only form present. Urine bilirubin is typically absent in such circumstances. Increased conjugated bilirubin is also rarely seen with congenital defects in bilirubin excretion (such as, Dubin-Johnson syndrome) and with impaired bilirubin excretion (as occurs in sepsis or other acute illness).

Hepatic Synthetic Function

The liver has extensive synthetic capacity and plays a major role in the regulation of protein, carbohydrate, and lipid metabolism. For example, (1) protein, (2) glucose, (3) glycogen, (4) triglyceride, (5) fatty acid, (6) cholesterol, and (7) bile acid synthesis all occur within the liver. Because details of these are discussed in other chapters (see Chapters 18, 22, and 23), discussion in this section is limited to tests useful for evaluation of liver function.

Protein Synthesis

The liver has a significant reserve capacity, preventing protein concentrations from decreasing unless there is extensive liver damage. In addition, many liver proteins have relatively long half-lives, such as albumin at approximately 3 weeks. The clinical sensitivity and specificity of protein concentrations for diagnosis of liver disease are far from ideal. The patterns of plasma protein alterations seen in liver disease depend on the (1) type, (2) severity, and (3) duration of liver injury. For example, in acute hepatic dysfunction, there is usually little change in the plasma protein profile or the total plasma protein concentration. With **fulminant hepatic failure** or severe liver injury, concentrations of short-lived hepatic proteins (such as, transthyretin and prothrombin) will decrease quickly and become abnormal. Proteins with longer half-lives may not be affected. In advanced cirrhosis, concentrations of all liver-synthesized plasma proteins decrease, whereas immunoglobulins increase (probably related to impaired Kupffer cell function). Serial determination of plasma proteins provides prognostic information; for example, a worsening of prothrombin time (PT) during acute hepatitis suggests a poor prognosis, while PT has been used as part of the **Model for End-Stage Liver Disease (MELD)** score for predicting prognosis in patients with cirrhosis.

Plasma Proteins

The plasma proteins discussed below are discussed in more detail in Chapter 18.

Albumin. Albumin is the most commonly measured serum protein and is synthesized exclusively by the liver. With liver disease, hypoalbuminemia is noted primarily in (1) cirrhosis, (2) autoimmune hepatitis, and (3) **alcoholic hepatitis**. One important consideration in measurement of albumin is the inaccuracy of dye-binding methods in patients with liver disease. Although bromcresol green measurements tend to overestimate albumin concentration at low concentrations, bromcresol purple methods give falsely low values in patients with **jaundice** because of interference of bilirubin at the site of binding.

Transthyretin. This protein has a short half-life of 24 to 48 hours, making it a sensitive indicator of current synthetic ability. Failure of transthyretin to increase is an indicator of fulminant hepatic failure in acute hepatitis and is associated with a poor prognosis. It is more commonly used as a measurement of nutritional status.

Immunoglobulins. Immunoglobulins are commonly increased in (1) cirrhosis, (2) autoimmune hepatitis, and (3) **primary biliary cirrhosis (PBC)** but are normal in most other types of liver disease. Immunoglobulin G (IgG) is increased in **autoimmune hepatitis (AIH)** and cirrhosis; Immunoglobulin M (IgM) is increased in PBC. Immunoglobulin A (IgA) tends to be increased in all types of cirrhosis. None of these findings is specific, and they are seldom used in the diagnosis of liver disease.

Ceruloplasmin. This protein is decreased in (1) **Wilson disease**, (2) cirrhosis, and (3) many causes of chronic hepatitis. It may also be increased by (1) inflammation, (2) cholestasis, (3) **hemochromatosis**, (4) pregnancy, and (5) estrogen therapy, masking the decrease expected in Wilson disease. It is discussed in more detail later in the section on Wilson disease.

α_1-Antitrypsin. This protein is the major serine protease inhibitor (serpin) in plasma, and is decreased in homozygous deficiency and cirrhosis and increased by acute inflammation. It is discussed in more detail later in the section on α_1-antitrypsin deficiency.

α-Fetoprotein. This protein, a normal, major component of fetal blood, falls to adult concentrations by 1 year of age. Mild increases are seen in patients with acute and chronic hepatitis and indicate hepatocellular regeneration. High levels in the setting of acute liver failure indicate **hepatocyte** regeneration and indicate a good prognosis. It is present at higher concentrations in **hepatocellular carcinoma (HCC)** and is discussed in more detail later and in Chapters 20 and 44.

Coagulation Proteins

Because of the large functional reserve of the liver, failure of hemostasis usually does not occur except in severe or long-standing liver disease. The PT measures activity of (1) fibrinogen (factor I), (2) prothrombin (factor II), and (3) factors V, VII, and X. Since all of these factors are synthesized in the liver, a prolonged PT often indicates the presence of significant liver disease. In cholestasis, vitamin K deficiency may also cause an increase in PT. In this case, the coagulation abnormality is corrected within a few days by parenteral injection of 10 mg of vitamin K. In contrast, if PT is prolonged because of hepatocellular disease, factor synthesis is decreased and administration of vitamin K does not

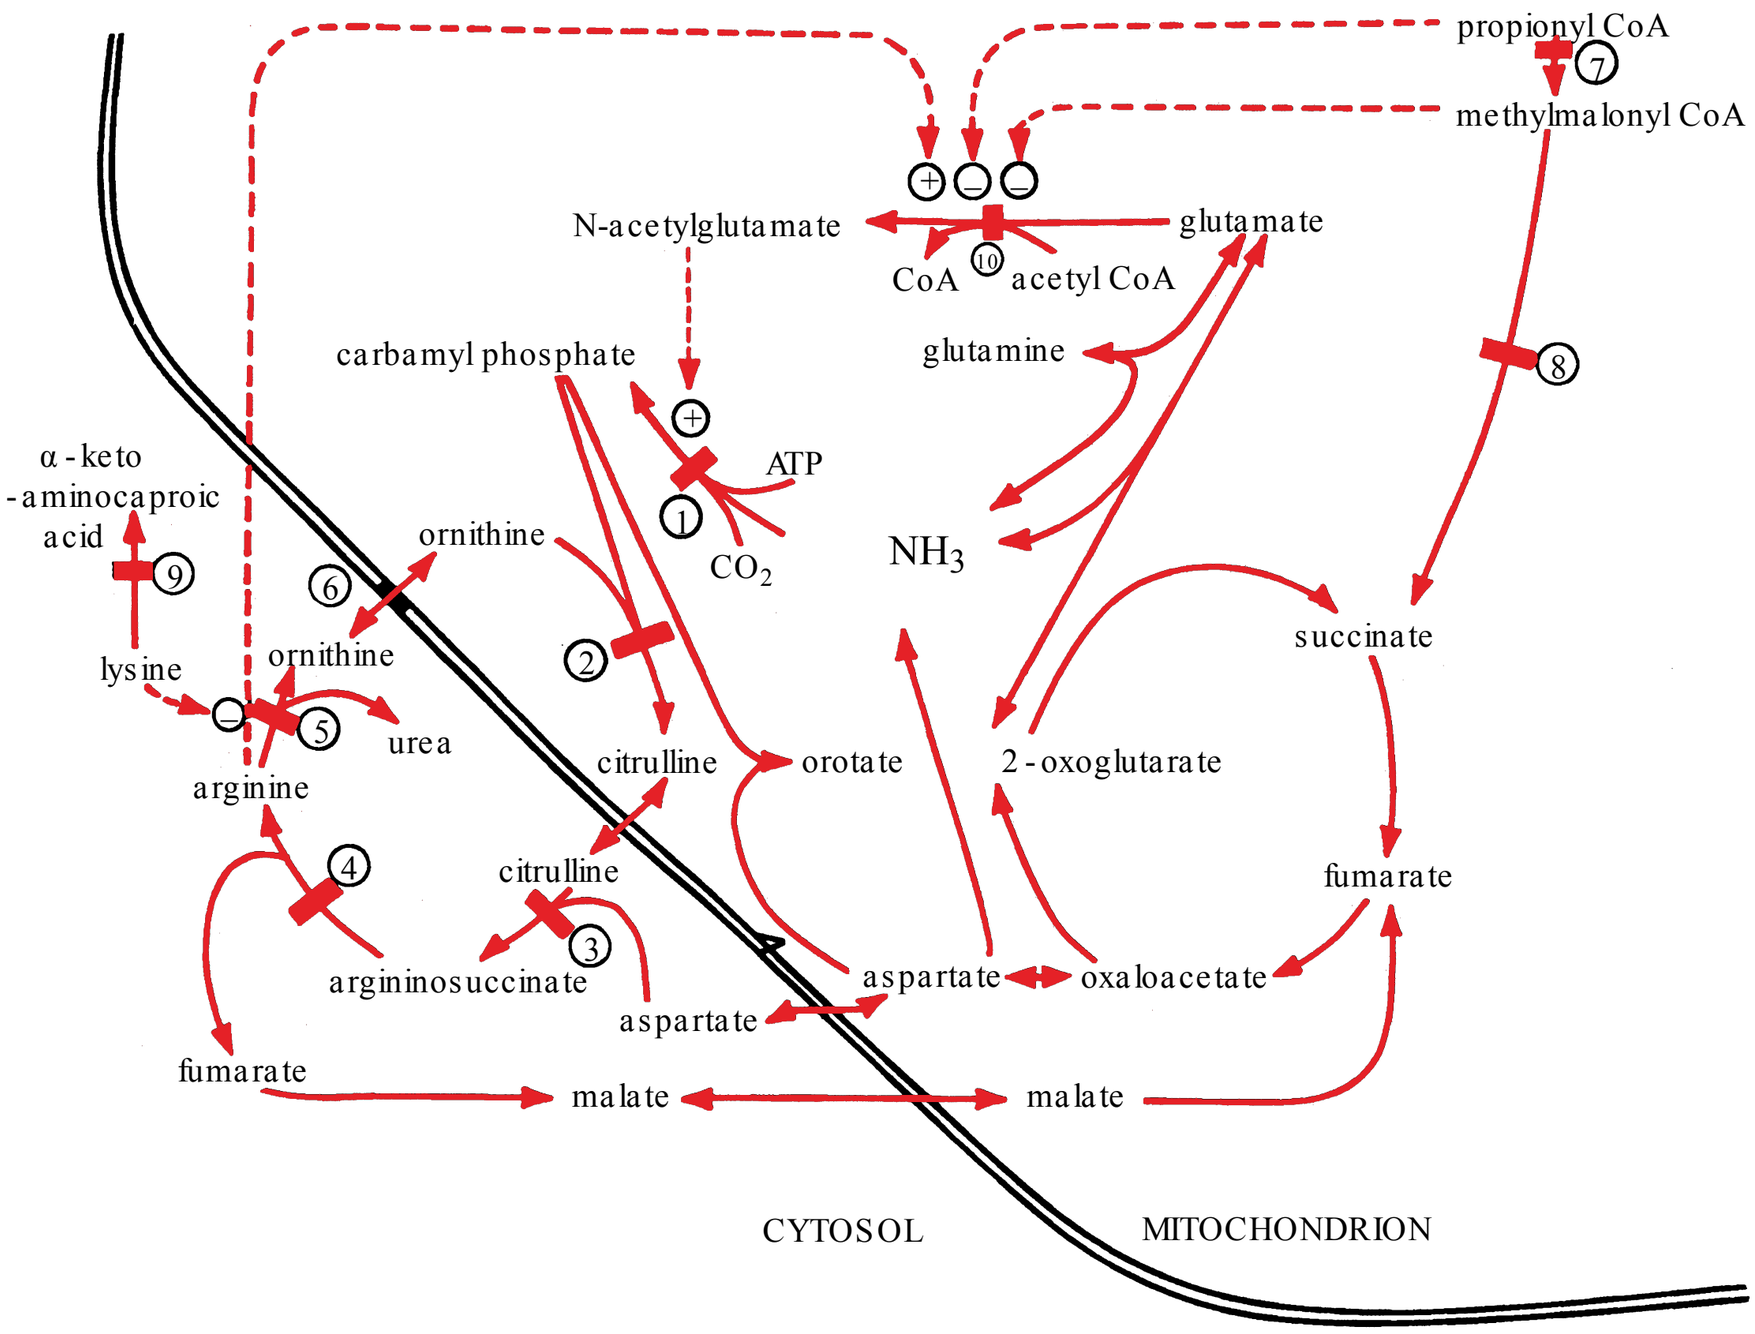

Figure 37-4 The major metabolic pathways for the use of ammonia by the hepatocyte. Solid bars indicate the sites of primary enzyme defects in various metabolic disorders associated with hyperammonemia: (1) carbamyl phosphate synthetase 1, (2) ornithine transcarbamylase, (3) argininosuccinate synthetase, (4) argininosuccinate lyase, (5) arginase, (6) mitochondrial ornithine transport, (7) propionyl CoA carboxylase, (8) methylmalonyl CoA mutase, (9) L-lysine dehydrogenase, and (10) N-acetyl glutamine synthetase. Dotted lines indicate the site of pathway activation (+) or inhibition (−). (From Flannery OB, Hsia YE, Wolf B. Current status of hyperammonemia syndromes. Hepatology 1982;2:495-506. Copyright 1996 American Association for the Study of Liver Diseases. Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)

typically correct the problem. The method for reporting PT in liver disease remains controversial, but the International Normalized Ratio (INR)* does not standardize PT measurement in liver disease as it does in warfarin therapy.

Urea Synthesis

Patients with end-stage liver disease may have low concentrations of urea in plasma. The rate of urea excretion in urine is lower than in healthy individuals. In addition, plasma concentrations of urea precursors ammonia (see later) and amino acids are increased in end-stage liver disease.

Hepatic Metabolic Function

The liver has a central and important role in several metabolic and regulatory pathways. For example, the functional expression of the complex, integrated organelle structure includes the metabolism of drugs (activation and detoxification) and the disposal of exogenous and endogenous substances, such as ammonia. A classic example, for example, is galactosemia. In this condition, the congenital absence of the galactose-1-phosphate uridyltransferase enzyme allows accumulation of the toxic metabolite galactose 1-phosphate, which causes injury to the (1) liver, (2) brain, and (3) kidneys.

Ammonia Metabolism

The major source of circulating ammonia is the action of (1) bacterial proteases, (2) ureases, and (3) amine oxidases acting on GI tract contents. The ammonia concentration in the portal vein is typically fivefold to tenfold higher than that in the systemic circulation. Under normal circumstances, most ammonia is metabolized to urea in hepatocytes in the Krebs-Henseleit urea cycle (Figure 37-4).

Animal and human studies have shown that an elevated concentration of ammonia in the brain that results from high plasma ammonia concentration (hyperammonemia) exerts toxic effects on the central nervous system. There are several causes, both inherited and acquired, of hyperammonemia.

*The INR is a system established by the World Health Organization (WHO) and the International Committee on Thrombosis and Hemostasis for reporting the results of blood coagulation (clotting) tests. All results are standardized using the international sensitivity index for the particular thromboplastin reagent and instrument combination utilized to perform the test.

The inherited deficiencies of urea cycle enzymes are the major cause of hyperammonemia in infants.

The common acquired causes of hyperammonemia are advanced liver disease and renal failure. Severe or chronic liver failure (as occurs in **fulminant hepatitis** and cirrhosis, respectively) leads to a significant impairment of normal ammonia metabolism. **Reye syndrome**, which is primarily a central nervous system disorder with minor hepatic dysfunction, is also associated with hyperammonemia.

Hepatic encephalopathy, in the cirrhotic patient, is often precipitated by GI bleeding that enhances ammonia production. Other precipitating causes of encephalopathy include (1) excess dietary protein, (2) constipation, (3) infections, (4) drugs, or (5) electrolyte and acid-base imbalance. Because these conditions also increase ammonia concentrations, there is a small correlation between the degree of elevation in ammonia and the degree of impairment of liver function. There is, however, little correlation in an individual patient between plasma ammonia concentrations and degree of encephalopathy. The fasting venous plasma ammonia concentration is useful in the differential diagnosis of encephalopathy when it is unclear if encephalopathy is of hepatic origin. It is especially helpful in diagnosing Reye syndrome and the inherited disorders of urea metabolism. However, it is not useful in patients with known liver disease.

Should ammonia values in healthy subjects be much higher than expected, consideration should be given to the existence and correction of sources of preanalytical error. These include errors resulting from (1) contamination (from cigarette smoke, use of ammonium heparin anticoagulation), (2) the collection process (prolonged tourniquet use, fist clenching during collection), or (3) sample handling (delayed analysis, failure to put sample in ice water).

Xenobiotic Metabolism and Excretion

Xenobiotics are foreign substances that are cleared and metabolized by the liver and some have been used as tests of liver function. For example, certain lipophilic substances, such as (1) bromsulfophthalein (BSP), (2) indocyanine green (ICG), (3) aminopyrine, (4) caffeine, (5) lidocaine, and (6) the stain rose bengal are excreted into bile as the intact parent compound, its conjugates, or both. The clearance of these xenobiotics by the liver is normally very rapid, and it is believed that uptake by hepatocytes is a carrier-mediated, active-transport process. Little, if any, is cleared by other tissue. Excretion into bile is slow. The elimination of these compounds from the bloodstream therefore depends on (1) hepatic blood flow, (2) patency—the quality or state of being open or unobstructed—of the biliary tree, and (3) hepatic parenchymal function.

Clinical Manifestations of Liver Disease

A number of conditions are indicative of liver disease, including (1) jaundice, (2) portal hypertension, (3) disordered hemostasis, and (4) the release of enzymes into various body fluids.

Jaundice

Jaundice (also known as icterus) is characterized by a yellow appearance of the skin, mucous membranes, and sclera caused by bilirubin deposition. It is the most specific clinical manifestation of hepatic dysfunction. It is, however, not present in many individuals with liver disease (especially chronic liver disease), and also may occur with bilirubin overproduction (hemolysis) or congenital disorders of bilirubin metabolism. Jaundice is usually apparent clinically in older children and adults when the plasma bilirubin concentration reaches 2 to 3 mg/dL (34 to 51 μmol/L). When bilirubin clearance from the liver to the intestinal tract is impaired (as in acute hepatitis and bile duct obstruction), it may be accompanied by acholic (gray-colored) stools. Increases in water-soluble conjugated bilirubin lead to tea-colored urine. Bilirubin metabolism is discussed in Chapter 28. A classification of jaundice, based on the site of altered bilirubin metabolism, is shown in Box 28-3 in Chapter 28.

Portal Hypertension

The venous outflow of the GI tract, spleen, and pancreas passes through the portal circulation (Figure 37-5). Portal hypertension occurs when there is obstruction to portal flow anywhere along its course. The causes of obstruction leading to portal hypertension are classified by site as (1) presinusoidal, (2) sinusoidal, and (3) postsinusoidal. Presinusoidal portal hypertension is most commonly caused by portal vein thrombosis or schistosomiasis. Important causes of postsinusoidal hypertension include hepatic vein occlusion (Budd-Chiari syndrome) and congestive heart failure. The vast majority of cases of portal hypertension represent sinusoidal hypertension, most commonly caused by cirrhosis.

When portal pressure increases, the portal venous system becomes dilated and forms collateral connections to the systemic venous flow (Figure 37-6), leading to portosystemic shunting. Initially, this is clinically silent, but as portal hypertension worsens, it compromises many of the metabolic functions of the liver. One such abnormality is altered estrogen metabolism, leading to skin findings, such as spider telangiectasias and palmar erythema, gynecomastia in men, and abnormal vaginal bleeding and irregular menstrual periods in women. Impaired metabolic functions lead to the accumulation of ammonia and abnormal neurotransmitters and ultimately to hepatic encephalopathy. Because most nutrients arrive through the portal vein, synthetic functions are also impaired, resulting in decreased concentrations of most plasma proteins. This includes clotting factors and clotting factor inhibitors, such as antithrombin and proteins C and S. Patients with portal hypertension are thus predisposed to both excessive bleeding and to venous thrombosis.

Bleeding Esophageal Varices

The most life-threatening consequence of portosystemic shunting is the development of **varices** (enlarged and tortuous veins), which occur throughout the GI tract but are most common in the esophagus and stomach. Bleeding from varices is one of the leading causes of morbidity and mortality in patients with cirrhosis. Varices are present at the time of

Figure 37-5 The portal-venous system. (From Zakim O, Boyer TD. Hepatology: A textbook of liver disease, 3rd edition. Philadelphia: WB Saunders, 1996:721.)

diagnosis of cirrhosis in about 40% of patients and develop in an additional 6% per year.

Ascites

Ascites is the accumulation of fluid in the abdominal cavity. Ascites is the most common clinical finding in patients with portal hypertension. Ascites itself is usually not life threatening, but is uncomfortable and may compromise respiration. It also predisposes individuals to spontaneous bacterial peritonitis, which is life threatening. Since there are many causes of ascites, the feature that most distinguishes portal hypertension is an increase in the difference in albumin concentrations between plasma and ascitic fluid. T is is sometimes called the serum-ascites albumin gradient (SAAG). A gradient >1.1 g/dL is diagnostic of ascites caused by portal hypertension.

Spontaneous Bacterial Peritonitis

Ascites predisposes to spontaneous bacterial peritonitis, defined as bacteremia (typically gram negative) in the absence of mechanical disruption of the bowel. It usually presents in an individual with known cirrhosis who develops (1) abdominal pain, (2) fever, or (3) leukocytosis. T e diagnosis is established by examination of the ascitic fluid. Values of >250 neutrophils per microliter, or >500 in the absence of a positive blood culture, is considered diagnostic. In contrast, secondary peritonitis is usually associated with (1) higher neutrophil counts, (2) low glucose in ascitic fluid, and (3) high concentration of protein.

Hepatic (Portosystemic) Encephalopathy

Hepatic encephalopathy is a metabolic disorder characterized by a wide spectrum of neuropsychiatric dysfunction. It may occur (1) as an acute syndrome in patients with acute **hepatic failure** from viral or drug-induced hepatitis, or (2) as a chronic syndrome associated with liver failure and cirrhosis. A variety of neurotransmitter systems are dysfunctional in hepatic encephalopathy, but the exact cause for the changes is not known. Plasma ammonia concentrations are rarely helpful, either for diagnosis or for monitoring the patient's disorder. Normal ammonia concentrations, however, are helpful in excluding hepatic encephalopathy as a cause of cerebral dysfunction.

Hepatorenal Syndrome

Hepatorenal syndrome (HRS) refers to decreased renal function secondary to hepatic disease. Portal hypertension is a common factor in all cases of HRS developing in chronic liver disease.[1] HRS, however, also may develop in acute liver failure. Although formerly thought to be a rapidly progressing, terminal event in a person with end-stage liver disease, it is now recognized that HRS falls into two major groups. Type 2 HRS, a slowly progressive or stable decline in renal function that is due to peripheral vasodilation and renal vasoconstriction, is the most common form. Type 1, or classic, HRS represents rapidly declining renal function, usually developing in a person with preexisting type 2 HRS. Type 1 HRS usually develops in the setting of an acute decrease in blood pressure, often due to (1) spontaneous bacterial peritonitis, (2) variceal bleeding, or (3) excessive use of diuretics to treat ascites.

A common feature in both forms of HRS is activation of the renin-angiotensin-aldosterone axis caused by intravascular volume depletion, leading to salt and water retention. T is leads to development of (1) hyponatremia, (2) hypokalemia, (3) metabolic alkalosis, (4) low urine sodium and high urine potassium excretion, and (5) high urine osmolality.

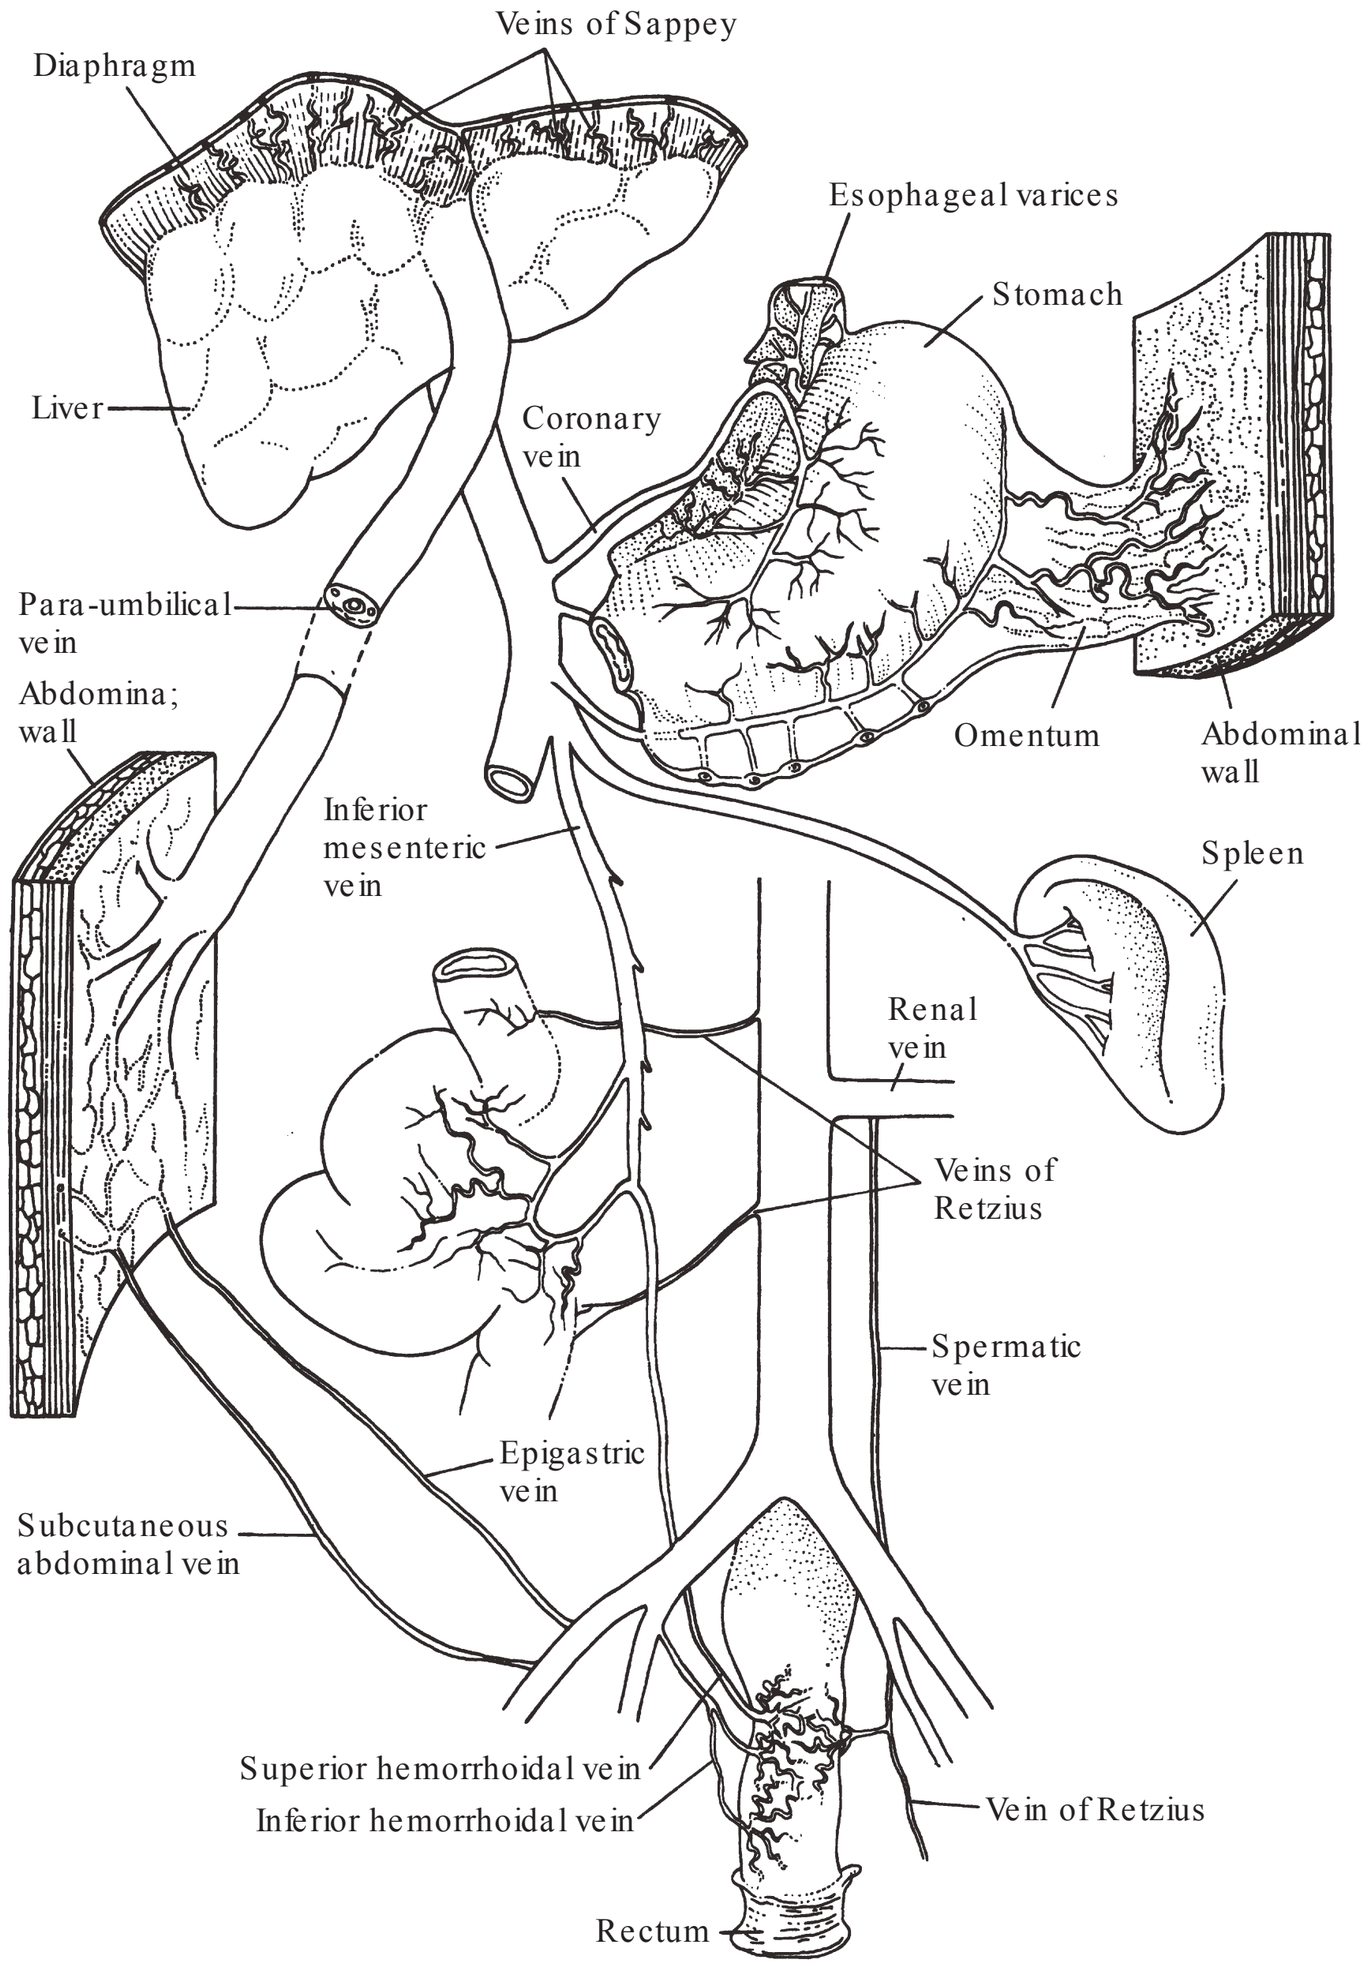

Figure 37-6 The sites of the portosystemic collateral circulation in cirrhosis of the liver. (From Sherlock S, Dooley J, eds. Diseases of the liver and biliary system, 9th edition. London: Blackwell Scientifc Publications, 1993:134.)

Disordered Hemostasis in Liver Disease

Numerous coagulation factors are manufactured by the liver. Thus, abnormal hemostasis is common in liver disease, particularly cirrhosis and acute liver failure. Disorders of fibrinogen (such as, dysfibrinogenemia) may also be seen in both acute and chronic liver disease, leading to prolongation of the partial thromboplastin time. Disseminated intravascular coagulation occurs with acute hepatic **necrosis**, presumably as a result of the release of tissue thromboplastin and defective clearance of inhibitors, such as antithrombin and protein C. Thrombocytopenia (common in persons with cirrhosis) may contribute to ineffective intravascular coagulation. Although commonly attributed to splenic sequestration (hypersplenism), there is evidence of antibody-mediated platelet destruction, and decreased production of thrombopoietin by the liver contributes to thrombocytopenia. Patients with AIH may have anticardiolipin antibodies and antibodies to platelets.

Enzymes Released from Diseased Liver Tissue

Because hepatic function is often normal in many patients with liver disease, the plasma activities of numerous enzymes are more reliable indicators of liver disease. For example, the pattern and degree of elevation of enzyme activity vary with the type of liver disease, their measurement is extremely helpful in the recognition and differential diagnosis of liver damage (see Chapter 19). A number of factors govern the ability of liver enzymes to assist in diagnosis, including their (1) tissue specificity, (2) subcellular distribution, (3) relative degree of enzyme activity in liver and plasma, (4) patterns of release, and (5) clearance from plasma

Tissue Specificity

The five enzymes that are commonly measured and used in the diagnosis of liver disease include (1) aspartate aminotransferase (AST; EC 2.6.1.1); (2) alanine aminotransferase (ALT; EC 2.6.1.2); (3) alkaline phosphatase (ALP; 3.1.3.1); (4) γ-glutamyltransferase (GGT; EC 2.3.2.2), all of which are commonly used to detect liver injury; and (5) lactate dehydrogenase (LD; EC 1.1.1.27), which is occasionally used. ALT and GGT are present in several tissues, but plasma activities primarily reflect liver injury. AST is found in (1) liver, (2) muscle (cardiac and skeletal), and to a limited extent in (3) red cells. LD has wide tissue distribution, and is thus relatively nonspecific. ALP is found in a number of tissues, but in normal individuals primarily reflects bone and liver sources. Thus, based on tissue distribution, ALT and GGT are considered the most specific markers for liver injury.

Subcellular Distribution

Enzymes are found at different locations within cells. AST, ALT, and LD are cytosolic enzymes. As such, they are released with cell injury, and appear in plasma relatively rapidly. In the case of AST and ALT, there are both mitochondrial and cytosolic isoenzymes in hepatocytes and other cells containing these enzymes. With ALT, the relative amount of mitochondrial isoenzyme is small, and its plasma half-life is extremely short, making it of no diagnostic significance. With AST, the mitochondrial isoenzyme represents a significant fraction of total AST within hepatocytes, although little is released in most forms of liver disease. In contrast, ALP and GGT are membrane-bound glycoprotein enzymes. The most important location of both enzymes is on the canalicular membrane of hepatocytes.

Relative Activity in Liver and Plasma

For cytoplasmic enzymes, the relative amount of enzyme in the liver relative to plasma is an important determinant of clinical utility. The activity of AST within hepatocytes is about twice that of ALT, although plasma activities are similar. In contrast, hepatocyte activities of LD are much lower (relative to plasma) than those of the other two enzymes, and plasma activities of LD are several times higher than those of AST and ALT. This causes less of an increase in LD with liver injury than occurs with AST and ALT. The relative amount of enzyme in tissue is not necessarily the same in disease. In (1) cirrhosis, (2) alcohol abuse, and (3) malnutrition, there are greater decreases in cytoplasmic ALT than in cytoplasmic AST.

Mechanisms of Release

Several mechanisms appear to be involved in release of enzymes from hepatocytes. Cell injury is the simplest mechanism and appears to allow leakage of cytoplasmic enzymes, but minimal release of other types of enzymes. Alcohol appears to induce expression of mitochondrial AST on the surface of hepatocytes. Not surprisingly, alcoholic hepatitis is associated with increased plasma activities of this isoenzyme. The mechanism of release of membrane-bound enzymes such as GGT and ALP into the circulation is less well understood, but there appears to be (1) increased synthesis, (2) membrane fragmentation by bile acids, and (3) solubilization of membrane-bound enzymes by the action of bile acids.

Rate of Clearance of Enzyme from Plasma

Clearance of liver enzymes from plasma occurs at variable rates. The half-life of ALT is about 48 hours, whereas that of cytosolic AST (the main form found in plasma) is about 16-18 hours; thus although more AST is released from liver, the much longer half-life of ALT leads to higher activities of ALT than AST in most forms of hepatocellular injury. The half-life of the liver isoenzyme of ALP has been variously reported as from 1 to 10 days; the former figure appears to correspond better to the changes seen with removal of **gallstones**. The half-life of GGT has been reported as 4.1 days. The mechanism by which enzymes are removed from circulation is not completely known, although receptor-mediated endocytosis by liver macrophages is likely involved.

Diseases of the Liver

The liver has a limited number of ways of responding to injury. Acute injury to the liver may be asymptomatic, but it often presents as jaundice. The two major acute liver diseases are acute hepatitis and cholestasis. Chronic liver injury generally takes the clinical form of chronic hepatitis; its long-term complications include cirrhosis and HCC. The discussion of liver disease will focus mainly on these patterns, and a few diseases that differ from this general pattern.

Mechanisms and Patterns of Injury

The target cell determines the pattern of injury with hepatocyte injury leading to hepatocellular disease and biliary cell injury leading to cholestasis. All cellular injury may induce fibrosis as an adaptive or healing response with the duration of injury and genetic factors determining whether cirrhosis and ultimately carcinoma occur (Figure 37-7).

Cell death occurs by necrosis or **apoptosis**, or both. Cellular necrosis occurs as the result of an injurious environment and has been referred to as "cell murder." Ischemic injury and toxic injury from compounds, such as (1) carbon tetrachloride, (2) aspirin, and (3) acetaminophen[9] occur for the most

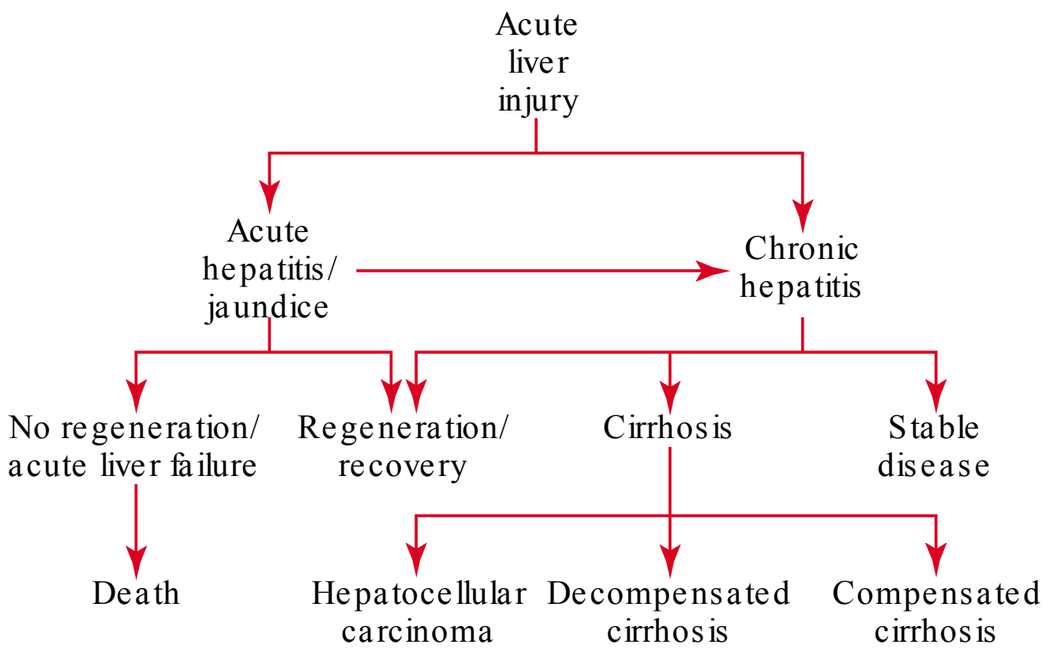

Figure 37-7 Natural history of liver disease.

part by necrosis. Apoptosis occurs as the result of accelerated programmed death in which the cell participates in its own demise and thus commits "cell suicide." Most forms of acute and chronic hepatitis are associated with apoptosis. Regardless of the cause, cell death typically results in leakage of cytoplasmic enzymes. Laboratory tests are helpful in distinguishing the (1) pattern of injury (hepatocellular versus cholestatic), (2) chronicity of injury (acute versus chronic), and (3) severity of injury (mild versus severe). In general, the aminotransferase enzymes and ALP are used to distinguish the pattern. With acute liver injury, the PT or factor V concentration are used to determine the severity. In chronic liver injury (detected by persistently elevated enzymes for over 6 months), prognosis is related to the degree of impairment in liver function, such as (1) increased bilirubin, (2) decreased albumin and platelets, and 3) prolonged PT. At the present time, the only way to accurately detect fibrosis is by a liver biopsy.

Disorders of Bilirubin Metabolism

Defects in bilirubin metabolism resulting in jaundice are known to occur at each step in the metabolic pathway. The pathway and the disorders related to these defects are discussed in Chapter 28.

Hepatic Viral Infection

Five viruses have been identified (A, B, C, D, E) as causes of infection that primarily targets the liver. In addition, certain other viruses may infect the liver as part of a more generalized infection, among them (1) cytomegalovirus (CMV), (2) Epstein-Barr virus (EBV), and (3) herpes simplex virus (HSV). The various hepatitis viruses are outlined in Table 37-1. Only hepatitis A, B, and C will be discussed in this section.

Hepatitis A Virus

Hepatitis A virus (HAV) is the most common cause of acute **viral hepatitis** in North America, although its incidence has markedly declined with the use of vaccination. Epidemics have been associated with waterborne and food-borne contamination. While most adults with acute HAV infection become jaundiced, most children remain asymptomatic. There is no chronic form of hepatitis A, but cholestasis (manifested by several weeks of jaundice and pruritus) may occur in some adults.

Tests commonly used to evaluate a patient for exposure to HAV include the measurement of total antibody to HAV and IgM anti-HAV. Total antibody to HAV develops after natural exposure or following immunization, and appears to persist for life with natural infection and for at least 20 years following vaccination. IgM anti-HAV develops rapidly with acute exposure, and generally remains detectable for 3 to 6 months. With the falling incidence of acute HAV infection, most positive IgM anti-HAV results represent false positives; the Centers for Disease Control and Prevention (CDC) recommends the test be used only in the setting of acute hepatitis.

Hepatitis B Virus

Hepatitis B virus (HBV) is the most common chronic viral infection. An estimated 350 million individuals are chronically infected with HBV, and approximately one third of the world population has been exposed to HBV. The frequency of chronic HBV is high in most of (1) Asia, (2) central Africa, and (3) southern Europe, but much less common among those born in North America (except Alaska) and northern Europe. HBV is transmitted through body fluids, primarily by parenteral or sexual contact. It has been found to be transmitted

TABLE 37-1 Types of Viral Hepatitis

	A	B	C	D	E
Type	RNA	DNA	RNA	Partial	RNA
Incubation period (d)	45-50	30-150	15-160	30-150	20-40
Transmission					
Fecal-oral	Yes	No	Min	No	Yes
Household	Yes	Min	Min	Yes	Yes
Vertical	No	Yes	Min	Yes	No
Blood	Rare	Yes	Yes	Yes	Unknown
Sexual	No	Yes	Min	Yes	Unknown
Diagnosis	Anti-HAV IgM	HBsAg, HBV DNA, anti-HBc IgM	Anti-HCV, HCV RNA	Anti-HDV, HDV RNA	Anti-HEV
Carrier state	No	Yes	Yes	Yes	Yes
Chronic hepatitis	No	Depends on age and immune system	50%-80%	Yes	Yes (in immunocompromised)
Liver cancer	No	Yes	Yes	Yes	No
Prevention					
Vaccine	Yes	Yes	No	Yes*	Yes
Immunoglobulin	Yes	Yes	No	Yes*	No
Response to interferon	Not used	50%	20%-45%	Yes	Not used

*Vaccination and passive immunization against HBV protects against HDV infection.

from mother to child, usually at or after delivery (termed vertical transmission). In parts of the world with high rates of chronic infection, much of the transmission is vertical. As discussed later, chronic HBV infection may take several forms, not all of which have the same significance.

Hepatitis B is caused by a 42-nm DNA virus that is a member of the hepadna virus family. Hepadna viruses are unusual in that they reproduce from an RNA template using reverse transcriptase and are prone to developing mutant strains. Several mutants have clinical importance. Mutants that prevent production of the hepatitis B e antigen (HBeAg), but allow production of antibody to the e antigen (anti-HBe) are common in much of the world, and represent up to 25% of chronic infections in North America. This limits the utility of HBeAg as a marker of viral replication. Mutants resistant to reverse transcriptase inhibitors, commonly used to treat chronic HBV, develop in many individuals treated long-term (although they are uncommon in those treated with entecavir and tenofovir). Rare mutants involve the portion of the surface antigen (HBsAg) recognized both by HBsAg kits and by antibodies developed in response to the HBV vaccine, and may cause infection that is not detected by routine laboratory tests.

Immunization

Hepatitis B may be prevented by either passive (hepatitis B immune globulin [HBIG]) or active (hepatitis B recombinant vaccine) immunization. Many countries require routine vaccination of children, which has markedly reduced the incidence of hepatitis B infection.

Diagnostic Tests for Hepatitis B

HBsAg is produced in excess by the virus, and its measurement is used as a laboratory test to detect current HBV infection. It is typically present with both acute and chronic infection. Antibody to the hepatitis B core antigen (anti-HBc) is the most commonly detected antibody against HBV. Two assays are usually employed: IgM and total anti-HBc. The total antibody assay measures both IgM and IgG antibodies and is usually positive for life after exposure. IgM anti-HBc is usually positive for 3 to 6 months after acute infection, but is occasionally present with chronic HBV infection as well. Antibody to the hepatitis B surface antigen (anti-HBs) is considered evidence of immunity to hepatitis B and is the only marker found in those receiving the hepatitis B vaccine; with "recovery" from natural infection, most individuals develop both anti-HBs and anti-HBc.

HBeAg and anti-HBe are typically used only in the setting of chronic HBV infection. HBeAg is produced along with, but is not part of the HBV viral particle. It is used as a marker of persistence of infectious virus; its clearance and the appearance of anti-HBe have been used as indicators of conversion to the nonreplicating state and as goals of antiviral treatment. Presence of HBeAg in untreated individuals always indicates persistent viremia; its absence is not reliable in indicating loss of circulating virus, as will be discussed later.

Hepatitis B viral DNA is a direct measure of circulating virus; it is most commonly measured by amplification assays. It is unclear how many copies of HBV DNA represents clinically important viremia. Clinical practice guidelines, however, have adopted 100,000 copies/mL (20,000 IU/mL) as a "clinically significant" level of viremia. Studies have shown that risk of complication begins to increase with **viral loads** between 1000 and 10,000 copies/mL.[11] With treatment, the first evidence of response is a fall in HBV DNA.

Hepatitis C Virus

The hepatitis C virus (HCV)[5] is the most common cause of chronic hepatitis in (1) North America, (2) Europe, and (3) Japan. It is estimated to infect approximately 170 million individuals worldwide. HCV infection primarily occurs through plasma. The major risk factors are injection drug use and transfusion before testing the blood supply, which began in 1990. HCV is an RNA flavivirus with a high rate of spontaneous mutation. There are six major genotypes (<70% nucleotide homology), along with a number of subtypes (77% to 80% homology).[5]

Prevention

Prevention of HCV has proved to be more difficult than with HAV and HBV. However, there has been an 80% decrease in incidence of acute HCV over the past decade, which is thought to be due to testing blood donors for HCV and to safe injection practices instituted to reduce risk of human immunodeficiency virus (HIV) infection. No successful vaccine has been developed against HCV.

Diagnostic Tests for Hepatitis C

Measurement of the antibody to HCV (anti-HCV) is the principal screening test for HCV exposure. Second generation assays become positive an average of 12 weeks after exposure, whereas third generation assays become positive an average of 9 weeks after exposure. The CDC have identified signal to cutoff ratios for most commercial anti-HCV assays that are associated with high likelihood of true positive results.

HCV RNA is used to detect active infection. Rapid separation of serum from clot is critical for accurate measurement of HCV RNA. Of note, EDTA plasma is more stable and is often preferred for testing. Assays for HCV RNA have generally used qualitative and quantitative reporting, although many laboratories no longer perform qualitative testing because newer quantitative tests (particularly those using real-time PCR) have limits of detection similar to or lower than the original qualitative assays. Also, quantitative testing is preferred over qualitative testing because treatment decisions require knowledge of the actual viral load. HCV genotype is an important pretreatment parameter. Genotype is determined by direct sequencing or line probe assay.

Acute Hepatitis

Acute hepatitis refers to an acute injury directed against the hepatocytes. The injury may be mediated either directly or indirectly. Direct injury occurs with certain drugs, such as acetaminophen, or with ischemia. Indirect injury is immunologically mediated injury that occurs with hepatitis viruses

and most drugs, including ethanol. In direct injury, there is typically a rapid rise in cytosolic enzymes, such as (1) AST, (2) ALT, and (3) LD, followed by a rapid fall with rates of decline similar to known half-lives of the enzymes. With indirect injury, there is a (1) gradual rise in cytosolic enzymes, (2) plateau phase, and (3) gradual resolution of enzyme elevation. Although jaundice is a key clinical finding leading to recognition of acute hepatitis, it is often absent. An increase of AST activity to greater than 200 IU/L, or of ALT activity to greater than 300 IU/L, has clinical sensitivity and specificity of greater than 90% for acute hepatitis. ALP is usually mildly elevated and is less than three times the upper reference limit in 90% of cases of acute hepatitis. Bilirubin elevation, when present, typically is predominantly direct-reacting bilirubin, in a percentage of total similar to that in bile duct obstruction. Liver synthetic function is usually well-preserved in most forms of acute hepatitis. However, impaired synthetic function is an important predictor of acute liver failure. These and other features that are helpful in the differential diagnosis of acute hepatitis are summarized in Table 37-2.

The outcome of acute hepatitis is variable. In most cases, complete recovery occurs and liver regeneration leads to normal structure and function. With some viruses, failure to clear infection results in the development of chronic hepatitis. In a small percentage of cases, massive destruction of the liver leads to acute (fulminant) hepatic failure, which is associated with high mortality unless liver transplantation occurs.

Acute Viral Hepatitis

All forms of acute viral hepatitis have a similar clinical course, with marked elevations in aminotransferases, usually between 8 and 50 times the upper reference limits. ALT is typically higher than AST because of slower clearance. Enzyme elevations typically peak before peak bilirubin occurs and remain increased for an average of 4 to 5 weeks (longer for ALT than AST because of its longer half-life). The incidence of acute viral hepatitis has declined to less than 10% of rates in the late 1980s, likely due to immunization for HAV and HBV and use of safer injection and sex practices.

Acute Hepatitis A

In adults, about 70% of those with acute HAV infection develop jaundice. In children, acute HAV infection typically goes unrecognized, and only 10% exhibit jaundice. IgM antibody (anti-HAV IgM) appears early in the course of illness and persists for an average of 2 to 6 months, and is the best test to diagnosis acute HAV infection.

Acute Hepatitis B

As with HAV, most infections in children are clinically silent. An estimated 30% to 50% of adolescents and adults with acute HBV infection develop jaundice. The outcome in acute HBV infection is strongly influenced by age and immune status. The serological course of acute hepatitis B infection is illustrated in Figure 37-8. HBsAg is the first serological marker to appear (1 to 2 months after infection, before evidence of hepatitis), and is the last protein marker to disappear. The first antibody to appear, usually coinciding with the onset of clinical evidence of hepatitis 3 to 6 months after infection, is anti-HBc, which usually persists for 3 to 6 months. It is usually considered diagnostic of acute hepatitis B infection. In practice, it is extremely rare to have individuals have negative HBsAg and anti-HBs at the time of initial presentation, leaving IgM anti-HBc as the only commonly measured

TABLE 37-2 Laboratory Features of Different Forms of Acute Hepatitis

Type	AST/ALT	ALP	Bilirubin	PT	Serology	Other
Viral	8-50 × URL	<3 URL	5-15 mg/dL	<15 s	Positive	
HAV					IgM anti-HAV	
HBV					HBsAg, IgM anti-HBc	
HCV					HCV RNA, ± anti-HCV	
Alcoholic	<8 × URL	>3 × URL in 25%	5-15 mg/dL	<15 s	Negative	AST > ALT
Toxic	>50 × URL	Normal	<5 mg/dL	>15 s	Negative	Toxin usually detectable; acute renal failure common
Ischemic	>50 × URL	Normal	<5 mg/dL	>15 s	Negative	Acute renal failure common
Drug induced	8-50 × URL	>3 × URL in 50%	5-15 mg/dL	<15 s	Negative	Eosinophilia, skin rash common
Autoimmune	8-50 × URL	<3 × URL	5-15 mg/dL	<15 s	Positive ANA or ASMA	Low albumin, high globulins
Wilson disease	3-10 × URL	Low normal or decreased	5-15 mg/dL	<15 s	Negative	Hemolytic anemia, renal failure common; low ceruloplasmin often absent

ALP, Alkaline phosphatase; ALT, alanine transaminase; ANA, antinuclear antibody; ASMA, anti-smooth muscle antibody; AST, aspartate transaminase; HAV, hepatitis A virus; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; IgM, immunoglobulin M; PT, prothrombin time; URL, upper reference limit.

marker to be positive. T is finding has been termed the "core window." "Recovery" is associated with loss of HBsAg and appearance of anti-HBs; more than 95% of healthy adults and adolescents have such an outcome, whereas the figure is lower in younger children or those who are immunosuppressed. Accumulating evidence indicates that HBV remains dormant in the body and HBV DNA circulates in low concentrations in "recovery." T is has been termed "occult" HBV infection. "Reactivation" of infection may occur with chemotherapy or severe immunosuppression.

Acute Hepatitis C

Acute HCV infection[5] is responsible for 10% to 15% of cases of acute hepatitis in the United States, but only 10% to 30% develop jaundice. HCV RNA is detectable in plasma 2 to 4 weeks after initial exposure with aminotransferases activities increasing about 6 to 8 weeks after infection. Anti-HCV is present in a little more than half of cases at the time of presentation. Diagnosis of acute HCV is likely if (1) anti-HCV is absent but HCV RNA is present, (2) HCV RNA viral load is high and anti-HCV titer is low, (3) anti-HCV titer increases with time, or (4) an initially positive HCV RNA becomes negative without treatment. Viral load falls with development of antibody to one or more HCV proteins, and may become transiently negative even in those who progress to chronic infection. An estimated 30% to 50% of those infected clear the virus spontaneously (more commonly in younger individuals); those who clear virus may fail to develop anti-HCV, or may lose antibody years after exposure.

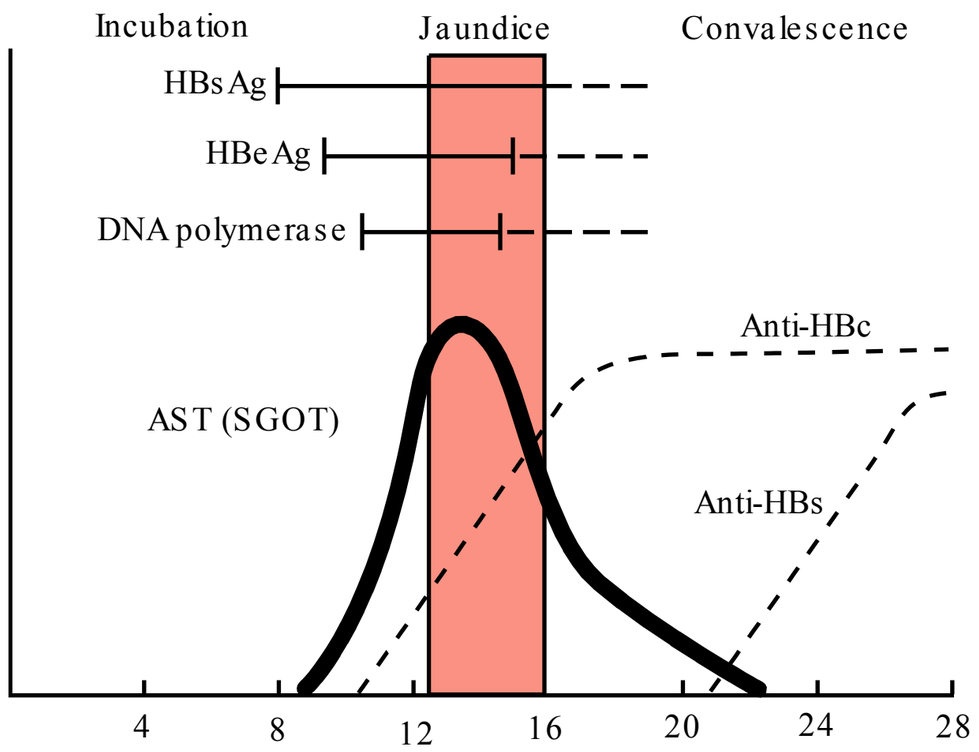

Figure 37-8 Course of acute type B hepatitis with recovery. 1, Onset of hepatitis with jaundice 3 months after exposure; 2, detection of hepatitis B surface antigen (HBsAg) 2 to 8 weeks after exposure, followed by appearance of its antibody (anti-HBs) 2 to 4 weeks after HBsAg is no longer detectable; 3, detection of hepatitis Be antigen (HBeAg) shortly after appearance of HBsAg disappears (this is usually followed by the appearance of antibody to HBeAg [anti-HBe], which persists); 4, detection of hepatitis B core antibody (anti-HBc) at the time of onset of disease 2 to 3 months after exposure. Anti-HBc IgM will be detectable at high levels for 5 months. (From Balistreri WF. Viral hepatitis: Unique aspects of infection during childhood. Consultant 1984;24:131-53.)

Acute Alcoholic Hepatitis

Alcoholic liver disease is discussed more fully below under chronic hepatitis. Acute alcoholic hepatitis clinically is an acute febrile illness, characteristically associated with leukocytosis and increased concentrations of acute phase response proteins.[13-14] It also causes mild increases in cytosolic enzymes. For example, AST activity is typically more than two times that of ALT, and it is rare for AST activity to be more than eight times the upper reference limit. A cholestatic form of the disease, with increases in ALP activity to greater than three times the upper reference limit, is seen in up to 20% of cases, and is associated with higher mortality. Increases in bilirubin concentration are common, and reduced liver-synthesized protein concentrations are also commonly present. Increased bilirubin, decreased albumin, and prolonged PT are poor prognostic markers in alcoholic hepatitis. A discriminant function [4.6 × (PT-control PT) + plasma bilirubin (mg/dL)] value >32 indicates individuals with a high mortality rate.

Toxic Hepatitis

Toxic hepatitis refers to direct damage of hepatocytes by a toxin or toxic metabolite. Toxic reactions are usually predictable, and are directly related to the dose of the agent ingested. In North America and Europe, the most common cause of toxic hepatitis is acetaminophen (Figure 37-9)[9]. T e first laboratory abnormality to appear is an increase in PT, followed by increased activities of cytosolic enzymes. Initially, LD activity is often increased to higher absolute amounts than AST, and AST tends to be higher than ALT. Peak activities (typically >100 times the upper reference limits) usually occur by 24 to 48 hours, followed by rapid clearance at rates approximating the known half-lives of the enzymes. PT elevations are typical and are >4 seconds above the control value in most cases. Prognosis is related most closely to the prolonged increase in PT. Persistent elevation of PT 4 days after ingestion is associated with a poor prognosis. Other markers of risk include development of acute renal failure or lactic acidosis with pH <7.30.

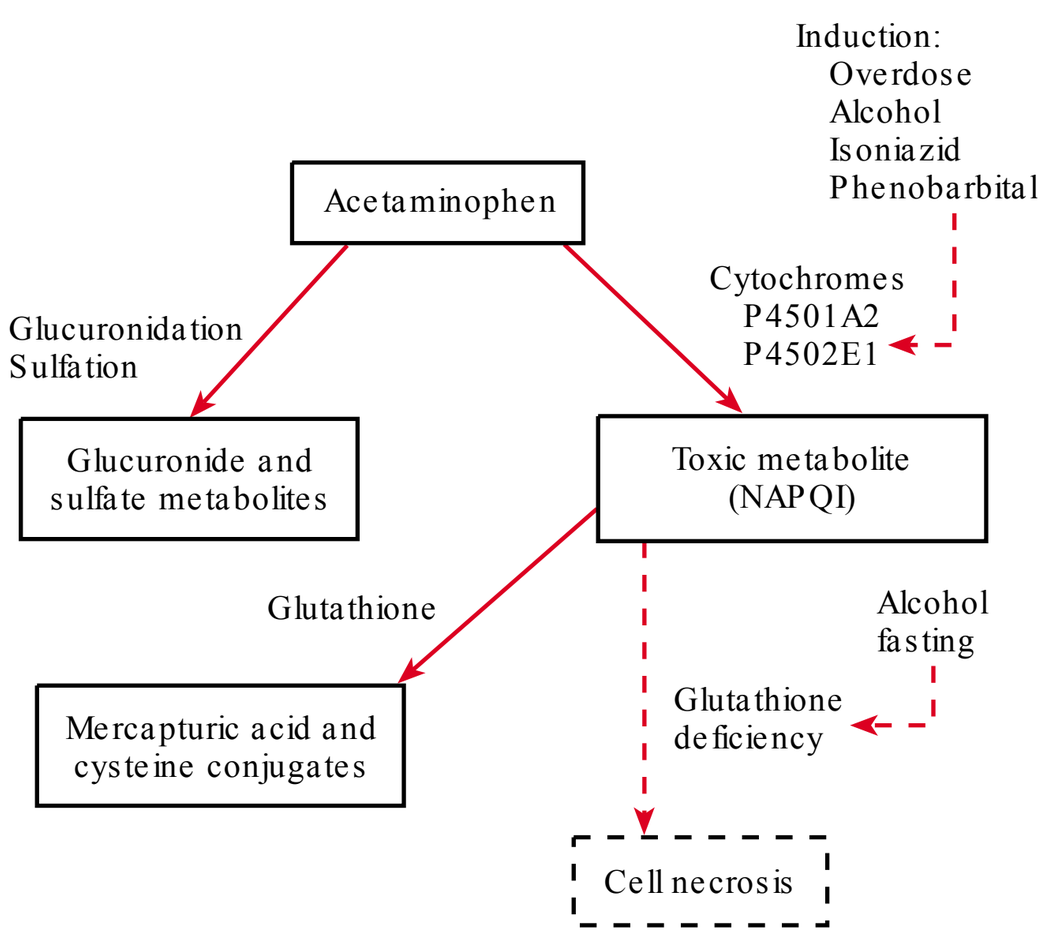

Figure 37-9 Metabolism of acetaminophen by the liver.

Ischemic Hepatitis ("Shock Liver")

Hepatic hypoperfusion (ischemic hepatitis) is one of the most common causes of elevated cytosolic enzymes in hospital patients. It is the cause of the majority of cases of acute liver injury identified clinically. Elevations of bilirubin concentration typically are minimal and usually peak several days after enzyme activities are highest. Laboratory findings are similar to those in toxic hepatitis (including having high LDH), and acute renal failure is a common complicating factor.

Other Causes of Acute Hepatitis

Drug-induced liver injury (DILI) occurs by a number of mechanisms, but the most common is idiosyncratic, immune-mediated injury to hepatocytes, characterized by elevations in the activities of ALT or AST. Cholestatic hepatitis, with increased aminotransferases and ALP, is more common in drug-induced hepatitis than with other causes of acute hepatitis. DILI is becoming more commonly recognized as a cause of acute liver injury. Approximately 60% of cases cause severe acute hepatitis with jaundice, and fatalities occur. Serious reactions are more common in individuals who are continued on the medication. In about one third of cases, liver injury becomes chronic following cessation of the drug.

Some disorders that eventually produce chronic hepatitis may occasionally present in an acute fashion. AIH (see later discussion) has an acute component in up to 40% of cases; it differs from other forms in having (1) decreased albumin, (2) increased globulins, and (3) a more protracted increase in aminotransferases. Wilson disease may also present as an acute hepatitis, often associated with fulminant hepatic failure. The classic biochemical findings of Wilson disease are often absent, and high urine copper is common to all forms of acute hepatitis. A number of additional features that may suggest the diagnosis include (1) hemolytic anemia, (2) acute tubular necrosis, (3) minimally elevated (usually <10×) AST activity, which typically remains higher than ALT activity, and (4) very low ALP activity with a ratio of ALP (in IU/L) to bilirubin (in mg/dL) of <2.

Follow-Up of Acute Hepatitis

The most important tests in determining extent of injury are tests of liver function, especially prolonged PT. In acute viral or alcoholic hepatitis, PT more than 15 seconds is associated with a poor prognosis, whereas persistent elevation more than 4 days after acetaminophen ingestion indicates high risk for liver failure. Other markers of synthetic function, such as transthyretin, or markers of hepatocyte regeneration, such as alpha-fetoprotein, have also been found to predict prognosis. With both hepatitis B and C, serological tests (loss of HBsAg or HCV RNA) are the most reliable way to determine resolution of infection.

Chronic Hepatitis

Chronic hepatitis is characterized by continuing inflammatory damage to hepatocytes (lasting more than 6 months), often accompanied by hepatocyte regeneration and scarring.[5] The common causes of chronic hepatitis and the tests used to make a specific etiological diagnosis are listed in Table 37-3. Most patients are asymptomatic, but nonspecific features, such as (1) fatigue, (2) lack of concentration, and (3) weakness may be present. Despite this relatively mild clinical picture, gradual scarring of the liver may occur, leading to cirrhosis. After 20 years of chronic viral hepatitis, 20% to 30% of individuals have developed cirrhosis, and ultimately this number increases to 50% developing cirrhosis. Most cases of chronic hepatitis are diagnosed because of increased activities of the aminotransferases (typically 1 to 5 times upper reference limits) or detection of positive tests for a cause of chronic hepatitis. Aminotransferases may sometimes be normal either intermittently or for a prolonged period in chronic hepatitis, especially with HCV and **nonalcoholic steatohepatitis (NASH)**. Characteristically, ALT activity is elevated to a greater degree than AST. Reversal of the AST:ALT ratio to >1 suggests coexisting alcohol abuse or development of cirrhosis. Results of most other tests are normal. The most common causes of chronic hepatitis are (1) chronic HBV, (2) chronic HCV, and (3) NASH, but a variety of other disease processes also cause chronic hepatitis.

Significance of Chronic Hepatitis

Fibrosis and necroinflammatory activity are the two major components of chronic hepatitis. The extent of fibrosis (stage) is strongly related to risk of progression to cirrhosis, whereas necroinflammatory activity (grade) is correlated with progression in some, but not all, studies. ALT activity is strongly correlated with necroinflammatory activity, but not with fibrosis. Fibrosis in the liver involves collagen. Proteoglycans, especially hyaluronate, are also part of scar formation.

Various combinations of (1) markers of cell injury (such as, AST, ALT, and GGT), (2) substances deposited in scar tissue (such as procollagen and hyaluronate), (3) inflammatory markers (such as, α_2-macroglobulin and haptoglobin), and (4) tests that are related to liver function (such, as bilirubin and platelet count) have been proposed to predict the degree

TABLE 37-3 Causes of Chronic Hepatitis and Diagnostic Strategies

Cause	Diagnosis
Hepatitis B	History, HBsAg, anti-HBs, anti-HBc, HBV DNA
Hepatitis C	Anti-HCV, HCV RNA by PCR
Autoimmune type 1	ANA, ASMA
Autoimmune type 2	SLA, anti-LKM$_1$
Wilson disease	Ceruloplasmin
Drugs	History
α_1-Antitrypsin deficiency	α_1-AT phenotype
Idiopathic	Liver biopsy, absence of markers

ANA, Antinuclear antibodies; anti-HBs, hepatitis B surface antigen; anti-HBc, hepatitis B core antigen antibody; anti-HCV, hepatitis C virus antibody; anti-LKM$_1$, liver kidney microsomal type 1 antibody; ASMA, anti-smooth muscle antibody; AT, antitrypsin; DNA, deoxyribonucleic acid; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; PCR, polymerase chain reaction; RNA, ribonucleic acid; SLA; smooth muscle antibody.

of fibrosis in the liver. There is, however, significant overlap in concentrations of markers in those with varying stages of fibrosis. Marker concentrations change with necroinflammatory activity and may reflect disease activity at the time of sampling, rather than cumulative fibrosis. Consequently, interest has focused more on identifying individuals with minimal fibrosis, who have little risk of progression to cirrhosis, or those likely to already have severe fibrosis or cirrhosis. The most commonly used predictive indices include the FIB4 (involving age, platelet count, and AST/ALT ratio), APRI (the ratio of AST activity to platelet count), and Fibrotest (a combination α_2-macroglobulin, apolipoprotein A_1, total bilirubin, GGT, and haptoglobin, along with age and sex).

Chronic Hepatitis B

Chronic HBV infection (identified by the persistence of HBsAg) exists in multiple forms, largely determined by the interaction between the virus and host immune response.[11] In persons infected early in life or with severe immune suppression, viral replication and circulating viral loads are high, but liver damage is minimal. This has been referred to as the immune tolerant phase of infection. In others, the immune response to the high amounts of circulating virus causes damage to the liver, but is inadequate to clear the infection. This is termed the immune active or chronic hepatitis phase. In some patients, the immune response is adequate to clear circulating virus and prevent further liver damage, but not to clear the virus completely. In this immune control phase, individuals have no circulating HBV DNA but remain HBsAg positive. As mentioned earlier, those whose immune system "clears" HBsAg often continue to have low levels of circulating and hepatocyte viral DNA, and in this "occult" phase of infection no further liver damage occurs unless the immune system becomes suppressed.

Historically, the measurement of plasma HBeAg has been used as a test to clarify stages of viremia (presence of viruses in the blood). Subsequently, it was recognized that persons who are HBeAg negative may have any of the four phases of HBV infection (while those who are HBeAg positive typically are only in the immune tolerant or immune active phases). In HBeAg positive persons, about 3% to 5% will convert to HBeAg negative status each year; this **seroconversion** is often associated with a worsening of liver injury, sometimes accompanied by jaundice that clinically mimics acute hepatitis. After the conversion, patients are typically in the immune control phase. A small percentage of patients (about 0.5% to 1% per year) will convert from one of the first three phases to the "occult" phase, again often associated with a flare up of liver injury before conversion to occult infection.

A variety of agents are used to treat chronic HBV, and are used in persons with positive HBV DNA, particularly if they also have elevated activities of ALT or significant liver injury on biopsy. The primary goals of treatment is (1) suppression of viral replication, detected first by a decrease in HBV DNA (preferably to undetectable), and (2) improvement in degree of liver injury, detected by normalization of ALT activity. These two goals are achieved in a high percentage of those treated with the most active agents available currently. Treatment is continued indefinitely except in the minority (about 30% in the first year, fewer in subsequent years) of those who were HBeAg positive before treatment and who clear HBeAg and develop anti-HBe. HBsAg rarely becomes undetectable. With the most active agents (entecavir, tenofovir), resistance rarely occurs as long as the patient continues to take the drug regularly.

Chronic Hepatitis C

Chronic HCV is defined by the persistent presence of HCV RNA for more than 6 months, accompanied in most patients by chronically or intermittently elevated ALT activity and chronic liver injury. The genotype of the patient is typically determined before patients are treated, as there are differences in treatment duration and agents, as well as likelihood of response, based on the genotype of the HCV infecting the person. The genotypes and subgenotypes used to categorize patients with chronic Hepatitis C are listed in Box 37-1. Genotype 1 is the most common type of Hepatitis C genotype in the United States and responds the least well to two drug treatment and requires 48 weeks of therapy. Individuals with genotypes 2 and 3 are almost three times more likely than individuals with genotype 1 to respond to therapy with alpha interferon or the combination of alpha interferon and ribavirin. They require only 24 weeks of therapy. Genotpye 4 responds well to two drug treatment given for 48 weeks. Genotype 1, the most commonly encountered form, responds the least well to two drug treatment and requires 48 weeks of therapy.

Treatment of patients with chronic HCV typically uses a combination of pegylated (polyethylene glycol [PEG]) interferon plus ribavirin. In patients infected with genotype 1, addition of a protease inhibitor produces rates of response similar to those in the other genotypes.[6] Currently, protease inhibitors cannot be used by themselves because of the very high likelihood of resistance developing. Combinations of protease inhibitors with other direct acting anti-viral agents has shown promise in early clinical trials, and future treatments may not require the use of interferon (which causes many of the complications of therapy). Treatment of HCV is often successful in permanently eradicating circulating virus.

Table 37-4 summarizes terms used for interpreting response to treatment of HCV with different agents. They include (1) rapid virologic response (RVR), (2) early virological response

BOX 37-1 Genotypes of Chronic Hepatitis C

Genotype 1a
Genotype 1b
Genotype 2a, 2b, 2c, 2d
Genotype 3a, 3b, 3c, 3d, 3e, 3f
Genotype 4a, 4b, 4c, 4d, 4e, 4f, 4g, 4h, 4i, 4j
Genotype 5a
Genotype 6a

(EVR), and (3) sustained virological response (SVR). An important consideration in monitoring treatment with HCV RNA is the detection limit used; because of the frequency of resistance, any residual virus (with detection limits of 10 to 15 IU/mL) indicates the need for longer treatment duration. In those achieving SVR, long-term control of HCV RNA replication occurs in 99% of patients, and histologic and clinical resolution of chronic hepatitis occurs in most. A number of factors influence response to treatment. The most important is genotype, as mentioned earlier. Persons who (1) are obese, (2) have excess iron in their liver, or (3) have significant scarring (especially those with cirrhosis) have lower rates of response to treatment. Response rates are lower in those of African or Hispanic ancestry. Genome-wide association studies have found a marker near the gene for IL-28b (which codes for a form of interferon) that is associated with response to interferon treatment. Those having the favourable CC genotype have approximately two times the response rate to interferon as those having CT or TT genotype, and at least half of the racial difference in response is related to frequency of the favourable genotype in those of different ancestry.[8]

Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis

Nonalcoholic fatty liver disease (NAFLD) and NASH refers to a disease entity associated with fat and inflammation in the liver in persons with minimal to no alcohol intake. It is most commonly observed in association with (1) diabetes, (2) obesity, and/or (3) dyslipidemia (high triglycerides, low high-density lipoprotein [HDL]-cholesterol). There is increasing recognition that fat accumulation in the liver without inflammation is also commonly found in individuals with obesity and diabetes, and those with other components of the metabolic syndrome. The more encompassing term, nonalcoholic fatty liver disease, has been introduced to include this latter form and NASH. The frequency of NAFLD is high in North America and Europe; it has been estimated that NAFLD occurs in 30% of the population and NASH in 2% to 3%.[3] Thus, NASH is as

TABLE 37-4 Tests for Evaluating Chronic Hepatitis C Infection and Its Treatment

Time of Testing	Test	Condition	Use/Interpretation
Pretreatment	HCV viral load	Detectable	To confirm current infection; as a baseline (to compare to 4-week and 12-week value)
	Genotype	2 or 3 vs. other	Length of treatment (24-week genotype 2 or 3, 48-week if other genotype), use of additional protease inhibitor (genotype 1)
4 weeks on treatment	HCV viral load*	a) Undetectable b) <1 log drop c) >1000 IU/mL	a) RVR—with PR or TPR, high likelihood of response to shorter duration treatment b) With BPR, longer treatment c) With TPR, discontinue treatment
8 weeks on treatment (used only for BPR)		a) Undetectable b) >100 IU/mL	a) Possible shorter treatment depending on patient characteristics b) Nonresponder, discontinue therapy
12 weeks on treatment	HCV viral load*	a) Undetectable b) <2 log drop c) >1000 IU/mL d) >100 IU/mL	a) With TPR or BPR, may use shorter treatment depending on patient characteristics (for TPR, termed extended RVR; with PR, termed EVR) b) Stop treatment (nonresponder)† c) With TPR, discontinue treatment d) With BPR, discontinue treatment
		>2 log drop	Continue treatment (on treatment responder)
24 weeks on treatment‡	Sensitive HCV RNA§	a) Detectable b) Not detectable	a) Stop treatment (nonresponder) b) Continue treatment (if genotype 2/3, treatment completed; with TPR or BPR, may discontinue treatment if eRVR depending on patient characteristics)
End of treatment	Sensitive HCV RNA§	a) Detectable b) Not detectable	a) Nonresponder b) Treatment responder
24 weeks after completion	Sensitive HCV RNA¶¶	a) Detectable b) Not detectable	a) Relapser b) SVR

*With PR, detection limit <50 IU/mL; with TPR or BPR, detection limit <10 to 15 IU/mL.
†Less than 3% chance of SVR; some continue treatment to 24 weeks and reevaluate.
‡With genotype 2/3, considered end of treatment.
§With PR, qualitative or quantitative assay with lower detection limit <50 IU/mL; with BPR or TPR, quantitative assay with detection limit <10 to 15 IU/mL.
¶¶Either qualitative or quantitative HCV RNA with detection limit <50 IU/mL.
BPR, Boceprevir/pegylated interferon/ribavirin (times are from start of PR, boceprevir introduced after week 4); EVR, early virologic response; HCV, hepatitis C; PR, pegylated interferon/ribavirin; RNA, ribonucleic acid; RVR, rapid virologic response; SVR, sustained virologic response; TPR, telaprevir/pegylated interferon/ribavirin.

common as chronic HCV. NASH has progressed to cirrhosis in 15% of cases in the small number of published prospective studies, although likelihood of progression seems much lower in those with only NAFLD. Laboratory diagnosis of NASH and NAFLD is not currently possible. The clinical features are similar to those of other causes of chronic hepatitis. To date, the major treatment has been weight loss, which is often associated with decreased ALT values.

Autoimmune Hepatitis

Autoimmune hepatitis (AIH) represents a rapidly progressing form of chronic hepatitis (up to 40% 6-month mortality in untreated individuals) associated with the presence of autoimmune markers and substantial hypergammaglobulinemia.[12] It most commonly occurs in young to middle-aged women. The most important antibodies for diagnosis include (1) antinuclear antibody (ANA), (2) antismooth muscle antibody (ASMA, now often tested for as anti-actin), and (3) anti-liver-kidney microsomal antigen type 1 (LKM_1). A summary of (1) the most common autoantibodies, (2) their associations, and (3) their molecular targets (when known) is given in Table 37-5. Immunosuppressive treatment using prednisone, alone or in combination with azathioprine, is effective in inducing a clinical remission of disease in about 80% of cases.

Drug-Induced Liver Diseases

As discussed earlier, most cases of drug-induced liver disease present as acute hepatitis. Less commonly, drugs have produced a chronic liver injury, in a pattern mimicking chronic hepatitis or other chronic liver injury (chronic cholestasis and hepatic granulomas). The most common drugs linked to chronic hepatitis are (1) nitrofurantoin, (2) methyldopa, and (3) HMG-CoA reductase inhibitors. Herbal medications also have been linked to chronic hepatitis. Establishing drugs as the cause of chronic hepatitis is often difficult as temporal relationships to drug ingestion are not as definitive as with acute hepatitis. Reactions are first seen in those who have been taking the medication for many months. Most chronic drug reactions resolve when the drug is discontinued.

Inherited Liver Diseases Presenting as Chronic Hepatitis

Inherited liver diseases that present as chronic hepatitis include (1) hemochromatosis (discussed in Chapter 28), (2) $alpha_1$-antitrypsin (AAT) deficiency (discussed in Chapter 18), and (3) Wilson disease (discussed in Chapters 18 and 32).

Alcoholic Liver Disease

Alcoholic liver disease[13] differs clinically and biochemically from other forms of hepatitis and liver disease. It is a common cause of liver disease in the developed world. The incidence of acute alcoholic hepatitis, however, seems to be declining in North America and Europe. Risk factors for developing alcoholic liver disease include (1) duration and magnitude of alcohol abuse (rare if intake <40 g/day in men and 10 g/day in women), (2) sex (women may be more likely to develop cirrhosis), (3) presence of co-infection with HBV or HCV (both of which increase risk of cirrhosis), and (4) nutritional state (poor nutrition increases risk of cirrhosis). In addition, there is evidence for an immunological component in alcoholic liver disease, and there is evidence that modification of liver proteins by ethanol metabolites is involved in the pathogenesis. Compared with other causes of chronic hepatitis, alcoholic hepatitis is less likely to have increased activities of AST or ALT, and more likely to have activities of AST higher than those of ALT. The prognosis of chronic alcoholic liver disease

TABLE 37-5 Serological Markers of Autoimmune Liver Disease

Antibody Name	Antigen Target	Associations
Antiactin	Actin	AIH type 1; more specific than ASMA, poor response to corticosteroids, early age onset
Antiasialoglycoprotein receptor (ASGPR)	Transmembrane antigen binding protein	AIH, correlate with activity, disappear with successful treatment
Anti-LKM_1	Cytochrome P450 IID6	AIH type 2; seen in only 4% of US cases; usually in children
Antiliver specific cytosol (LC_1)	Enzyme (possibly formimino-transferase cyclodeaminase or argininosuccinate lyase)	AIH in younger patients, often with anti-LKM_1, PSC; vary with activity of disease
Antimitochondrial antibody (AMA M2 type)	Dihydrolipoamide acyltransferase	PBC
Antineutrophil cytoplasmic antibodies (ANCA)	Bactericidal/permeability protein, cathepsin G, lactoferrin	PSC (50%-70%), ulcerative colitis (50%-70%), AIH; nonspecific
Antinuclear antibody (ANA)	Multiple targets (centromere, ribonucleoproteins); may not be detected by ELISA	AIH type 1, some PSC cases
ASMA	Actin, tubulin, vimentin, desmin, Skelitin	AIH type 1, seen in other autoimmune diseases in lower titers
Antisoluble liver antigen/liver pancreas (SLA)	Selenocysteine pathway protein serine hydroxymethyltransferase)	AIH type 3; very specific for AIH, correlate with relapse after corticosteroid withdrawal

AIH, Autoimmune hepatitis; anti-LKM_1, anti-liver kidney microsome; ASMA, antismooth muscle antibody; ELISA, enzyme-linked immunosorbent assay; PBC, primary biliary cirrhosis; PSC, primary sclerosing cholangitis.

is thought to be similar to that of other causes of chronic hepatitis. T e primary treatment is abstinence from alcohol.

Cirrhosis

Cirrhosis, defined anatomically as diffuse fibrosis with nodular regeneration, represents the end stage of scar formation and regeneration in chronic liver injury. T e common causes of chronic hepatitis that lead to cirrhosis and their therapies (which may prevent or, in some cases, reverse cirrhosis) are listed in Table 37-3. Virtually all chronic liver diseases are known to lead to cirrhosis, but most cases of cirrhosis occur as a result of chronic hepatitis.

In the early stages of transition from chronic hepatitis to cirrhosis, termed compensated cirrhosis, there may be no signs or symptoms of liver damage. Laboratory abnormalities usually appear before clinical findings begin to develop. T e latter include (1) ascites, (2) gynecomastia, (3) palmar erythema, and (4) portal hypertension. T e earliest laboratory abnormalities are (1) fall in platelet count, (2) increase in PT, (3) decrease in the albumin to globulin concentration ratio to <1, and (4) increase in the AST/ALT activity ratio to >1. Survival in those with compensated cirrhosis is good; in one large study, 10-year survival rate was 90%. As cirrhosis progresses, decompensation (loss of functionality) occurs with clinical evidence of portal hypertension. Once decompensation occurs, 10-year survival is only about 20%. Currently, prognosis in cirrhosis is usually based on the Model for End-Stage Liver Disease (MELD) score,[7] which is calculated as:

MELD score =
3.8 + ln bilirubin (mg/dL)
+ 11.2 Ln INR
+ 9.6 Ln creatinine (mg/dL)
+ 6.4 × etiology score (O if alcohol or obstruction 1, for all other causes)

Risk of death over 3 months is low in those with MELD scores below 10, intermediate in those with scores of 10 to 20, and high in those with scores above 20.7 MELD scores are the primary means used to assign priority for liver transplantation.

Laboratory findings in cirrhosis reflect ongoing liver injury and decreased hepatic function. Activities of aminotransferases are variable in cirrhosis, and reflect underlying necroinflammatory activity. If the cause of cirrhosis has been eliminated (as by abstinence from ethanol or successful treatment of viral hepatitis), aminotransferase activity is often within the reference interval. Persistence of elevation is a risk factor for development of HCC. Increases in alpha fetoprotein (AFP) are common in cirrhotic patients, even in the absence of HCC.

Cholestatic Liver Diseases

Cholestasis (stoppage or suppression of the flow of bile) is associated with retention of bile within the excretory system. T e term obstruction is often used inappropriately, since cholestasis also occurs without mechanical obstruction to the biliary tract. Although intrahepatic cholestasis may be due to either functional or mechanical problems, extrahepatic cholestasis is always due to physical obstruction of the bile ducts by processes, such as (1) gallstones in the bile ducts (choledocholithiasis), (2) narrowing (strictures), and (3) tumors, both primary in the bile ducts (cholangiocarcinoma) or head of the pancreas, or involving the lymph nodes adjacent to the bile ducts. T e major cholestatic diseases are (1) physical obstruction of the bile ducts, (2) primary biliary cirrhosis PBC[10], and (3) **primary sclerosing cholangitis (PSC)**.[4] Cholestatic hepatitis, which has been discussed previously, may also cause cholestasis, but generally presents in a manner closer to hepatitis.

Prolonged cholestasis may lead to bile acid deficiency, causing malabsorption of fat and the fat-soluble vitamins A, D, E, and K (see Chapter 27). Accumulation of normal bile contents leads to jaundice and development of an abnormal lipoprotein-X, containing (1) phospholipids, (2) cholesterol, (3) fragments of cell membrane (along with ALP), and (4) albumin. Lipoprotein-X will be included in low-density lipoprotein (LDL) cholesterol in the Friedewald formula (see Chapter 23) and in most direct LDL cholesterol methods.

Laboratory indicators of cholestasis include an increase in plasma activities of canalicular enzymes, such as ALP and GGT. In general, there is a short lag period between the onset of cholestasis and the increase in plasma activities. In the early stages of mechanical obstruction (especially from gallstones), there may be transient increases in plasma activities of liver cytosolic enzymes, such as AST and ALT, which may exceed 400 IU/L, and, in 1% to 2% of cases, may be over 2000 IU/L. Even with continued obstruction, AST and ALT activity gradually decrease, and AST is typically within the reference interval within 8 to 10 days. Increases in total bilirubin, with predominance of conjugated bilirubin, reflect extent of obstruction, and are seen with both extrahepatic or intrahepatic cholestasis. Prolonged PT is the most commonly detected coagulation abnormality. It usually is corrected by administration of parenteral vitamin K. Transient increases in the quantity of Cancer Antigen 19-9 (CA 19-9) occur with bile duct obstruction. T is is an important consideration, as CA 19-9 is often used as a diagnostic test for pancreatic and bile duct carcinomas. A key feature of extrahepatic obstruction is dilation of more proximal and intrahepatic bile ducts, which are visualized by imaging studies.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC), or nonsuppurative destructive cholangitis, is an uncommon autoimmune disorder targeting intrahepatic bile ducts primarily in middle-aged women (6:1 female to male ratio, median age at onset 50 years). T ere is an association with human leukocyte antigen (HLA) class II antigen DR8, and up to 80% of cases are associated with other autoimmune processes, most commonly **Sjögren syndrome** and hypothyroidism (which often develop before onset of PBC). At least 95% of patients have antimitochondrial antibodies that react against the dihydrolipoamide acyltransferase component of the pyruvate decarboxylase complex. Part of this complex is found on the apical surface of biliary epithelial cells, suggesting a role for this antigen as an immune target.

PBC typically presents as an asymptomatic elevation of ALP, but may occur with cholestasis or fatigue. Aminotransferase activities are increased in 50% of cases, but are more than twice the upper reference limit in only 20% of cases. An increased concentration of bilirubin is a late finding and is important in predicting decompensation. PBC progresses slowly in most patients and ultimately leads to portal hypertension, and increases risk of development of HCC.

Primary Sclerosing Cholangitis

PSC is a chronic inflammatory disease of the biliary tree, most commonly affecting extrahepatic bile ducts. Involvement of intrahepatic ducts, either with extrahepatic involvement or as an isolated finding, is also possible. In contrast to PBC, PSC has a male predominance and a younger median age at onset of 30 years. In 80% of patients, PSC is associated with ulcerative colitis, which usually (but not always) precedes onset of PSC. An autoimmune component is likely, as 97% of patients with PSC have one or more plasma autoantibodies present in their plasma. Antineutrophil cytoplasmic antibodies (ANCA), usually with an atypical perinuclear pattern, are present in approximately 50% to 80% of patients, but are not specific for PSC; they are also present in PBC and autoimmune hepatitis. Antigens include (1) lactoferrin, (2) bactericidal/permeability increasing protein, and (3) cathepsin G.

The clinical presentation of PSC, like that of PBC, is typically an asymptomatic patient with elevated activities of ALP found during routine laboratory screening. Symptoms are ultimately present in most patients with PSC; the most common are (1) pruritus, (2) intermittent abdominal pain, but (3) fever may also occur. The major cause of death in individuals with PSC is cholangiocarcinoma, which ultimately develops in up to one third of patients.

Drug-Induced Cholestasis

Drugs are a common cause of cholestasis, causing about 15% of cases. Drug reactions are especially common in older individuals, where up to 50% of individuals have increased enzyme activities because of medications. Drugs cause a cholestatic picture by two major mechanisms. In some cases, only conjugated bilirubin is increased, whereas the activities of canalicular enzymes are not elevated.[11] This condition is often seen with estrogen and anabolic steroids. More commonly, drugs induce a cholestatic hepatitis.

Gallstones

Gallstones are solid formations in the gallbladder that are composed of cholesterol and bile salts. Although they vary in chemical composition, they generally contain a mixture of (1) cholesterol, (2) bilirubin, (3) calcium, and (4) mucoproteins. In the United States, 70% to 85% of all gallstones are predominantly cholesterol and more than 10% of the adult population is affected.

Hepatic Tumors

The liver is host to a wide variety of both benign and malignant primary tumors. It is also the second most common site of metastases, which account for 90% to 95% of all hepatic malignancies. While primary tumors may arise from many cell lines in the liver, the most important primary liver tumor is HCC.

HCC is the fifth most common cancer worldwide and a leading cause of cancer death. Historically, approximately 75% of HCC cases occurred in Asia, but the falling prevalence of cases due to HBV in Asia and the increase in cases in Europe and North America due to HCV and NASH cirrhosis are changing this percentage. The incidence is twofold to threefold higher among men than it is among women. Although cirrhosis is present in most patients with HCC, it is absent in about 25% to 30% of cases, often in association with HBV. The major risk factor for development of HCC is infection with HBV or HCV, but any cause of chronic hepatitis and cirrhosis appears equally likely to cause HCC.

Clinical features of HCC usually do not occur until late in the course of disease, when the tumor is large and resection is impossible. Nonspecific signs and symptoms, such as (1) fever, (2) malaise, (3) anorexia, and (4) anemia are common, and (5) jaundice may occur with central tumors that obstruct biliary drainage. In a small number of cases, paraneoplastic features, such as (1) hypoglycemia, (2) hypercalcemia (due to parathyroid hormone–related peptide [PTHrP] production), or (3) erythrocytosis (due to erythropoietin production), may be the initial presenting findings. Laboratory findings include those of cirrhosis and cholestasis, and (except for tumor markers discussed later) are nonspecific.

Because treatment is usually not possible with advanced HCC, there has been much interest in screening high-risk individuals.[2] Smaller tumors detected by screening may be treatable by (1) resection of part of the liver, (2) local/regional treatment (most frequently radiofrequency ablation [RFA] and/or transarterial chemoembolization [TACE]), or (3) liver transplantation in some cases. The most common screening programs use plasma tumor markers and/or imaging studies. The most widely used tumor marker is AFP; recently, the more specific L3 isoform has also been used. Des-gammacarboxy prothrombin (DCP, also called PIVKA-II) appears a more sensitive and specific marker of HCC than AFP but is not widely used. Elevation of AFP (and less frequently DCP) is also common in individuals with cirrhosis, the group at highest risk for HCC. In the author's experience, AFP above the upper reference limit has a positive predictive value of only 16% for HCC. Use of higher cutoff values than the upper reference limit improves clinical specificity of total AFP at the expense of clinical sensitivity.

Diagnostic Strategy

Liver function and integrity tests are useful in (1) detecting, (2) diagnosing, (3) evaluating severity, (4) monitoring therapy, and (5) assessing the prognosis of liver disease and dysfunction (Table 37-6).

By using a combination of the tests listed in Table 37-6, it is possible to categorize broad types of liver disease, which then are more accurately diagnosed through disease-specific tests. An algorithm for that process is presented in Figure 37-10.

TABLE 37-6 Tests of Hepatic Function

Test	Utility
Bilirubin	Diagnosing jaundice, modest correlation with severity
ALP	Diagnosing cholestasis and space-occupying lesions
Bilirubin fractionation	Diagnosing disorders of metabolism and disorders of the newborn
AST	Sensitive test of hepatocellular disease; AST > ALT in alcoholic disease, cirrhosis
ALT	Sensitive and more specific test of hepatocellular disease
Albumin	Indicator of chronicity and severity
PT	Indicator of severity, early indicator of cirrhosis in chronic hepatitis

ALP, Alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; PT, prothrombin time.

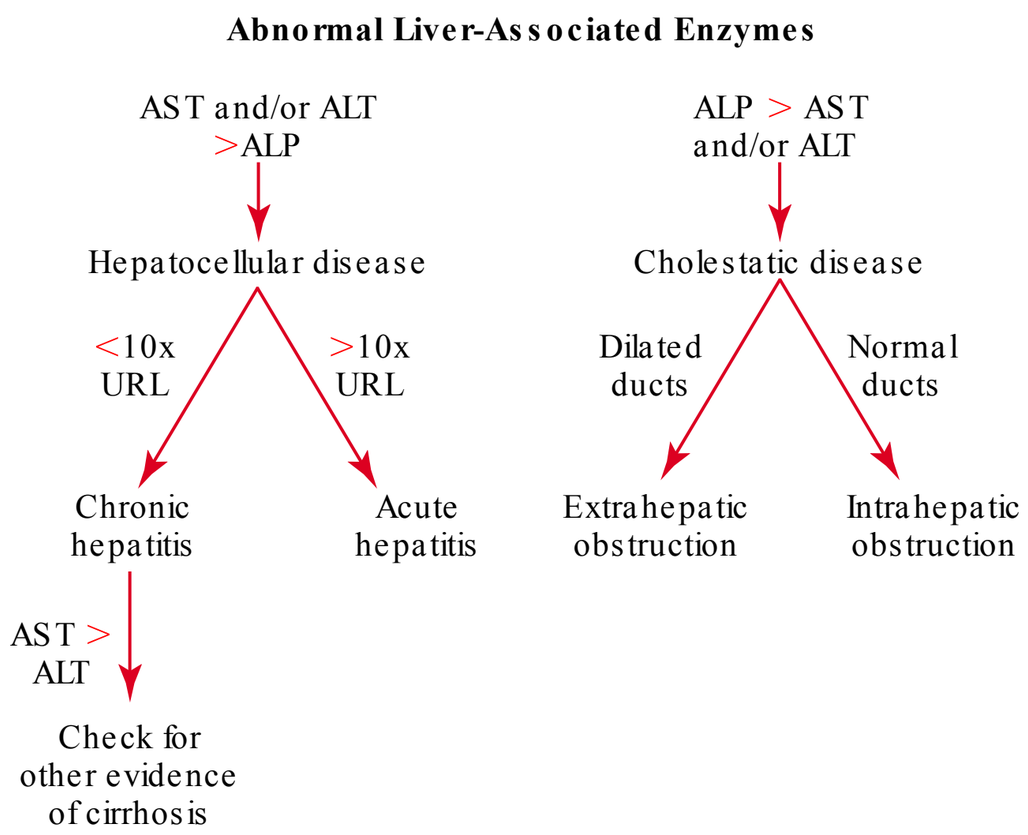

Figure 37-10 Algorithm for using abnormal liver function tests to classify and diagnose various types of liver disease. ALP, Alkaline phosphatase; AST, aspartate aminotransferase; URL, upper reference limit.

Plasma Enzymes

In practice, serum activities of AST, ALT, and ALP are the most useful tests because they allow differentiation of hepatocellular disease from cholestatic disease. Timely differentiation is important because failure to recognize cholestatic disease caused by extrahepatic biliary obstruction will result in liver failure if the obstruction is not quickly corrected. It also is important to recognize that there may be a gray zone of mixed hepatocellular and cholestatic disease where the tests do not distinguish one disease from the other. In this case, it is wise to assume that the problem is cholestatic and to rule out biliary obstruction.

Patients are occasionally seen with isolated elevations in ALP or aminotransferase enzyme activities. In practice, an isolated increase in ALP activity is difficult to interpret. In children, benign transient hyperphosphatasemia should always be considered, and it is important to use age-appropriate reference intervals because bone growth causes ALP values to be as much as several times the upper reference limit for adults. In adults, it is necessary to first confirm that the ALP is of hepatobiliary origin. This has been done by isoenzyme fractionation or by measuring another canalicular enzyme (such as, GGT), which should be normal if ALP increases are not of liver origin. The most important aspect of the work-up is to rule out space-occupying lesions by visualizing the liver and biliary tract with various imaging techniques.

Elevated plasma activities of AST and ALT are common in many disorders. The liver is the likely source of elevation if ALT activity is greater than that of AST. If AST activity is greater than that of ALT, other evidence to suggest liver as the origin would include abnormalities in liver function (albumin, PT, bilirubin) and increased ALP activity. If the values for all of these related tests are within their reference intervals in an individual with an AST activity greater than that of ALT, it is reasonable to measure creatine kinase (CK) activity to assure that muscle injury is not the cause. If liver is determined to be the source, administration of all potentially hepatotoxic drugs and alcohol intake (especially if AST is higher than ALT) should be discontinued. If the elevation persists, ultrasound (looking for nonalcoholic fatty liver) and hepatitis B and C serology should be performed. More than 90% of isolated enzyme elevations of liver origin will be caused by these disorders. A liver biopsy is often needed to make a more specific diagnosis, as well as to determine extent of damage. There is no reliable test other than a liver biopsy to detect fibrosis, although there is promise that laboratory tests may at least help to exclude serious fibrosis.

Serum Albumin

Serum albumin measurements are useful in assessing the chronicity and severity of liver disease. For example, the serum albumin concentration is decreased in chronic liver disease. However, its utility for this purpose is somewhat limited, as the serum albumin concentration is also decreased in (1) severe acute liver disease, as well as in (2) inflammatory disorders and (3) malnutrition, and with (4) nephrotic syndrome. Serial measurements of serum albumin also are used to assess the severity of liver disease.

Prothrombin Time

Serial PT measurements are used to determine synthetic liver function. They are thought to be more reliable than the measurement of the concentration of albumin because fewer conditions (other than warfarin administration) affect PT than affect albumin. PT is the most important prognostic marker in acute liver disease and is usually the first function test to become abnormal as chronic hepatitis evolves into cirrhosis. PT is also one of the parameters used in calculating the MELD score, which is used to predict need for transplantation in cirrhosis.

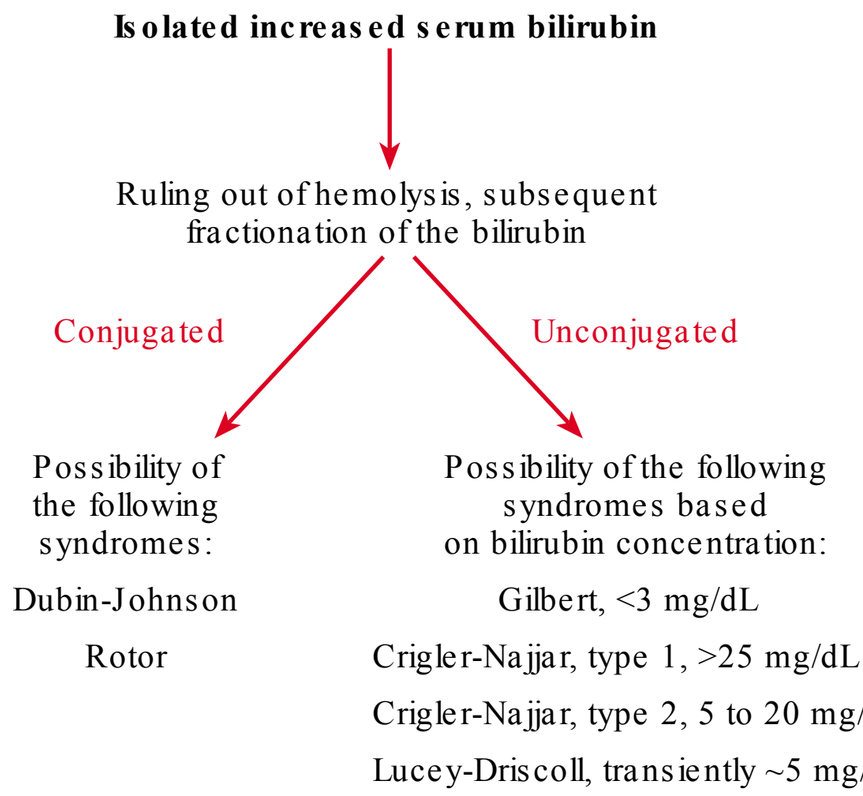

Figure 37-11 Algorithm for differentiating the familial causes of hyperbilirubinemia.

Plasma Bilirubin

Serial measurement of bilirubin is helpful in measuring the severity of acute and chronic liver disease.

Patients are occasionally seen with isolated elevations in their bilirubin concentration. In most cases, this is due to inherited disorders of bilirubin metabolism, or hemolysis. It is not difficult to distinguish hemolysis severe enough to cause hyperbilirubinemia, because the patient with hemolysis will have anemia and may have other disease manifestations. An algorithm for differentiating the familial causes of hyperbilirubinemia is presented in Figure 37-11.

Review Questions

1. In the liver, bilirubin is conjugated to:
   a. vinyl groups.
   b. methyl groups.
   c. hydroxyl groups.
   d. glucuronide.
2. Functions of the liver include the synthesis of all of the following except:
   a. albumin.
   b. immunoglobulins.
   c. glycogen.
   d. coagulation factors.
3. In the liver, the small grooves between adjacent hepatocytes that carry bile to the gall bladder are the:
   a. cords.
   b. canaliculi.
   c. lobules.
   d. sinusoids.
4. Hepatocellular carcinoma (HCC) can be directly related to:
   a. an acute viral hepatitis infection.
   b. cholestasis.
   c. a chronic hepatitis B infection.
   d. the synthetic function of the liver.
5. Which type of viral hepatitis is usually spread parenterally by transfusion, shared needles, or dialysis and is considered the most common chronic viral infection in North America?
   a. Hepatitis B
   b. Hepatitis C
   c. Hepatitis A
   d. Cirrhosis
6. Laboratory tests that are initially run to determine the presence of any liver disease include:
   a. liver enzymes only.
   b. viral antigens and antibodies, serum cholesterol.
   c. hepatitis antigens and antibodies, coagulation times, and serum proteins.
   d. bilirubin, liver enzymes, prothrombin time (PT), and albumin.
7. Blockage of the bile ducts or blockage of bile flow from within the liver due to inflammation will stop normal bile flow. This is referred to as:
   a. hepatitis.
   b. hepatocellular carcinoma (HCC).
   c. cholestasis.
   d. cirrhosis.
8. A genetic disorder that is associated with elevated amounts of copper in the liver and other tissues and leads to decreased ceruloplasmin concentration in blood is:
   a. Wilson disease.
   b. Reye syndrome.
   c. cholestasis.
   d. autoimmune hepatitis.
9. A woman visits her physician with symptoms of jaundice, hepatic pain, and chalky-appearing stools. Lab values indicate elevated conjugated bilirubin, alkaline phosphatase (ALP) and γ–glutamyltransferase (GGT). These findings are most likely due to:
   a. hemolytic anemia.
   b. ineffective erythropoiesis.
   c. cholestasis due to gallstones.
   d. Reye syndrome.
10. The type of portal hypertension seen in the majority of cases is sinusoidal hypertension, which is most commonly caused by:
    a. blockage of the portal veins.
    b. hepatic vein occlusion.
    c. congestive heart failure.
    d. cirrhosis.

CHAPTER

38 Gastrointestinal and Pancreatic Diseases

Peter G. Hill, Ph.D., F.R.C.Path.

Objectives

1. Define the following:
   Diarrhea
   Digestive process
   Disaccharidase
   Gastritis
   Inflammatory bowel disease (IBD)
   Lactose intolerance
   Malabsorption
   Maldigestion
   Pancreatitis
   Protein-losing enteropathy
   Steatorrhea
   Zollinger-Ellison syndrome
2. List the components of the gastrointestinal (GI) tract and state the function of each component.
3. Outline the three phases of the digestive process including the specific events and peptide hormones involved during each phase.
4. List five hormones/regulatory peptides synthesized by the intestinal tract.
5. State the function of cholecystokinin (CCK), gastrin, secretin, vasoactive intestinal polypeptide, and glucose-dependent insulinotropic peptide (GIP).
6. List and describe three diseases of the stomach; list possible causes of each disease.
7. State the involvement of Helicobacter pylori in peptic ulcer disease and gastric cancer.
8. List four invasive tests and four noninvasive tests used to diagnose the presence of H. pylori.
9. Describe urea breath testing and its use in analysis of peptic ulcer disease.
10. State the cause of Zollinger-Ellison syndrome; list and describe two laboratory tests used to diagnose this syndrome, including special specimen requirements and handling.
11. Describe celiac disease, including possible causes; define a laboratory test used to diagnose this disease.
12. Compare congenital and acquired lactase deficiency.
13. Describe the oral lactose tolerance test.
14. Outline the protocol for noninvasive breath-hydrogen testing for lactase deficiency; state how results are interpreted.
15. State how bacterial overgrowth in the intestine leads to fat malabsorption.
16. Describe inflammatory bowel disease (IBD); compare IBD to irritable bowel syndrome (IBS).
17. List two hormones, three enzymes, and one regulatory peptide synthesized in the pancreas.
18. State the functions of amylase, lipase, insulin, and somatostatin.
19. Define pancreatic insufficiency.
20. List the most common autosomal recessive disease involving the pancreas, and state one diagnostic test for this disorder in children over the age of 2 weeks.
21. List three adult disorders of the exocrine pancreas; list causes of acute and chronic pancreatitis.
22. List three invasive and two noninvasive tests of pancreatic exocrine function; discuss the issues involved with the two types of testing.
23. Describe a GI neuroendocrine tumor, and list five of them.
24. State the use of the fecal osmolal gap in testing for diarrhea; calculate the formula used to determine fecal osmotic gap (FOG).

Key Words and Definitions

Acute pancreatitis An acute episode of enzymatic destruction of the pancreatic substance due to the escape of active pancreatic enzymes into the pancreatic tissue.

Breath tests Tests that detect products of bacterial metabolism in the gut or products of human metabolism by measuring, most commonly, CO_2 and H_2 in the breath.

Celiac disease A disease caused by the destructive interaction of gluten with the intestinal mucosa causing malabsorption. In most cases, the mucosal damage is reversed by withdrawing all gluten-containing foods from the diet. Also called gluten-sensitive enteropathy.

Cholecystokinin (CCK) A 33–amino-acid peptide secreted by the upper intestinal mucosa and also found in the central nervous system. It causes gallbladder contraction and release of pancreatic exocrine (or digestive) enzymes, and affects other gastrointestinal (GI) functions.

Chronic pancreatitis An inflammatory disease characterized by persistent and progressive destruction of the pancreas.

Key Words and Definitions—cont'd

Chyme Food that has been acted upon by the churning action of the stomach and by stomach juices and expelled by the stomach into the duodenum.

Crohn disease A chronic inflammatory disease that may affect any part of the intestine from the mouth to the anus.

Cystic fibrosis (CF) An inherited disease caused by genetic alteration of a cystic fibrosis transmembrane conductance regulator (CFTR) protein that leads to chronic pancreatic and obstructive pulmonary disease.

Diarrhea The passage of loose or liquid stools more than three times daily and/or a stool weight greater than 200 g/day.

Digestion The conversion of food, in the stomach and intestines, into soluble and diffusible products, capable of being absorbed.

Digestive process A three-phase process—neurogenic, gastric, and intestinal. The neurogenic (vagal) phase is initiated by the sight, smell, and taste of food. The gastric phase is initiated by the distention of the stomach by the entry of food. The intestinal phase begins when the partly digested food enters the duodenum from the stomach.

Dumping syndrome Following gastric surgery, hyperosmolar chyme is "dumped" into the small intestine causing rapid hypovolemia and hemoconcentration.

Gastrin A group of peptide hormones secreted by gastrointestinal (GI) mucosa cells in response to mechanical stress or high pH, both of which are produced by the presence of food in the stomach. Gastrin stimulates the stomach parietal cells to produce hydrochloric acid (HCl).

Gastrinoma A tumor of the pancreatic islet cells that results in an overproduction of gastric acid, leading to fulminant ulceration of the esophagus, stomach, duodenum, and jejunum. Gastrinomas may also occur in the stomach, duodenum, spleen, and regional lymph nodes.

Gastritis Mucosal inflammation of the stomach.

Glucose-dependent insulinotropic peptide (GIP, gastric inhibitory polypeptide) A peptide hormone (42 amino acids) that stimulates insulin release and at supraphysiological concentrations inhibits the release of gastric acid and pepsin.

Helicobacter pylori A bacterium found in the mucous layer of the stomach. All strains secrete (1) proteins that cause inflammation of the mucosa and (2) the enzyme urease that produces ammonia from urea; some strains produce toxins that injure the gastric cells.

Lactose intolerance A condition due to lactase deficiency leading to malabsorption of lactose and causing symptoms of flatulence, abdominal discomfort, bloating, or diarrhea after ingesting milk or foods containing lactose.

Malabsorption An abnormality in the absorption of nutrients.

Maldigestion An abnormality of the digestive process due to dysfunction of the pancreas or small intestine.

Peptic ulcer disease The collective name given to duodenal and gastric ulceration.

Postgastrectomy syndrome A syndrome following surgery for peptic ulcer disease that includes the dumping syndrome, diarrhea, maldigestion, weight loss, anemia, bone disease, and gastric cancer.

Secretin A peptide hormone of the gastrointestinal (GI) tract (27 amino acids) found in the mucosal cells of the duodenum. Among its multiple functions, secretin increases water and bicarbonate secretion to buffer the incoming protons of the acidic chyme. It has considerable homology with GIP, vasoactive intestinal polypeptide (VIP), and glucagon.

Sprue A chronic form of malabsorption syndrome occurring in tropical and nontropical forms.

Steatorrhea A condition of excessive fat in feces (more than 5 g/day).

Ulcerative colitis Recurrent inflammatory disease of the large bowel that involves the rectum and spreads to involve a variable amount of colon. Ulcerative colitis, like Crohn disease, is a form of inflammatory bowel disease (IBD).

Vasoactive intestinal polypeptide (VIP) A peptide of 28 amino acids found in the central and peripheral nervous systems where it acts as a neurotransmitter. It is located in the enteric nerves in the gut. It relaxes smooth muscle in the gut and increases water and electrolyte secretion from the gut.

Zollinger-Ellison (Z-E) syndrome A condition resulting from a gastrin-producing tumor (gastrinoma) that results in an overproduction of gastric acid, leading to ulceration of the esophagus, stomach, duodenum, and jejunum, and causing hypergastrinemia, diarrhea, and steatorrhea.

Efficient **digestion** of food and absorption of nutrients are the result of coordinated functions that occur in the gastrointestinal (GI) tract. Coordination and regulation of these functions depend on hormones that stimulate or inhibit secretion of fluids containing hydrochloric acid (HCl), bile acids, bicarbonate, and digestive enzymes.

Anatomy

The GI tract is an 8-meter-long tube beginning with the mouth and ending with the anus. The esophagus, which is about 25 cm in length, is a muscular tube connecting the pharynx to the stomach. The major organs of the GI tract include the (1) stomach, (2) small and large intestines, (3) pancreas, and (4) gallbladder, all of which are involved in the digestive processes that commence with the ingestion of food and water and culminate in the excretion of feces.

Stomach

The stomach consists of three major zones: the cardiac zone, the body, and the pyloric zone (Figure 38-1). The upper cardiac zone, which includes the fundus, contains mucus-secreting

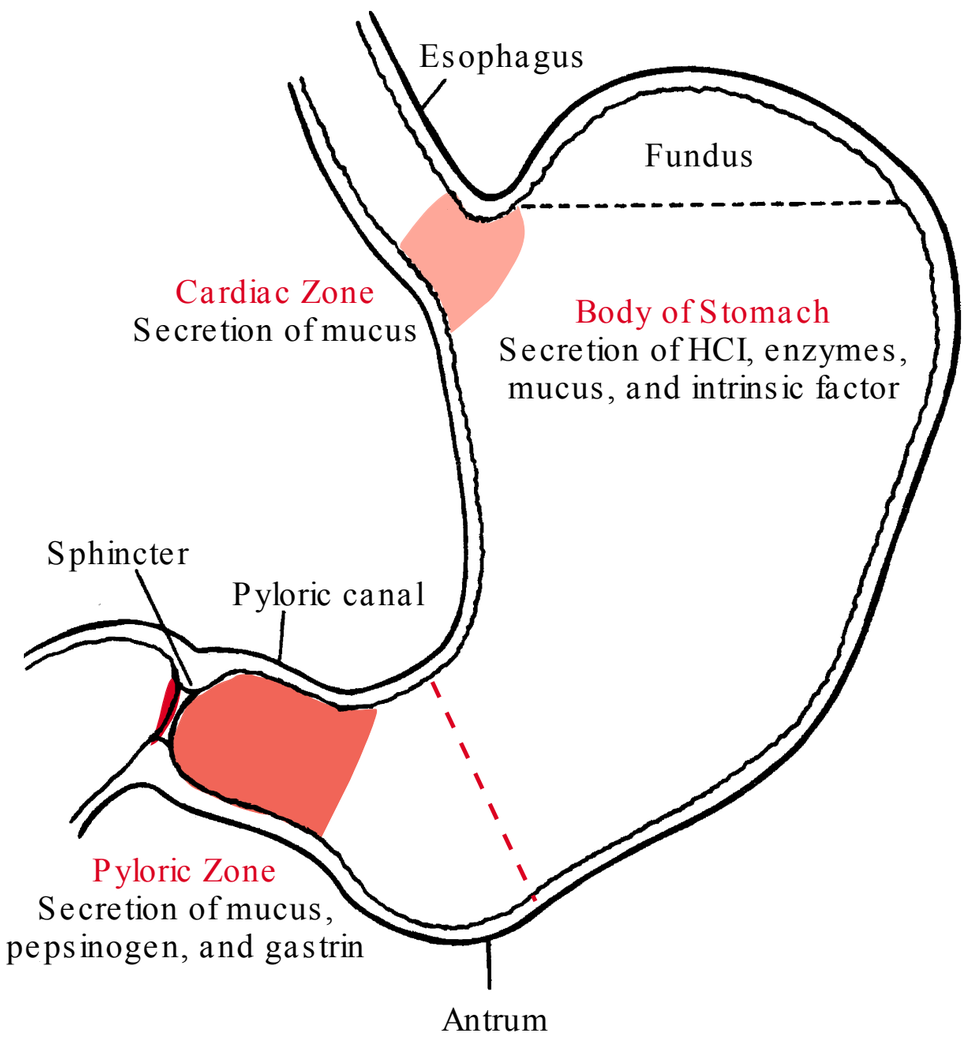

Figure 38-1 Schematic drawing of the stomach with major zones.

surface epithelial cells and several types of endocrine secreting cells. The body of the stomach contains cells of many different types, including mucus-secreting cells and parietal (oxyntic) cells, which secrete HCl and intrinsic factor. Cells in all three zones of the stomach produce pepsinogens, the precursors of the enzyme pepsin that degrades proteins in the food. The pyloric zone is subdivided into the antrum (the distal third of the stomach), the pyloric canal, and the sphincter. The cells of the pyloric zone secrete mucus, pepsinogens, serotonin, **gastrin**, and several other hormones but no HCl.

Small Intestine

Food is converted in the stomach into a homogeneous, gruel-like material (**chyme**) that passes through the pyloric sphincter into the small intestine, which consists of three parts: the duodenum, jejunum, and ileum. In the adult human, the small intestine is approximately 6 m long and decreases in cross-section as it proceeds distally. The duodenum (about 25 cm long) is the shortest and widest part of the small intestine. The jejunum and ileum make up the remainder of the small intestine.

The internal surface of the upper small intestine contains valvelike circular folds projecting 3 to 10 mm into the lumen of the intestine. Very small (1 mm) fingerlike projections (villi) cover the entire internal surface of the small intestine, giving it a "velvety" appearance. The absorptive surface area of the small intestine is about 250 m^2, comparable to the area of a doubles tennis court.

Large Intestine

The large intestine is approximately 1.5 m long and includes the cecum, appendix, colon, rectum, and anal canal.

Pancreas

The pancreas is 12 to 15 cm in length and lies across the posterior wall of the abdominal cavity. The head is located in the duodenal curve; the body and tail are directed toward the lef (Figure 38-2).

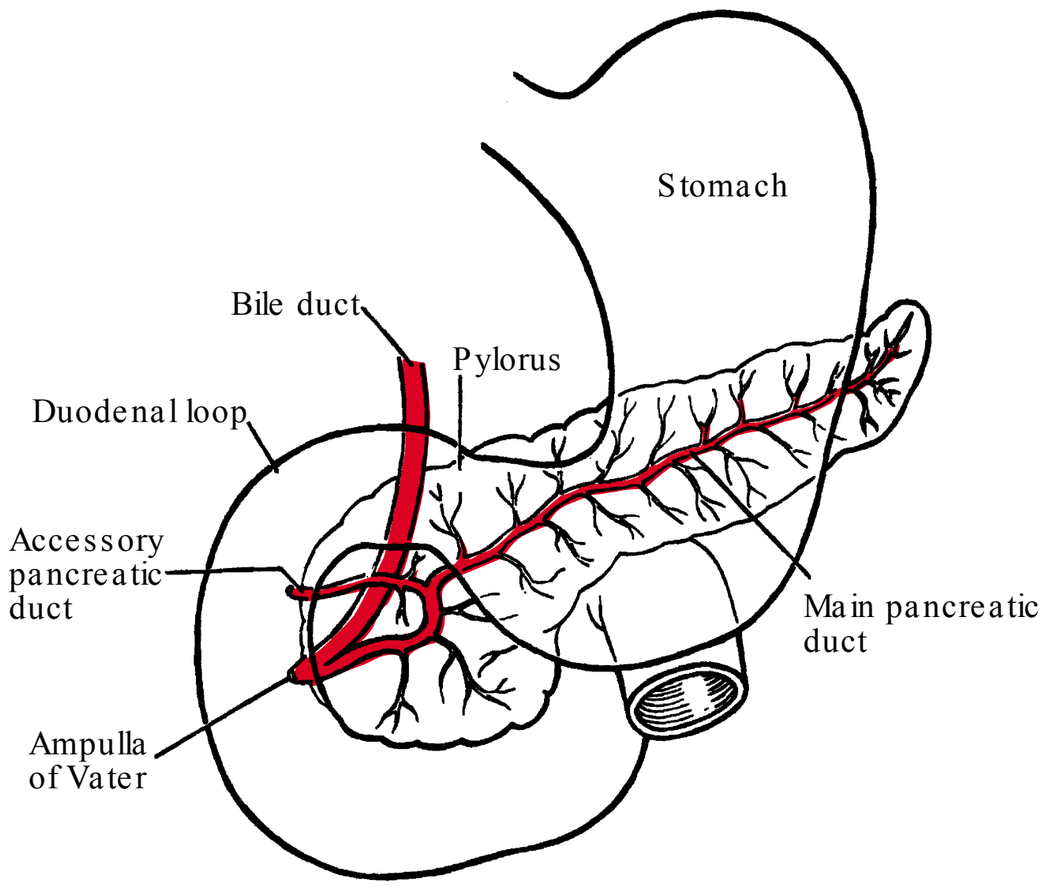

Figure 38-2 Cross-section through the pancreas.

The Digestive Process

The neurogenic, gastric, and intestinal phases constitute the **digestive process**. The neurogenic (vagal) phase is initiated by the (1) sight, (2) smell, and (3) taste of food. These all stimulate the cerebral cortex and subsequently the vagal nuclei and result in secretion of pepsinogen, HCl, and gastrin. The process is chemically mediated by acetylcholine from postganglionic parasympathetic nerve endings, which act on gastric parietal cells. The vagus also stimulates gastric chief and parietal cells to secrete pepsinogen and HCl. Hydrogen ion secretion takes place against a 1 million-fold concentration gradient, an energy-dependent process catalyzed by H^+, K^+-ATPase; it is mediated by acetylcholine, histamine, and gastrin acting through their respective neurocrine, paracrine, and endocrine pathways to stimulate the parietal cells.

The parietal cell is transformed morphologically when acid secretion is stimulated. Cimetidine (Tagamet) and other H_2-receptor antagonists (such as ranitidine [Zantac] and famotidine [Pepcid]) block both the morphological transformation of the parietal cell and H^+ secretion. Proton pump inhibitors (PPIs) have a different mechanism of action. Omeprazole (a PPI) is taken up by the parietal cell and converted to an active metabolite that inactivates the parietal H^+, K^+-ATPase, inhibiting hydrogen ion secretion until new ATPase is synthesized—a process that requires at least 24 hours.

The distention caused by food entry into the stomach initiates the gastric phase of digestion. HCl release is caused by (1) direct stimulation of the parietal cells by the vagus nerve; (2) local distention of the antrum and stimulation of antral cells by the vagus nerve to secrete gastrin, which in turn causes HCl release from parietal cells; and (3) release of gastrin, stimulated by the near neutralization (pH 5 to 7) of gastric

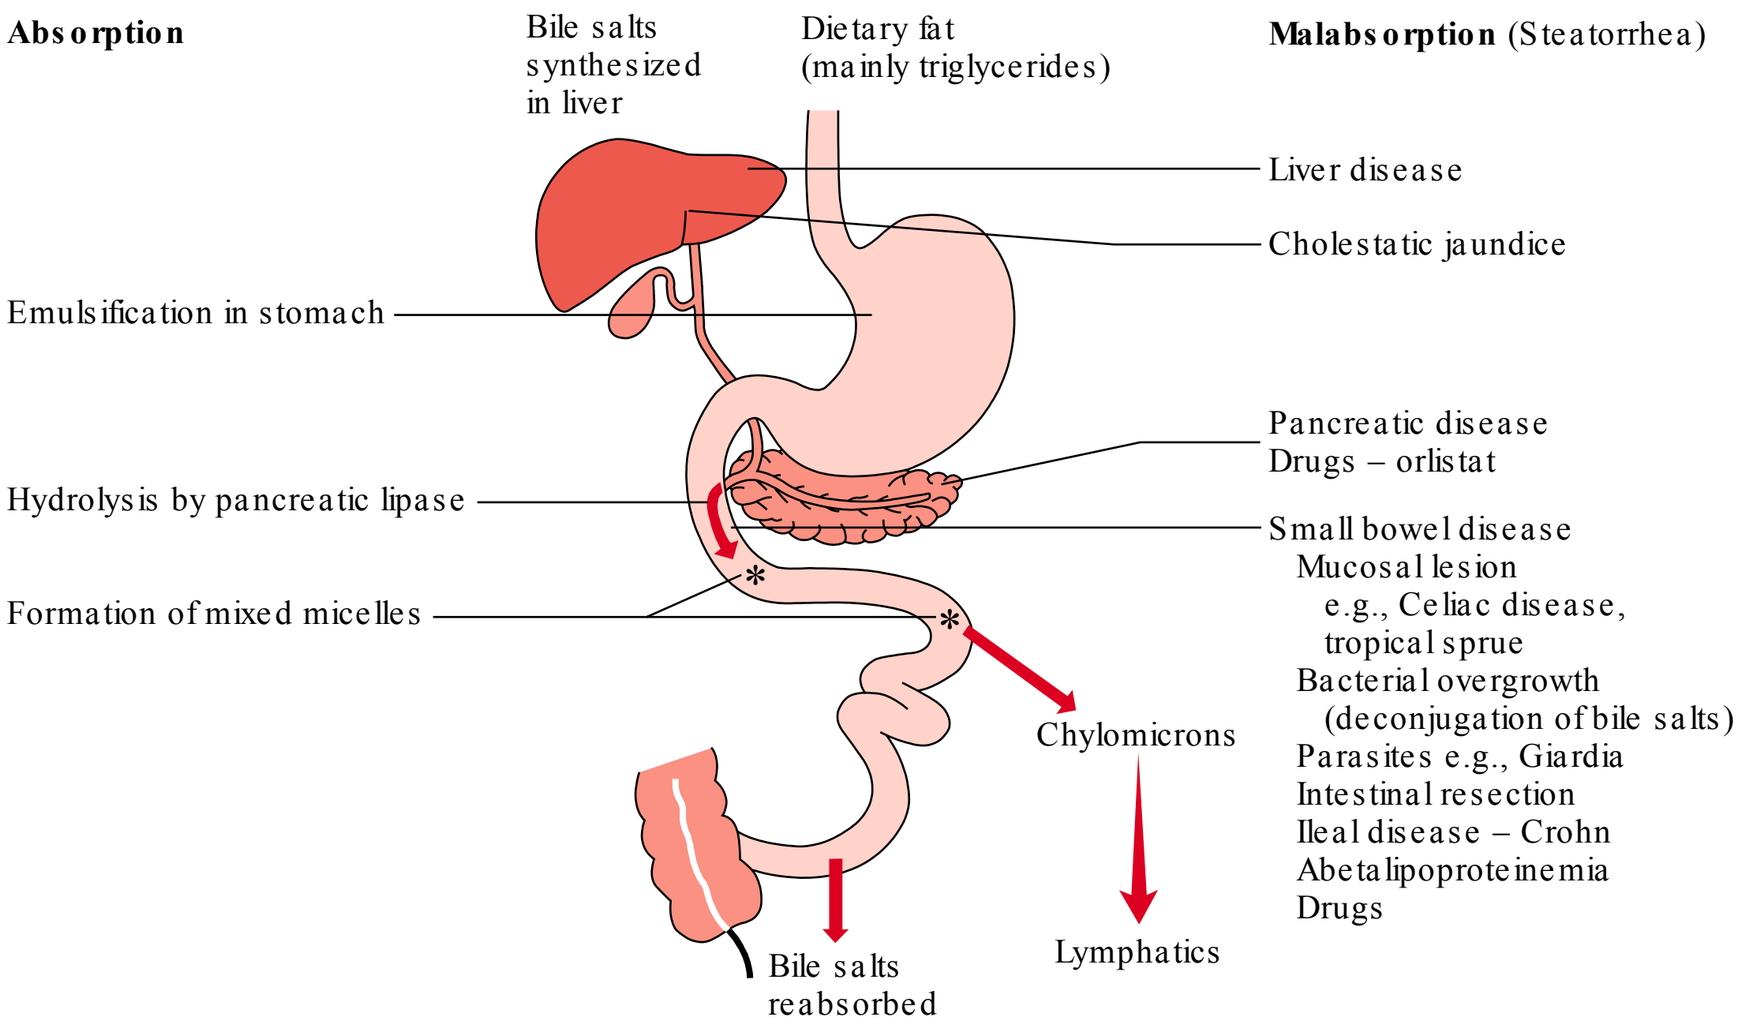

Figure 38-3 Summary of the processes involved in fat absorption and malabsorption. (From Clark ML, Silk DB. Gastrointestinal disease. In: Kumar P, Clark M, eds. Clinical medicine, 6th edition. Edinburgh: WB Saunders, 2005:265-345.)

HCl by ingested food entering the pyloric zone. Gastrin also stimulates (1) antral motility, (2) the secretion of pepsinogens and pancreatic fluid rich in enzymes, and (3) the release of GI hormones, such as **secretin**, insulin, acetylcholine, somatostatin, and pancreatic polypeptide (PP). As a result of the acidic environment, pepsinogens are converted rapidly to the active proteolytic enzyme, pepsin. As food enters the stomach, it is mixed by the contractions of the stomach. Chemical secretions of the stomach then partially degrade the food into a mucus-containing mixture called chyme, which then is moved through the pylorus into the duodenum. T e pylorus plays a role in emptying food into the duodenum by virtue of its strong musculature.

The intestinal phase of digestion begins when the weakly acidic digestive products of proteins and lipids (Figure 38-3) enter the duodenum. Several GI hormones, including gastrin, are released by both neural and local stimulation and act on various regions of the GI tract to regulate digestion and absorption. In addition, the action of gastrin is potentiated by the secretion of **cholecystokinin (CCK)**. Additional gastrin is released as the upper duodenal mucosa comes in contact with partially digested proteins and lipids and gastric HCl. CCK is released in the duodenum in response to the presence of fat, protein, and HCl. Its principal actions are stimulation of gallbladder contraction; secretion of enzymes, bicarbonate, insulin, and glucagon from the pancreas; and stimulation of intestinal motility and stomach contraction.

Secretin is released by gastric acid in the duodenum and (1) augments the effect of CCK on gallbladder contraction and pancreatic secretions, (2) stimulates pepsinogen secretion by the stomach, (3) inhibits gastrin and gastric acid secretion, and (4) reduces gastric and duodenal motility. Gastric inhibitory polypeptide (GIP) is secreted by the duodenum and jejunum. It reduces intestinal motility and increases insulin secretion in the presence of hyperglycemia. **Vasoactive intestinal polypeptide (VIP)**, present throughout the gut and in nerve fibers, is a potent vasodilator and aids in the relaxation of smooth muscle. It has a large number of physiological actions, some of which are shared with secretin and GIP. Somatostatin is secreted to inhibit most GI secretory and motor functions, thus preventing excessive reactions.

Pancreatic digestive enzymes, in a bicarbonate-rich juice, enter the duodenum through the ampulla of Vater and sphincter of Oddi (see Figure 38-2) and mix with the food bolus in the duodenum. During passage through the small intestine, carbohydrates are broken down by amylase and saccharidases into monosaccharides, which then are absorbed actively into the bloodstream. Protein is degraded further in the duodenum by trypsin, chymotrypsin, and carboxypeptidase from the pancreas and aminopeptidases from the small intestine. T e resulting dipeptides and amino acids are absorbed in the jejunum and ileum by specialized absorptive mechanisms in the mucosal surface. Dietary fats are emulsified in the duodenum by the action of bile. T ey are hydrolyzed by lipase (aided by colipase) to individual fatty acids, monoacylglycerols (monoglycerides), and glycerol and then are absorbed in the remainder of the small intestine. Most nutrients, including vitamins and minerals, have been absorbed by the time the food passes into the large intestine, where water is absorbed actively, electrolyte balance is regulated, and bacterial actions take place. T ese processes end ultimately in the formation of feces.

Gastrointestinal Regulatory Peptides[13]

The gut is the largest endocrine organ in the body and also a major target for many hormones, released locally and from other sites. GI regulatory peptides are released from the pancreatic islets (e.g., somatostatin) or from endocrine cells within the gut mucosa (e.g., CCK). Many of these peptides (such as, VIP and somatostatin) are present in the enteric nerves and are also found in the central nervous system and have important roles in the neuroendocrine control of the gut. Although many of them (such as, secretin and gastrin) fulfill the classic criteria for a hormone by acting on distant cells (see Chapter 25), others function as neurotransmitters or have local (paracrine) effects on adjacent cells. Collectively, they influence motility, secretion, digestion, and absorption in the gut. They regulate bile flow and secretion of pancreatic hormones and affect tonicity of vascular walls, blood pressure, and cardiac output.

There is a growing understanding of the role of the neuroendocrine system and gut peptides, and of the importance of the gut-hypothalamic pathway, in the normal control of food intake, and of the possibility of disorders in these mechanisms as causes of obesity. The gastric peptide ghrelin and CCK act as short-term regulators of appetite and satiety. The neuropeptide $PYY_{(3-36)}$ is secreted by endocrine cells in the distal small intestine and colon in response to the ingestion of food. Infusion of $PYY_{(3-36)}$ to physiological plasma concentrations in humans significantly decreases appetite with a 33% reduction in food intake over 24 hours. $PYY_{(3-36)}$ is therefore a further addition to a growing list of hormones with a role in the regulation of energy balance.

Table 38-1 summarizes basic chemical characteristics of five of the major GI regulatory peptides and indicates their site of origin and major functions.

Cholecystokinin

Cholecystokinin (CCK) is a linear polypeptide that exists in multiple molecular forms. In all of them, the five C-terminal amino acids are identical to those of gastrin and are necessary, together with a sulfated tyrosyl residue, for physiological activity. All of the forms of CCK are produced by enzymatic cleavage of a single 115–amino acid precursor, preprocholecystokinin.

CCK is found in the cells of the upper small intestinal mucosa. Circulating concentrations of CCK are increased following ingestion of a mixed meal. CCK secretion is stimulated by mixtures of polypeptides and amino acids (especially tryptophan and phenylalanine), but not by undigested protein. Secretion is also stimulated by gastric acid entering the duodenum and by fatty acids with chains of nine or more carbons, especially in the form of micelles. CCK is rapidly cleared from plasma (half-life of less than 3 min), predominantly by the kidneys. Secretion of CCK is completely inhibited after somatostatin infusion.

CCK regulates gallbladder contraction and increases small intestinal motility. Because it has the same terminal pentapeptide as gastrin, it has a mild stimulatory effect on (1) gastric HCl and pepsinogen secretion, (2) antral motility, and (3) pancreatic bicarbonate secretion. Gastrin and CCK are additive in their stimulation of the pancreas, and both increase the effect of secretin on pancreatic function. CCK also (1) stimulates pancreatic growth, (2) relaxes the sphincter of Oddi, and (3) stimulates secretions from Brunner (duodenal) glands.

TABLE 38-1 Characteristics of Prominent Forms of Principal Gut Regulatory Peptides

Hormone/Peptide	Molecular Weight (Da)	Number of Amino Acids	Main Gut Localization	Principal Physiological Actions
Gastrin Family				
CCK	3918	33 (also 385, 59)	Duodenum and jejunum Enteric nerves	Stimulates gallbladder contraction and intestinal motility; stimulates secretion of pancreatic enzymes, insulin, glucagon, and PPs; has a role in indicating satiety; the C-terminal 8–amino acid peptide CCK-8 retains full activity
Little gastrin	2098	17	Both forms of gastrin are found in the gastric antrum and duodenum	Gastrins stimulate the secretion of gastric acid, pepsinogen, intrinsic factor, and secretin; stimulate intestinal mucosal growth; increase gastric and intestinal motility
Big gastrin	3839	34		
Secretin-Glucagon Family				
Secretin	3056	27	Duodenum and jejunum	Stimulates pancreatic secretion of HCO_3, enzymes, and insulin; reduces gastric and duodenal motility, inhibits gastrin release and gastric acid secretion
VIP	3326	28	Enteric nerves	Relaxes smooth muscle of gut, blood, and genitourinary system; increases water and electrolyte secretion from pancreas and gut; releases hormones from pancreas, gut, and hypothalamus
GIP	4976	42	Duodenum and jejunum	Stimulates insulin release; reduces gastric and intestinal motility; increases fluid and electrolyte secretion from small intestine

CCK, Cholecystokinin; GIP, glucose-dependent insulinotropic peptide; PP, pancreatic polypeptide; VIP, vasoactive intestinal polypeptide.

CCK is widely distributed throughout both the central and peripheral nervous systems, with highest concentrations in the cerebral cortex; its function in the central nervous system is unclear. When released from the GI tract, it acts as a short-term, meal-related satiety signal, thus regulating appetite.

Gastrin

Gastrin also occurs in multiple molecular forms in blood and tissue; the most important of these are big gastrin (G-34), a linear polypeptide of 34 amino acids and little gastrin (G-17). The principal circulating form of gastrin is G-34 in healthy individuals and in patients with hypergastrinemia. All forms of gastrin originate from a single precursor, preprogastrin, a peptide consisting of 101 amino acids. The smallest peptide sequence of gastrin possessing biological activity is the carboxy-terminal tetrapeptide (G-4, tetrin). A synthetic pentapeptide (pentagastrin) has been used for stimulation of HCl secretion in gastric function testing.

Gastrin is produced and stored mainly by endocrine cells of the antral mucosa and to a lesser extent in the proximal duodenum and in cells of the pancreatic islets. After secretion, gastrin is transported by the blood through the liver to the parietal cells of the fundus of the stomach. There it stimulates the secretion of gastric acid. It also stimulates (1) secretion of gastric pepsinogens and intrinsic factor by the gastric mucosa, (2) release of secretin by the small intestinal mucosa, (3) secretion of pancreatic bicarbonate and enzymes and hepatic bile. It increases (1) gastric and intestinal motility, (2) mucosal growth, and (3) blood flow to the stomach. It is secreted in response to antral distension by meals, and by amino acids, peptides, and polypeptides from partially digested proteins in the stomach. Other stimuli of gastrin include alcohol, caffeine, insulin-induced hypoglycemia, ingestion or intravenous infusion of calcium, and vagal stimulation initiated by smelling, tasting, chewing, and swallowing food.

Maximal secretion of gastrin occurs at an antral pH of 5 to 7. At pH 2.5, secretion is reduced by about 80%; maximal suppression occurs at pH 1.0. Secretion is inhibited by the direct action of acid on the endocrine cells producing gastrin. This negative feedback safeguards against overacidification by any and all stimulants.

Secretin

Secretin is a linear polypeptide containing 27 amino acids and has structural similarities to several hormones, including glucagon, VIP, and GIP. The intact secretin molecule is required for biological activity, and in contrast to gastrin there is no minimum active fragment.

It is secreted by the mucosal granular S cells located in greatest concentration in the duodenum but present throughout the small intestine. It is released primarily on contact of the S cells with gastric HCl; however, as pancreatic juice flows into the duodenum, it neutralizes gastric acid and thereby removes one stimulus for its own secretion. Secretin is not released until the pH is lowered to at least 4.5. However a pH less than 4.5 normally occurs only in the first few centimeters of the duodenum, causing little increase in plasma secretin after a normal meal. Thus secretin release after exposure of S cells to HCl may not be an important physiological stimulus. However, plasma secretin concentrations that are too low to measure may stimulate the pancreas in the presence of physiological concentrations of CCK, which strongly potentiates the action of secretin. Undigested fat does not stimulate secretin release, but fatty acids with chains of ten or more carbons are weak stimulants. Alcohol increases secretin release by stimulation of gastric acid secretion with subsequent lowering of duodenal pH rather than by a direct stimulatory effect. The half-life of secretin is about 4 minutes. The kidney is the major site of its degradation. The only known physiological inhibitor of secretin release is somatostatin.

The primary physiological role of secretin is the stimulation of the pancreas to secrete an increased volume of juice with high bicarbonate content. Other actions include (1) stimulation of bicarbonate and water secretion from the liver and from Brunner glands, (2) augmentation of gallbladder contraction and increased hepatic bile flow, (3) stimulation of parathyroid hormone (PTH) secretion, (4) release of pancreatic enzymes and of pepsinogen by the chief cells of the stomach, (5) reduction of gastric and duodenal motility, (6) reduction of the lower esophageal sphincter pressure, and (7) promotion of pancreatic growth. Secretin inhibits normal gastrin secretion (but does not decrease serum gastrin in the **Zollinger-Ellison syndrome**) and therefore gastric acid secretion.

Vasoactive Intestinal Polypeptide

Vasoactive intestinal polypeptide (VIP) is a linear polypeptide of 28 amino acids and has structural similarities to secretin, GIP, and glucagon. VIP is present throughout the body and is found in highest concentrations in the nervous system and gut. Unlike secretin and other GI hormones, VIP is not found in the mucosal endocrine cells of the GI tract. It is believed to be a neurotransmitter limited to peripheral and central nervous tissue. VIP-containing nerve fibers are found throughout the GI tract from the esophagus to the colon.

Little is known about the conditions that cause VIP to be released into the circulation. There is no evidence that VIP is released during digestion, but its secretion is increased by vagal stimulation. It has a plasma half-life of about 1 minute, and most of the hormone is inactivated by a single passage through the liver. It has a large number of physiological actions, which are summarized in Table 38-1. Most of the actions of VIP tend to be of short duration because of its rapid degradation.

Glucose-Dependent Insulinotropic Peptide (GIP, Gastric Inhibitory Polypeptide)

Glucose-dependent insulinotropic peptide (GIP) is a linear peptide consisting of 42 amino acids. Its N-terminal end has a close resemblance to glucagon and secretin, but the C-terminal amino acid sequence of 17 residues is not common to any other known intestinal hormone.

GIP is synthesized and released by cells located in the duodenal and jejunal mucosa. Plasma GIP is increased by oral administration of glucose or triacylglycerols or by intraduodenal infusions of solutions containing a mixture of amino acids.

Protein ingestion does not significantly increase GIP. For food components to stimulate GIP release, they must be absorbed by the intestinal mucosa.

The biological actions of GIP are summarized in Table 38-1. The insulinotropic action of GIP appears to be the most important of its biological actions, and as a result, this hormone has more recently been called "glucose-dependent insulinotropic peptide" as a more accurate description of its physiological action.

Other Regulatory Peptides

A large number of other GI regulatory peptides, hormones, and growth factors have now been shown to be localized within the gut although the function of some of these is still unclear. Growth factors belonging to several families of peptides have important roles in the control of a wide range of cell functions in the intestine. The current clinical use of GI hormones/regulatory peptide measurements is in the diagnosis of neuroendocrine tumors of the pancreas and GI tract. It is likely that they will have wider applications as understanding of their functions grow (e.g., in the fields of obesity and appetite modulation).

Stomach, Intestinal, and Pancreatic Diseases and Disorders

Diseases of the GI tract include those for the stomach, intestines, and pancreas.

Diseases of the Stomach

The growth in endoscopic procedures, with direct visualization of the interior of the stomach, has largely removed the need for the clinical laboratory to carry out the analysis of gastric contents. Situations remain, however, in which the laboratory continues to play a significant role in the diagnosis of gastric diseases and in monitoring the effectiveness of treatment. For example, the laboratory provides such services for peptic ulcer disease, the Zollinger-Ellison (Z-E) syndrome, and **gastritis**.

Peptic Ulcer Disease and Helicobacter pylori[12]

Description

Spiral-shaped organisms have been observed in the stomach for many years but it was only in 1985 that the association was made between Helicobacter pylori (known then as Campylobacter pylori) and **peptic ulcer disease**. Most estimates suggest that the bacterium is present in the mucous layer of the stomach in half of the population of the world. In Europe 30% to 50% of adults, and in the United States at least 20% of the adult population, are infected with the organism. Colonization with H. pylori causes a chronic inflammatory reaction in the gastric mucosa even when direct endoscopic observation appears normal. Carriers of the organism are at increased risk of gastric cancer (twofold to tenfold) and peptic ulcer (threefold to tenfold). About 90% of gastric cancer patients are infected with H. pylori, compared with 40% to 60% of age-matched controls and there is a significant correlation between infection rates and gastric cancer incidence and mortality. However, although a large proportion of gastric cancer can be attributed to infection with H. pylori, only in a minority of infected subjects will the inflammatory reaction progress to gastric cancer. Gastric cancer rates have declined in Western countries in recent decades but the incidence remains high in less developed countries.

At least 95% of patients with duodenal ulcer disease are infected with H. pylori, and eradication of H. pylori is the recommended treatment for patients with duodenal or gastric ulcer who are H. pylori–positive. Effective combined antibiotic and acid suppression regimens (using PPIs) are available with eradication rates of about 90%.

The reason for a gastric mucosal infection causing duodenal ulceration is complex but involves a number of pathways leading to increased acid production. Before the role of H. pylori in the development of peptic ulcer disease was understood, vagotomy (surgical sectioning, or cutting, of the vagus nerve) was the main form of treatment used to reduce gastric acid output, thereby leading to an environment more conducive to healing of the ulcer.

H. pylori produces urease, and hydrolysis of endogenous urea to bicarbonate and ammonia may create a more hospitable microenvironment for its survival in the stomach. The ability of the organism to rapidly hydrolyze urea is the basis of the urea **breath tests** and of the direct urease tests on gastric biopsy samples. Mammalian cells do not produce urease.

Diagnostic Tests for Helicobacter pylori

Tests for H. pylori (Box 38-1) are required for diagnosis of the infection and to ascertain, when symptoms continue, that eradication therapy has been successful. High clinical sensitivity is required to ensure that positives are not missed; similarly, high clinical specificity is essential to prevent inappropriate use of eradication therapy. The Maastricht III Consensus guidelines[12] recommend a "test and treat" strategy in adults with appropriate dyspeptic symptoms under the age of 45 years using either the breath test or stool antigen test. The age limit may vary depending on local prevalence and the age

BOX 38-1 Diagnostic Tests for Helicobacter pylori

Invasive Tests—Using Gastric Mucosal Biopsy Samples
- Histology: Microscopy after Giemsa or silver staining
- Histology: Microscopy after immunohistochemical staining
- Direct urease test: A biopsy incubated in urea/indicator solution; visual endpoint
- Culture: Incubation on suitable media for 4 to 10 days
- Polymerase chain reaction: Amplification of specific DNA sequences

Noninvasive Tests—Using Breath, Blood, Saliva, or Feces
- Breath tests: Rise in breath $^{14}CO_2$ or $^{13}CO_2$ after ingestion of ^{14}C- or ^{13}C-labeled urea
- Serum tests: Laboratory measurement of specific IgG antibody
- Whole blood tests: Point-of-care tests for specific IgG antibody
- Saliva tests: Detection of specific IgG antibody
- Fecal tests: Detection of specific antigen

IgG, Immunoglobulin G.

distribution of gastric cancer. Successful eradication should be confirmed with the urea breath test or by a direct urease test when endoscopy is clinically indicated; a monoclonal antibody-based stool antigen test may be used if urea breath tests are not available. Currently the urea breath test is the preferred procedure, both for initial diagnosis and for confirmation of eradication. Testing to confirm eradication should be done at least 4 weeks af er completion of the course of treatment. PPIs can lead to falsely negative urea breath test results. If PPIs cannot be withheld for at least 2 weeks before a breath test, a negative result must be interpreted with caution.

Urea breath tests are simple to perform, with sensitivity and specificity both greater than 95%. Urea labeled with either ^{14}C or ^{13}C is given orally as a drink or a capsule to swallow with water; urease from gastric H. pylori rapidly hydrolyzes the ingested urea to produce labeled bicarbonate, which is absorbed into the blood and exhaled as $^{14}CO_2$ or $^{13}CO_2$. T e principal advantages of the stable isotope ^{13}C-urea breath test over the radioactive ^{14}C-urea breath test are the simplicity of breath collection and the avoidance of the regulations related to the use and disposal of radioisotopes. In the ^{13}C-urea breath test, the patient blows through a straw into an empty 15 mL tube, which is then capped. $^{13}CO_2/^{12}CO_2$ ratios are compared for basal and postdose samples using isotope ratio mass spectrometry or alternative infrared measurement methods.

In the stool test, specific H. pylori antigens are detected in microtiter plates coated with monoclonal antibodies. T e test is currently recommended for posteradication testing if the urea breath test is not available.[12] Serological tests are recommended only in specific situations, e.g. when PPI therapy cannot be withheld or when a patient with a bleeding ulcer is investigated. T eir diagnostic accuracy in subjects more than 50 years of age is unsatisfactory although laboratory-based tests generally perform well in younger people. Office-based serology has inadequate sensitivity and specificity and is not recommended.

Zollinger-Ellison Syndrome[1,2]

Description

T e Zollinger-Ellison (Z-E) syndrome results from a tumor (**gastrinoma**) of the pancreatic islet cells. Its characteristics include (1) fulminant peptic ulcers, (2) massive gastric hypersecretion, (3) hypergastrinemia, (4) **diarrhea**, and (5) **steatorrhea**. T e primary tumors classicaly occur in the pancreas, duodenum or intestinal lymph nodes, but also occur in other organs. About half of all gastrinomas are multiple, and about two thirds are malignant. One fourth of all gastrinomas occur in people with multiple endocrine neoplasia syndrome, type 1 (MEN 1), with associated tumors, or hyperplasia, in pancreatic islets and parathyroid and pituitary glands. In individuals with Z-E syndrome, fasting gastrin concentrations usually are increased substantially, ranging from 2 to 2000 times normal. Fasting plasma gastrin is usually greatly increased, also ranging from 2 to 2000 times normal. Concentrations more than 10 times the upper limit of normal, in the presence of gastric acid hypersecretion, are virtually diagnostic of gastrinoma. T e fasting plasma gastrin concentration at presentation in sporadic Z-E syndrome correlates with the size and site of the tumor and the presence of hepatic metastases and therefore has prognostic value.

Because management of the patient with Z-E syndrome usually requires surgical intervention, it is important to distinguish hypergastrinemia caused by gastrinoma from other conditions that may lead to similar increases in plasma gastrin. For example, increased concentration of plasma gastrin occurs in (1) hypochlorhydria or achlorhydria, (2) patients being treated with acid-suppressing drugs (e.g., histamine H_2-receptor antagonists or PPIs), (3) H. pylori infection, (4) pernicious anemia, and (5) patients with chronic atrophic gastritis associated with parietal cell antibodies. Surgical resection or diseases of the kidneys or small intestine also can cause hypergastrinemia, possibly because these are important sites of gastrin degradation or excretion.

Increased basal gastrin concentrations may be classified as "appropriate" or "inappropriate" according to their association with decreased or increased gastric acid secretion. For example, in patients with very low or absent acid secretion and a functionally intact gastric antrum, an increase in plasma gastrin is physiologically appropriate and is expected.

Measurement of Plasma Gastrin

In serum from healthy subjects, the predominant forms of gastrin are amidated G-34 and G-17. In subjects with gastrinomas, the circulating gastrins display unpredictable heterogeneity with a shif toward larger peptides. For the detection of gastrinomas, immunoassays are designed to detect all secreted forms of gastrin to prevent false negatives

Gastrin is unstable in serum or plasma, with up to 50% loss of immunoreactivity during 48 hours at 2 ℃ to 8 ℃, due to the action of proteolytic enzymes. Blood samples should be collected into tubes containing heparin as anticoagulant and aprotinin (e.g., Trasylol, 0.2 mL, 2000 KIU, in a 10-mL tube) to prevent proteolysis. Samples should be mixed by inversion, transported rapidly on ice to the laboratory, and the plasma separated in a refrigerated centrifuge. T e plasma should be frozen at - 20 ℃ within 15 minutes of venipuncture. Samples collected in this way are suitable for the analysis of gastrin, VIP, PP, somatostatin, neurotensin, and chromogranins A and B.

Determination of Basal Acid Output

T e documentation of an increased basal acid output (BAO) in gastric juice provides strong evidence that a high serum gastrin concentration is caused by Z-E syndrome. T e test is therefore used in patients with duodenal ulceration and a raised serum gastrin concentration. T e test is not appropriate in patients with atrophic gastritis. Pernicious anemia, which also causes hypergastrinemia, should be excluded before assessing BAO. PPIs must be stopped for at least 14 days, and H_2-receptor antagonists for at least 3 days, before the test. H. pylori as a cause of increased serum gastrin should also be excluded before BAO estimation.

Typically, a 12-hour overnight collection of gastric juice is used to measure BAO. A satisfactory alternative is the

collection of gastric juice for 60 minutes after the patient has had a satisfactory night's sleep in a quiet separate room. After waking, the patient must remain fasting; smoking and exercise must be avoided before and during the test. To collect a specimen, a gastric tube is inserted orally, or nasal intubation may be used if the patient has a hyperactive gag reflex. X-ray or fluoroscopic confirmation that the tip of the radiopaque tube is in the lowest portion of the stomach is necessary. Ten or 15 minutes after the patient has become calm and adjusted to the presence of the tube, the patient is positioned with the trunk upright and inclined slightly to the left. Gastric juice is then aspirated and discarded. The total volume of the collected juice is recorded and free acid determined by titration with sodium hydroxide to a pH end-point of 3.5.

BAO reference intervals are 0 to 10.5 mmol/hr for males and 0 to 5.6 mmol/hr for females. Patients with the Z-E syndrome have BAO values of 15 to 100 mmol/hr, or more than 5 mmol/hr if there was previous acid-reducing surgery. A free acid output more than 15 mmol/hr should prompt a suspicion of gastrinoma but is not diagnostic; a value more than 25 mmol/hr with high serum gastrin is virtually diagnostic of Z-E syndrome.

Gastritis

Gastritis is the term used to denote mucosal inflammation of the stomach. Different types of gastritis are classified as (1) erosive, (2) nonerosive, and (3) specific (very rare).

Erosive Gastritis

Erosive gastritis (acute gastritis) occurs in individuals after severe trauma or severe burns (Curling ulcer) and craniotomy or traumatic head injuries. It also is found in individuals with intracranial disease (Cushing ulcer) and in those who chronically ingest drugs, such as corticosteroids, ethanol, or aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs). Endoscopy is usually the definitive technique to establish the diagnosis.

Nonerosive Gastritis

Nonerosive gastritis (chronic gastritis) is associated with peptic ulcer disease or gastric carcinoma, the period after partial gastrectomy, pernicious anemia, H. pylori infection, and healthy elderly individuals. Serum gastrin is increased in achlorhydric individuals because of the absence of negative feedback by HCl.

Diseases of the Intestine

Diseases of the intestine include (1) **celiac disease**, (2) disaccharidase deficiency, (3) bacterial overgrowth, (4) bile salt **malabsorption,** (5) inflammatory bowel disease (IBD), and (6) protein-losing enteropathy. The main laboratory tests associated with these diagnoses are described here.

Celiac Disease (Celiac Sprue, Gluten-Sensitive Enteropathy)[5,15]

Celiac disease is sometimes called nontropical sprue, celiac sprue, or gluten-sensitive enteropathy.

Description

Celiac disease is a lifelong autoimmune intestinal disorder that is found in individuals who are genetically susceptible.[6] The external trigger to its development in these individuals is found in gluten, which is a complex group of proteins present in wheat. All of the proteins (and peptides) that are toxic to the small bowel mucosa in subjects with celiac disease contain large amounts of glutamine. The major toxic proteins of wheat are the gliadins with homologous proteins (the hordeins and secalins) occurring in barley and rye, respectively. The gliadins account for about 50% of the wheat protein. The development of celiac disease is believed to be initiated by these toxic cereal proteins causing intestinal epithelial damage, which releases tissue transglutaminase (tTG).[3] Cross linking by the enzyme produces gliadin-gliadin or gliadin-enzyme complexes, which in genetically susceptible individuals produces an immune response by gut-derived T cells. The characteristic enteropathy is then induced by the release of interferon-γ and other proinflammatory cytokines.

A 33–amino acid peptide of gluten is probably the primary initiator of the inflammatory response. It is resistant to breakdown by all gastric, pancreatic, and intestinal brush-border membrane proteases, thus allowing it to reach the small intestine intact. After deamidation by tTG, it is a potent inducer of gut-derived human T-cell lines from patients with celiac disease.

There is a wide spectrum in the clinical presentation of celiac disease, with the majority of diagnoses made in adult life. Most adults have nonspecific symptoms, such as (1) abdominal pain, (2) fatigue, (3) weight loss, (4) osteoporosis, (5) short stature, and often (6) mild iron deficiency. In addition, there is a strong association with other autoimmune disease, especially with type 1 diabetes mellitus and autoimmune thyroid disease.

Tests for Celiac Disease

Serological tests played a significant role in raising awareness of the high prevalence of the disorder (1% in Caucasian populations). Appropriately standardized tests have high clinical sensitivity and specificity for diagnosis and for monitoring treatment compliance with a gluten-free diet.

Immunoglobulin A (IgA) antibodies are used to diagnose celiac disease. The measurement of tTG antibodies has several advantages over the older tests for endomesial antibodies (EMA), antireticulin antibodies (ARA) and antigliadin antiboides. A laboratory strategy based on tTG antibody testing as a first-line test has been described.[10] The tTG antibody test is now preferred for serological testing and for assessing dietary compliance of subjects on a gluten-free diet. The tTG test is a quantitative procedure; several reagent sets are now commercially available to measure IgA-class anti-tTG antibodies using human recombinant tTG or purified human enzyme as antigen ("second generation methods"). In patients with IgA deficiency, tests for IgG antibodies may be useful. Tests for antibodies against gliadin are rarely if ever indicated, but measurements of antibodies against deamidated gliadin have recently been shown to be useful for diagnosis.

For a definitive diagnosis, current guidelines require a jejunal biopsy with (1) the characteristic changes of villous atrophy, (2) increased intraepithelial lymphocytes, and (3) hyperplasia of the crypts. Wider use of serology has led to the recognition of more cases and to the development of the concept of the "celiac iceberg" to highlight the fact that many cases remain hidden if serology is restricted to those having classic signs of the disorder.

Subjects with selective IgA deficiency (IgA less than 0.05 g/L, incidence about 1:600) are at greater risk of celiac disease and small bowel biopsy should be considered in all IgA-deficient subjects with symptoms of celiac disease.

With the availability now of serological tests with high diagnostic accuracy, older tests used to investigate celiac disease should be abandoned. T ese include the xylose absorption test and tests of fat malabsorption. Tests of pancreatic function (e.g., fecal elastase) may be indicated in patients diagnosed with celiac disease who fail to respond to a gluten-free diet.

Disaccharidase Deficiencies

Brush-border disaccharidases are essential for carbohydrate absorption and a reduction in their activity has been known to result in carbohydrate malabsorption and intolerance. Carbohydrate malabsorption, however, does not always lead to clinical symptoms, but when symptoms occur such as (1) abdominal pain, (2) flatulence, and (3) diarrhea as a consequence of the malabsorption, the patient is described as having carbohydrate intolerance. **Lactose intolerance** is the single most common absorptive defect in adults with an incidence of 5% to 90% depending on the racial group.

Description

Lactase deficiency may be congenital or acquired. Sucrase-isomaltase and trehalase deficiencies also are disaccharidase deficiencies and affect carbohydrate absorption.

Congenital Lactase Def ciency. Intestinal lactase is essential in infancy, and congenital lactase deficiency is a very rare disorder in which lactase activities in the mucosa are low or undetectable at birth. Symptoms occur as soon as milk is taken; stools have a low pH and contain glucose produced by bacterial action on undigested lactose. A definitive diagnosis must be deferred until maturation of the lactase synthesis system has occurred.

Acquired Lactase Def ciency. Expression of the enzyme diminishes with age and by adulthood the concentrations of lactase activity are 10% or less of those seen in infancy. If symptoms of (1) flatulence, (2) abdominal discomfort, (3) bloating, or (4) diarrhea occur af er consumption of one or two glasses of milk or of a large portion of ice cream or yogurt, lactose intolerance should be suspected.

Secondary lactose intolerance may occur as a result of reduced enzyme activity following diffuse intestinal damage from (1) infections (giardiasis, bacterial overgrowth, or viral gastroenteritis), (2) **ulcerative colitis**, (3) celiac disease, and (4) tropical **sprue**. T is deficiency is usually reversible following recovery from the disorder.

Sucrase-Isomaltase and Trehalase Def ciencies. Sucrase-isomaltase deficiency usually presents clinically in infancy when sucrose and fruit are introduced in the diet, but also may present in adults. Deficiencies of both lactase and sucrase-isomaltase may occur secondary to other small bowel diseases (e.g., celiac disease, **Crohn disease**, or acute gastroenteritis). Trehalase deficiency is a rare disorder, except in Greenland, where it occurs in 8% of the population. It is manifested by diarrhea following the ingestion of mushrooms.

Malabsorption of Monosaccharides. Malabsorption of monosaccharides may cause intestinal symptoms similar to those attributed to **maldigestion** of disaccharides. For example, glucose-galactose malabsorption is inherited as an autosomal recessive trait. Symptoms occur in the affected neonate as soon as milk (lactose) is taken, but also follow ingestion of glucose- or galactose-containing foods. Symptoms caused by fructose malabsorption occur on ingestion of fruit. T is dietary intolerance is a different disorder from hereditary fructose intolerance in which the hepatic enzyme aldolase is defective.

Diagnostic Tests for Lactase Def ciency

Many methods have been proposed for detecting lactase deficiency (Box 38-2).

Oral Lactose Tolerance Tests. Oral tolerance tests measure the increase in plasma glucose or galactose following the ingestion of lactose and are used to diagnose lactase deficiency. T e usual dose of lactose is 50 g in 200 mL water, although lower doses should be used in children (2 g/kg, up to a maximum of 50 g). Multiple blood samples are collected over a 2-hour period, and the peak increment in glucose (or galactose) is noted.

Because of problems with the oral tolerance test, noninvasive breath-hydrogen testing (Box 38-3) is now the technique of choice for diagnosing lactase deficiency. T is technique is based on hydrogen not being an end-product of mammalian metabolism and consequently breath hydrogen is derived from bacterial

BOX 38-2 Methods for Detecting Lactase Deficiency

Lactase in mucosal biopsy
Oral lactose tolerance
- Measure increase in plasma glucose
- Measure increase in plasma galactose
- Measure increase in breath H_2
- Measure increase in breath $^{13}CO_2$

BOX 38-3 Protocol for Lactose Tolerance Test with Measurement of Breath Hydrogen

Meal before 1900 hours (restriction on wheat and fiber), then fasting until test completed.
Brush teeth (night and morning) or use mouthwash.
Measure end-expiratory fasting breath H_2.
Give lactose solution (50 g in 180 mL water).
Rinse mouth with further 20 mL water and swallow.
Measure breath H_2 at 15, 30, 60, 90, and 120 min.
Test can be stopped early if H_2 increases more than 20 ppm above fasting concentration.

metabolism in the intestine. Following an oral dose of lactose, the disaccharide will normally be split into its constituent monosaccharides and absorbed. With lactase deficiency, unabsorbed disaccharide will pass into the large bowel and bacterial metabolism will produce hydrogen that is absorbed into the systemic circulation and exhaled in the breath. Breath hydrogen is then measured in end-expiratory breath using laboratory or hand-held direct-reading electrochemical hydrogen monitors.

In most patients with normal lactose absorption, breath hydrogen concentrations will remain at 2 to 5 μL/L (2 to 5 ppm) throughout the test. In lactose malabsorption, breath hydrogen is typically increased (30 to 100 μL/L, 30 to 100 ppm) at 60 to 120 minutes after lactose ingestion. In a few subjects, the large bowel bacteria do not produce hydrogen; in such patients a normal result does not exclude lactase deficiency. Very low hydrogen concentrations (fasting and throughout the test) may therefore indicate a false-negative result. Such false negatives can be confirmed by the failure to produce hydrogen at 45 to 180 minutes after ingestion of lactulose (10 g), which is a nonabsorbable disaccharide and therefore available for bacterial metabolism in the large bowel.

A positive breath hydrogen result following ingestion of lactose may also occur in glucose-galactose malabsorption, which also causes intestinal symptoms. When necessary, glucose-galactose malabsorption can be confirmed or excluded by a breath test in which 25 g each of glucose and galactose are substituted for 50 g lactose. An increase in breath hydrogen confirms the diagnosis.

Sucrose and Trehalose Tolerance Tests. Sucrase deficiency is investigated by using 50 g sucrose instead of lactose. An increase in breath hydrogen of more than 20 μL/L (>20 ppm) within 2 hours is diagnostic. It is rarely necessary to test for trehalase deficiency.

Bacterial Overgrowth

The duodenum and jejunum normally contain few bacteria. Most ingested bacteria do not survive the acidic environment of the stomach and therefore few live organisms normally enter the small bowel. The motility of the jejunum prevents fecal-type organisms from progressing up into the jejunum from the cecum. The ileum normally contains some fecal type of bacteria. Colonization of the upper small bowel is described as bacterial overgrowth and usually occurs as a consequence of other abnormalities (structural or motility disorders) of the small intestine (Box 38-4). Use of PPIs is associated with an increased risk of bacterial colonization.

The bacteria colonizing the small bowel (such as, Escherichia coli and Bacteroides species) deconjugate and dehydroxylate bile salts, leading to conjugated bile salt deficiency, which causes fat malabsorption. Bacterial metabolism of vitamin B_{12} may also occur, leading to vitamin B_{12} deficiency. The clinical symptoms of bacterial overgrowth are (1) abdominal pain, (2) diarrhea, and (3) steatorrhea.

The diagnostic "gold standard" requires intubation with aspiration of jejunal contents and the demonstration of a bacterial count of $>10^7$ organisms/mL and $>10^4$ anaerobes/mL. In practice, hydrogen breath tests that have glucose or lactulose as substrates are used more frequently.

BOX 38-4 Abnormalities of the Small Intestine Associated with Bacterial Overgrowth

- Jejunal diverticuli
- Crohn disease
- Autonomic neuropathy
- Scleroderma (systemic sclerosis)
- Pseudo-obstruction
- Postgastrectomy

Bile Salt Malabsorption

Bile acids are synthesized in the liver and pass into the lumen of the small bowel via the gallbladder. They are present in bile as taurine or glycine conjugates. As the pH of bile is slightly alkaline and contains significant amounts of sodium and potassium, most of the bile acids and their conjugates exist as salts (i.e., bile salts). The terms bile acids and bile salts are frequently used as synonyms. Their major function is to act as surface-active agents, forming micelles and facilitating the digestion of triglycerides and the absorption of cholesterol and fat-soluble vitamins. Little reabsorption of bile acids occurs in the proximal small bowel, but normally more than 90% is reabsorbed in the terminal ileum. They return to the liver in the portal circulation and are resecreted into the bile. This is known as the enterohepatic circulation. Less than 10% of secreted bile acids are lost in the feces, or about 0.2 to 0.6 g/day.

Bile acid malabsorption leading to chronic diarrhea occurs when there is ileal disease (e.g., Crohn disease), or after resection of the terminal ileum; it may also occur following cholecystectomy and in some patients with irritable bowel syndrome (IBS). Malabsorption of bile salts produces diarrhea by two different mechanisms. In one, significant deficiency of intraluminal bile salts leads to fat malabsorption and steatorrhea. In the second, which is typically more common, malabsorption of bile salts in the ileum leads to higher concentrations in the colon where they alter water and electrolyte absorption leading to net secretion of water into the lumen and diarrhea. Bile salt malabsorption is probably underdiagnosed and should be suspected in patients with unexplained chronic diarrhea.

Procedures used in the diagnosis of bile salt malabsorption include (1) the ^{75}selenohomocholyltaurine (^{75}SeHCAT) test, (2) measurement of serum 7α-hydroxy-4-cholesten-3-one in serum, and (3) a therapeutic trial of bile acid sequestrants, such as cholestyramine. The first is the most widely used and involves the oral administration of the synthetic radioactive bile acid ^{75}SeHCAT. Whole body gamma counting is carried out to estimate the basal activity 1 hour after the dose. The gamma count is measured again after 7 days, when normally more than 15% of the administered dose is retained. Retention of 110% indicates bile salt malabsorption.

Inflammatory Bowel Disease[11]

IBD includes Crohn disease, ulcerative colitis, and a number of microscopic inflammatory bowel disorders. IBD has a high prevalence in the United States and Europe and a much lower, although increasing, prevalence in most Asian countries.

Significant overlap in the clinical presentation has been noted, as well as in radiologic and histologic findings, in Crohn disease (which may affect any part of the GI tract) and ulcerative colitis (which is confined to the large bowel). Both conditions present with diarrhea and abdominal pain or discomfort, often associated with fatigue and anemia, and less commonly with inflammation of the joints, skin, and eyes.

Intestinal symptoms are common to both IBD and IBS, although the latter is not an inflammatory disorder and is not associated with organic disease of the bowel. Fecal lactoferrin or calprotectin can be used to differentiate between IBD and IBS when required and to monitor disease activity or response to anti-inflammatory treatment in patients with IBD. The two tests have similar diagnostic accuracies and are markers of the infiltration of neutrophils into the mucosa. Negative tests for these proteins therefore exclude significant neutrophilic intestinal inflammation but may not exclude other organic bowel diseases, such as celiac disease. Lactoferrin and calprotectin can also be used as predictors of relapse in IBD and as markers of mucosal healing following treatment.

Protein-Losing Enteropathy

Loss of significant amounts of serum proteins into the bowel lumen and their passage in the feces occurs in a wide range of GI disorders associated with (1) inflammation or ulceration of a segment of the small or large bowel (as in Crohn disease and ulcerative colitis) or stomach, (2) diseases in which the intestinal lymphatics are obstructed, (3) conditions where there is increased lymphatic pressure (e.g., lymphoma and Whipple disease), or (4) disorders with altered immune status, such as systemic lupus erythematosus and some food allergies.

The diagnosis of protein-losing enteropathy is considered in patients with hypoalbuminemia in whom renal loss, liver disease, and malnutrition have been excluded. The diagnosis can be made by measuring the fecal clearance of $alpha_1$-antitrypsin (AT) as a marker of GI protein loss. AT in feces and serum is measured most conveniently by radial immunodiffusion. Feces should be collected quantitatively, preferably for 3 days, in preweighed containers and kept refrigerated. The AT is extracted into saline before analysis. AT clearance (mL/d) is calculated as [(fecal weight × fecal AT concentration)/serum AT] where fecal weight is expressed in g/day, fecal AT in mg/kg feces, and serum AT in mg/L.

Diseases of the Pancreas and Assessment of Exocrine Pancreatic Function[8]

Pancreatic insufficiency is the inability of the pancreas to produce and/or transport enough digestive enzymes to metabolize food in the intestine and allow its absorption. It typically occurs as a result of chronic pancreatic damage. It is most frequently associated with **cystic fibrosis (CF)** in children and with **chronic pancreatitis** in adults. It is less frequently but sometimes associated with pancreatic cancer. In addition, disorders of the exocrine pancreas are frequently associated with GI symptoms of malabsorption or diarrhea because of its central role in the absorption of carbohydrates, fats, and proteins. In this section, pediatric and adult exocrine pancreatic disorders are briefly discussed and tests for assessing exocrine pancreatic function are described.

Pediatric Disorders of the Exocrine Pancreas

Pancreatic disorders in childhood are summarized in Box 38-5.

Cystic fibrosis (CF) is the most common severe autosomal recessive disease with an estimated gene frequency in Western Europe and the United States of between 1:25 and 1:35 and a disease incidence of about 1 in 2500 to 1 in 3200. The pathogenesis and diagnosis of CF are described in Chapter 24. Pancreatic insufficiency is present at birth in 65% of infants with CF, and a further 15% develop it during infancy and early childhood. The 20% who do not develop pancreatic insufficiency have a better prognosis and develop fewer complications.

The measurement of pancreatic elastase-1 in feces is a reliable test for pancreatic insufficiency in infants over the age of 2 weeks with CF and in older children at diagnosis of the disorder. The test also is used to detect the onset of pancreatic insufficiency in those previously pancreatic sufficient.

Adult Disorders of the Exocrine Pancreas

The major exocrine pancreatic disorders presenting in adult life are (1) **acute pancreatitis**, (2) chronic pancreatitis, and (3) carcinoma of the pancreas.[8] The use of enzyme tests in the diagnosis of acute pancreatitis is discussed in Chapter 19. The causes of pancreatitis are given in Box 38-6.

Chronic pancreatitis is an inflammatory disease characterized by persistent and progressive destruction of the pancreas leading to destruction of both endocrine and exocrine function. In Western countries, the most common cause is alcohol (60% to 90% of all cases); however there are clearly other predisposing factors (e.g., smoking and diets high in fat and protein), because only 5% to 15% of heavy drinkers develop the disease.

BOX 38-5 The Spectrum of Pancreatic Disease in Childhood

Disorders of Morphogenesis
Annular pancreas, pancreas divisum, pancreatic hypoplasia and agenesis, heterotopic pancreas

Inherited Syndromes Affecting the Pancreas
Cystic fibrosis (CF)
Shwachman-Diamond syndrome, Johanson-Blizzard syndrome, Pearson bone marrow pancreas syndrome

Gene Mutations Leading to Pancreatic Disease
Hereditary pancreatitis; cationic trypsinogen gene mutations, trypsin inhibitor gene mutations

Pancreatic Insufficiency Syndrome
Isolated enzyme deficiencies, lipase, colipase, enterokinase

Pancreatic Insufficiency Secondary to Other Disorders
Celiac disease

Acquired Pancreatitis in Childhood
Idiopathic, traumatic, drugs, viral, metabolic, collagen vascular diseases, autoimmune, fibrosing, nutritional (tropical)

BOX 38-6 Causes of Pancreatitis in Adults

Acute
Gallstones
Alcohol
Infections (e.g., mumps, Coxsackie B)
Pancreatic tumors
Drugs (e.g., azathioprine, estrogens, corticosteroids, didanosine)
Iatrogenic (e.g., postsurgical, ERCP)
Hyperlipidemias
Miscellaneous—trauma, scorpion bite, cardiac surgery
Idiopathic

Chronic
Alcohol
Tropical (nutritional)
Hereditary (trypsinogen and inhibitory protein defects, CF)
Idiopathic
Trauma
Hypercalcemia

CF, Cystic fibrosis; ERCP, endoscopic retrograde cholangiopancreatography.

TABLE 38-2 Summary of Invasive Tests of Pancreatic Exocrine Function

Procedure	Pancreatic Stimulant	Analysis of Duodenal Contents
Lundh test	Standardized meal	Enzyme output
Secretin stimulation test	Purified or synthetic porcine secretin	Bicarbonate output
Secretin-CCK test	Secretin as above plus CCK analogue (CCK-8 or ceruletide)	Bicarbonate and enzymes

CCK, Cholecystokinin.

Tests of Exocrine Function of the Pancreas

The predominant exocrine functions of the pancreas are the production and secretion of pancreatic juice, which is rich in enzymes and bicarbonate. Normal pancreatic juice (1) is colorless and odorless, (2) has a pH of 8.0 to 8.3, and (3) has a specific gravity of 1.007 to 1.042. The total 24-hour secretion volume may be as high as 3000 mL.

A number of invasive (Table 38-2) and noninvasive laboratory tests are available to measure exocrine function in the investigation of pancreatic insufficiency. Invasive tests require GI intubation to collect pancreatic samples. Noninvasive tests (or "tubeless tests") were developed to avoid intubation, which is (1) uncomfortable for the patient, (2) time-consuming, and (3) expensive. Noninvasive tests are simpler and less expensive to perform, but in general they lack the clinical sensitivity and specificity of the invasive tests, particularly for the diagnosis of mild pancreatic insufficiency.

Invasive Tests of Exocrine Pancreatic Function

Invasive tests include measuring the (1) total volume of pancreatic juice, (2) amount or concentration of bicarbonate, and (3) activities of pancreatic enzymes in duodenal contents. The enzyme most commonly measured is (1) trypsin, but (2) amylase, (3) lipase, (4) chymotrypsin, and (5) elastase are also measured. The Lundh test consists of giving a standardized meal as a physiological stimulus to the pancreas. Administration of the meal, however, prevents determination of the total enzyme and bicarbonate output or secretory volume. Moreover, it provides inadequate stimulation in the presence of mucosal diseases (e.g., celiac disease), in which hormone release from the duodenal mucosa is impaired. In view of these limitations, the Lundh test is largely of historical interest.

The secretin test is based on the principle that secretion of pancreatic juice and bicarbonate output are related to the functional mass of pancreatic tissue. After an overnight fast, basal samples of fluid are collected from the stomach and duodenum. Secretin is then administered intravenously, and duodenal fluid is collected at 15-minute intervals for at least 1 hour. Secretin stimulates the secretion of pancreatic juice and bicarbonate, but stimulation of the secretion of pancreatic enzymes is inconsistent. Addition of CCK (or a synthetic equivalent) stimulates the secretion of pancreatic enzymes, giving a more complete assessment of pancreatic function than with secretin alone.

BOX 38-7 Noninvasive Tests Used to Assess Pancreatic Exocrine Function

Fecal chymotrypsin
Fecal elastase-1
N-benzoyl-L-tyrosyl-p-aminobenzoic acid (NBT-PABA)
Pancreolauryl
^{13}C-Mixed chain triglyceride absorption

Noninvasive Tests of Exocrine Pancreatic Function

A variety of noninvasive tests have been used (Box 38-7), but none has adequate clinical sensitivity for reliably detecting early pancreatic disease. When malabsorption is present, such tests are of value in confirming or excluding pancreatic disease. Considerable overlap often occurs between results observed in normal individuals and those found in patients with pancreatic disorders, which is mainly due to the large functional reserve of the pancreas. An estimate has been made that pancreatic insufficiency cannot clearly be demonstrated until at least 50% of the acinar cells have been destroyed. Clinical signs of pancreatic insufficiency often do not appear until the destruction of 90% of acinar tissue. In general, these tests may be used when investigating causes of malabsorption but have inadequate sensitivity for diagnosing chronic pancreatitis. Fecal elastase (measured by the monoclonal antibody method) is currently the noninvasive test of choice for assessing pancreatic insufficiency. Further information on noninvasive tests is found in an expanded version of this chapter. [9]

Neuroendocrine Tumors

The watery diarrhea hypokalemia achlorhydria (WDHA) syndrome also is known as the Werner-Morrison syndrome and

as a VIPoma. This syndrome may be suspected in a patient producing large volumes of secretory diarrhea (more than 1 L per 24 hours) with dehydration and hypokalemia. The diagnosis is confirmed by finding a high plasma VIP concentration and demonstration of the tumor by somatostatin-receptor imaging.

GI neuroendocrine tumors are either endocrine pancreatic tumors or carcinoid tumors arising from enterochromaffin cells, which occur throughout the GI tract. Carcinoid tumors are discussed in Chapter 26.

Approximately two thirds of patients with tumors arising from pancreatic islet cells have clinical syndromes associated with excessive hormone production. This group of tumors includes (1) insulinomas, (2) gastrinomas, (3) VIPomas, (4) glucagonomas, and (5) somatostatinomas. Insulinomas and glucagonomas are not usually associated with GI symptoms. The somatostatinoma syndrome is associated with steatorrhea, gallstones, and diabetes. The remaining one third of patients with endocrine pancreatic tumors have no specific clinical symptoms associated with the tumors, which are described as nonfunctional.

The pattern of hormone and precursor production by neuroendocrine tumors is complex. Most secrete several tumor markers. Measurement of the circulating concentration of chromogranin A provides the highest diagnostic sensitivity (94%) for endocrine pancreatic tumors, followed by measurements of PP (74%). Measurement of chromogranin A is an alternative to more specific markers in monitoring the effectiveness of surgery or drug therapy. However, as with other protein and peptide tumor markers, the epitope specificity of the antiserum has a profound effect on the diagnostic sensitivity of the assay. Although chromogranin A has high sensitivity, false positives have been observed in a number of nonendocrine tumors including prostatic cancer.

Disorders of Maldigestion/Malabsorption

Box 38-8 summarizes the main causes of malabsorption. Clinical presentation of the patient suffering from malabsorption or maldigestion classically includes the following features:

- Evidence of general ill health, including (1) anorexia, (2) weight loss, (3) fatigue following minor effort, and (4) dyspnea. In addition, edema (due to hypoalbuminemia), or weakness, tetany, and dehydration due to electrolyte imbalance and water loss may be present. In pancreatic exocrine insufficiency, however, hyperphagia is the rule; patients often report a very high (5000 kcal/day) food intake.
- Isolated nutritional deficiencies. Iron, folate, or vitamin B_{12} deficiency may manifest as anemia, which may be mild; vitamin K deficiency as a bleeding tendency; and vitamin D deficiency as bone disease. They are reflected by a variety of signs and symptoms including (1) glossitis, (2) pallor, (3) dermatitis, (4) petechiae, (5) bruising, (6) hematuria, (7) muscle or bone pain, or (8) neurological abnormalities.

BOX 38-8 Summary of Disorders Leading to Malabsorption

Disorders of Intraluminal Digestion	
a. Altered gastric function	Postgastrectomy syndrome
	Zollinger-Ellison syndrome
b. Pancreatic insufficiency	Chronic pancreatitis
	Cystic fibrosis (CF)
	Pancreatic cancer
c. Bile acid deficiency	Disease/resection of terminal ileum
	Small bowel bacterial overgrowth
Disorders of Transport into the Mucosal Cell	
a. Generalized disorders due to reduction in absorptive surface area	Celiac disease, tropical sprue
b. Specific disorders	Hypolactasia
	Vitamin B_{12} in pernicious anemia
	Zn in acrodermatitis enteropathica
Disorders of Transport Out of the Mucosal Cell	
a. Blockage of the lymphatics	Abdominal lymphoma, primary lymphangiectasia
b. Inherited disorders	a-β-lipoproteinemia

- Abdominal symptoms, such as discomfort, distension, flatulence, and borborygmi (rumbling and gurgling sounds due to movement of gas in the intestine). Such symptoms may also occur after gastric surgery leading to the **postgastrectomy** and **dumping syndromes**.
- Watery diarrhea and possibly steatorrhea. In severe cases of steatorrhea (excess fat in feces), the stool is typically loose, bulky, offensive, greasy, light-colored, and difficult to flush away. Alternatively the stools may appear normal, but be more bulky or be passed with greater frequency.

Early presentation of malabsorption is often subtle. For example, there may be only a slight alteration in volume or consistency of the stool and only mild symptoms attributable to the GI tract. The patient may complain only of anorexia, fatigue, and lack of interest in daily activities. It is in such cases that the physician who suspects malabsorption on clinical grounds will rely on the laboratory to assist in the diagnosis. The initial laboratory investigations are (1) routine tests; (2) tests where abnormalities may point to the possibility of malabsorption (e.g., blood hemoglobin concentration; mean red cell volume; serum concentrations of folate, ferritin, calcium, albumin, and alkaline phosphatase); and (3) tests for antibodies in celiac disease (celiac serology).

Chronic Diarrhea[7,14]

Although diarrhea is a common problem, no clear definition has existed to distinguish it from the range of stool weight, frequency, consistency, or volume that occurs in the normal population. In 2003, for a Western diet, diarrhea was defined as "the abnormal passage of loose or liquid stools more than three times daily and/or a volume of stool [with a weight]

BOX 38-9 Causes of Chronic Diarrhea

Colonic
Colonic neoplasia
Ulcerative and Crohn colitis
Microscopic colitis

Small bowel
Celiac disease
Crohn disease
Other small bowel enteropathies (e.g., Whipple disease, tropical sprue, amyloid, intestinal lymphangiectasia)
Bile salt malabsorption
Disaccharidase deficiency
Small bowel bacterial overgrowth
Mesenteric ischemia
Radiation enteritis
Lymphoma
Giardiasis (and other chronic infection)

Pancreatic
Chronic pancreatitis
Pancreatic carcinoma
Cystic fibrosis (CF)

Endocrine
Hyperthyroidism
Diabetes
Hypoparathyroidism
Addison disease
Hormone secreting tumors (VIPoma, gastrinoma, carcinoid)

Other
Factitious diarrhea
"Surgical" causes (e.g., small bowel resection, internal fistulae)
Drugs
Alcohol
Autonomic neuropathy

From Thomas PD, Forbes A, Green J, et al. Guidelines for the investigation of chronic diarrhoea, 2nd edition. Gut 2003;52(Suppl V):Vol. 1-Vol. 15; reproduced by permission from the BMJ Publishing Group.

greater than 200 g/day."[14] It may be defined as chronic when it has continued for 4 weeks; such persistence indicates the likelihood of a noninfectious cause requiring further investigation.

Several quite different mechanisms lead to diarrhea. In carbohydrate malabsorption, the presence of unabsorbed solutes in the bowel causes an osmotic diarrhea as water enters the bowel from the tissue. By contrast, the diarrhea of most laxative abuse and in VIPomas is due to active secretion of water and electrolytes into the bowel, which is described as secretory diarrhea. IBDs (ulcerative colitis and Crohn disease) cause diarrhea as a consequence of the inflammatory process with loss of fluid into the bowel.

Many diseases commonly thought to cause "diarrhea" in fact lead to more frequent passage of stools but not usually to an increased stool weight (or volume). Such disorders (e.g., IBS) generally fall outside the scope of the definition of "chronic diarrhea." Box 38-9 describes the many causes of chronic diarrhea; most is due to disease of the colon in which laboratory diagnostic tests are currently of little value. An algorithm for the investigation of chronic diarrhea is given in Figure 38-4.

Surreptitious laxative abuse is an important, often overlooked, cause of chronic diarrhea and is a diagnosis in which laboratory investigations have a significant role (Table 38-3).[4] The main initial prerequisite for making a diagnosis of surreptitious laxative abuse is a high index of clinical suspicion, followed by a request for appropriate analyses in urine and fecal samples at a time when the patient has diarrhea.

Measurement of the fecal osmotic (osmolal) gap (FOG) may be helpful in investigating diarrhea. It is based in the fact that the osmolality of stool "water" will normally be that of serum (290 mOsm/kg), but the contribution of electrolytes and of nonelectrolytes to the total osmolality will vary depending on the cause of the diarrhea. FOG expresses the difference between the theoretical normal osmolality (290 mOsm/kg) and the contribution of Na^+ and K^+ as follows:

$$FOG = 290 - [2 \times (\text{fecal } Na^+ + K^+)]$$

Fecal sodium and potassium are measured in the fluid obtained by rapid centrifugation of a fecal sample. Total fecal osmolality increases significantly in unrefrigerated samples and use of the serum osmolality or 290 mOsm/kg is recommended rather than a measurement of total fecal osmolality.

Measurement of FOG enables an estimate to be made of the contribution of electrolytes or nonelectrolytes to the retention of water in the bowel and therefore assists in distinguishing between secretory and osmotic diarrhea. In osmotic diarrhea, unabsorbed solutes lead to water retention and thus make a larger contribution than normal to fecal osmolality; fecal sodium and potassium will therefore be present at lower concentrations than normal, leading to a larger "osmotic gap." Conversely, in secretory diarrhea, it is electrolytes that lead to water retention, and the FOG will therefore be small. FOG >50 mOsm/kg is consistent with an osmotic diarrhea from carbohydrate malabsorption or magnesium-induced diarrhea. By contrast FOG <50 mOsm/kg suggests a secretory diarrhea, and further investigations might include a laxative screen for colonic stimulants or rarely tests for a neuroendocrine tumor.[7] A low FOG will be found in factitious diarrhea because of the addition of water to the stool; if this is suspected and if other causes are excluded, then measurement of total stool osmolality may be helpful.

Measurement of creatinine has been used as an indication of contamination of the fecal sample with urine.

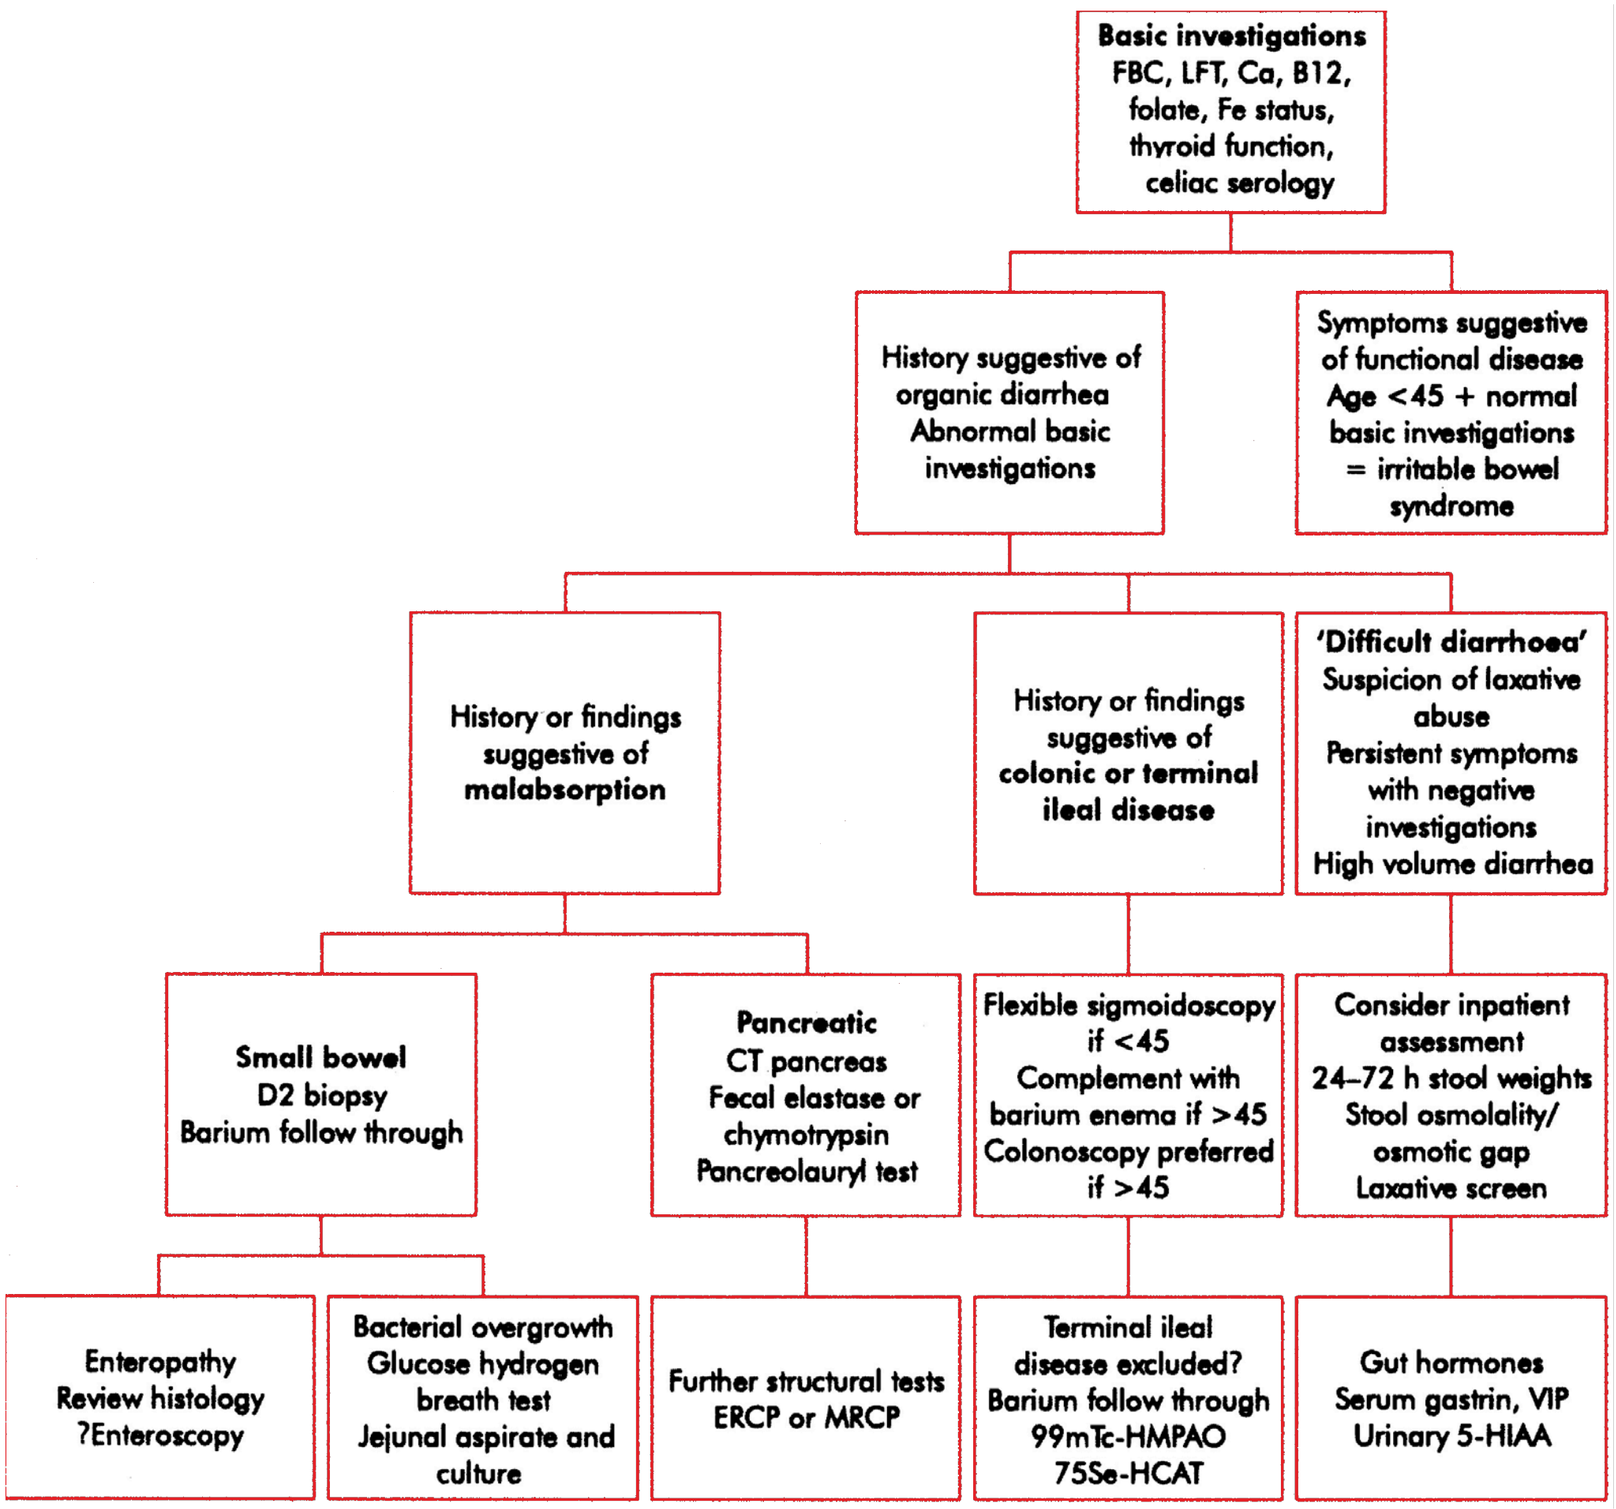

Figure 38-4 An algorithm for the investigation of chronic diarrhea. 5-HIAA, 5-hydroxyindoleacetic acid; 75Se-HCAT, 75Se homotaurocholate; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; FBC, full blood count; LFT, liver function tests; MRCP, magnetic resonance cholangiopancreatography; Tc-HMPAO, technetium hexa-methyl-propyleneamine oxime. (From Thomas PD, Forbes A, Green J, et al. Guidelines for the investigation of chronic diarrhoea, 2nd edition. Gut 2003;52(Suppl V):v1-v15. Used with permission from the BMJ Publishing Group.)

TABLE 38-3 Laboratory Tests to Assess Gastrointestinal Function

Clinical Application	Appropriate Laboratory Investigations
Investigating diarrhea	Possible lactase deficiency: breath hydrogen after oral lactose
	Possible bacterial overgrowth: breath hydrogen after oral glucose or lactulose
	Possible laxative abuse: urine laxative screen
	Possibly induced by bile acid: ^{75}selenohomocholyltaurine (^{75}SeHCAT) whole body retention or serum 7α-hydroxy-4-cholesten-3-one
	Fecal osmotic gap (FOG); fecal Na, K
Assessing pancreatic function	Pancreolauryl test, fecal elastase
Screening for celiac disease	Tissue transglutaminase (tTG) antibodies
Assessing fat absorption	^{14}C-triolein absorption (breath $^{14}CO_2$) or fecal microscopy
Other tests	Fecal α-1-antitrypsin for protein-losing enteropathy; gut hormones (gastrin)

From Hill PG. Faecal fat: time to give it up. Ann Clin Biochem 2001;38:164-7.

Review Questions

1. Gastrin
   a. is secreted by the liver and stomach.
   b. is secreted when stomach pH is low.
   c. stimulates gastric acid secretion.
   d. inhibits secretion of intrinsic factor.
2. The hydrogen breath test using glucose or lactulose as substrates is assessing
   a. intestinal bacterial overgrowth.
   b. celiac disease.
   c. the presence of H. pylori.
   d. bile acid malabsorption.
3. A peptide neurotransmitter that relaxes smooth muscle in the gut and increases water and electrolyte secretion is
   a. cholecystokinin (CCK).
   b. secretin.
   c. vasoactive intestinal polypeptide (VIP).
   d. gastric inhibitory polypeptide.
4. The three phases of the digestive process include the neurogenic, gastric and the intestinal phases. The intestinal phase is initiated
   a. by distention of the stomach.
   b. by the sight, smell and taste of food.
   c. upon stimulation of the cerebral cortex in the brain.
   d. when weakly acidic digestive products of proteins and lipids enter the duodenum.
5. An example of an invasive test for detection of H. pylori in peptic ulcer disease would be
   a. breath testing following ingestion of ^{14}C-labeled urea.
   b. microbiological culture of a gastric biopsy sample.
   c. lab measurement of a specific IgG antibody.
   d. detection of a specific fecal antigen.
6. Which one of the following is considered to be a disease of the intestine?
   a. Zollinger-Ellison syndrome.
   b. peptic ulcer disease.
   c. celiac disease.
   d. cystic fibrosis (CF).
7. The correct formula for determining the fecal osmotic gap (FOG) of a fecal specimen is
   a. $290 - [2(\text{fecal } Na^+ + K^+)]$.
   b. fecal Na^+ + fecal K^+.
   c. [fecal Na^+ − fecal K^+] + 290.
   d. $2 - [\text{fecal } Na^+ + \text{fecal } K^+]$.
8. In Western countries, the most common cause of chronic pancreatitis in adults is
   a. gallstones.
   b. infections.
   c. pancreatic tumors.
   d. alcohol consumption.
9. Which one of the following peptides stimulates increased pancreatic secretion of bicarbonate?
   a. Glucose-dependent insulinotropic peptide (GIP)
   b. Gluten
   c. Secretin
   d. Vasoactive intestinal polypeptide (VIP)
10. A tumor of the pancreatic islet cells that produces in part massive gastric hypersecretion, diarrhea, and steatorrhea causes
    a. the Zollinger-Ellison syndrome.
    b. celiac disease.
    c. lactose intolerance.
    d. cystic fibrosis (CF).

CHAPTER 39

Disorders of Bone and Mineral Metabolism*

Juha Risteli, M.D, Ph.D., F.E.B.M.B., William E. Winter, M.D., Michael Kleerekoper, M.D., F.A.C.B., M.A.C.E., and Leila Risteli, M.D., Ph.D., M.A., F.E.B.M.B.

Objectives

1. Define the following:
   - Bone marker
   - Matrix
   - Osteoblast
   - Osteoclast
   - Osteomalacia
   - Osteopenia
   - Osteoporosis
   - Rickets
   - Type I collagen
2. Describe the structure and function of bone, including organic matrix, cellular components, mineral makeup and remodeling units.
3. Detail the physiology and regulation of calcium and phosphate, including biochemical states, factors that alter the distribution of calcium between these states, and the roles of parathyroid hormone (PTH), calcitonin, and vitamin D.
4. List causes, symptoms, and laboratory analyses used in the differential diagnosis of the following:
   - Hypercalcemia
   - Hypermagnesemia
   - Hyperphosphatemia
   - Hypocalcemia
   - Hypomagnesemia
   - Hypophosphatemia
5. List and describe commonly used methods in the measurement of the following analytes, including principles of reactions, specimen requirements, potential preanalytical errors in the measurement of total/free calcium, and how these analytes are affected in bone or mineral disorders:
   - Bone alkaline phosphatase (BALP)
   - Magnesium
   - Parathyroid hormone (PTH)
   - Parathyroid-related protein
   - Phosphate
   - Total/free calcium
   - Vitamin D and metabolites
6. State the effect each of the following disorders has on total and free calcium, phosphate, albumin, and parathyroid hormone (PTH):
   - Primary and secondary hyperparathyroidism
   - Primary and secondary hypoparathyroidism
   - Pseudohypoparathyroidism
7. Discuss 1,25-dihydroxyvitamin D, including its metabolism, physiology, and roles in bone health, mineral metabolism, and disease.
8. List and describe five markers of bone formation and resorption, including what they are products of, how they reflect specific bone diseases, specimen requirements, and controllable pre-analytical variables.
9. For the following disorders, state the cause(s), symptoms, laboratory analyses, and lab results used to diagnose:
   - Adynamic bone disease
   - Osteitis fibrosa
   - Osteomalacia
   - Osteoporosis
   - Paget disease
   - Rickets
10. Analyze and solve case studies related to bone disorders, biochemical bone markers, and laboratory analysis of these.

Key Words and Definitions

Adynamic bone disease (ABD) A type of renal osteodystrophy characterized by reduced osteoblasts and osteoclasts, and low bone turnover of bone.

Bone alkaline phosphatase (BALP) An isoenzyme of alkaline phosphatase and a biochemical marker of bone formation.

Calcitonin A 32-amino-acid polypeptide hormone elaborated by the parafollicular cells of the thyroid gland in response to hypercalcemia.

CTx An antigen produced when type I collagen is digested by the proteinase cathepsin K yielding cross-linked carboxy-terminal telopeptide of type I collagen; a serum marker for bone resorption and action of cathepsin K.

Deoxypyridinoline (DPD) A deoxypyridinoline crosslink of type I collagen present in bone that is excreted, free or protein-bound, in urine and serves as a marker of bone resorption.

*The authors gratefully acknowledge the original contributions by David B. Endres and Robert K. Rude, on which portions of this chapter are based.

Key Words and Definitions—cont'd

Familial hypophosphatemic rickets Any of several inherited disorders of proximal renal tubular function causing phosphate loss, hypophosphatemia, and skeletal deformities, including rickets and osteomalacia.

Humoral hypercalcemia of malignancy (HHM) A malignancy caused by bone resorption mediated by circulating factors released from distant tumor cells.

Hypercalcemia Increased concentration of calcium in plasma; manifestations include fatigability, muscle weakness, depression, anorexia, nausea, and constipation; most commonly caused by primary hyperparathyroidism or malignancy.

Hypercalcemia-associated malignancy (HAM) A malignancy characterized by hypercalcemia.

Hypermagnesemia A condition characterized by abnormally high concentrations of magnesium in blood plasma.

Hyperphosphatemia A condition characterized by abnormally high concentrations of phosphates in blood plasma.

Hypocalcemia A condition characterized by a low concentration of calcium in plasma.

Hypomagnesemia A condition characterized by a low concentration of magnesium in blood.

Hypoparathyroidism The condition produced by greatly reduced function of the parathyroid glands.

Hypophosphatemia A condition characterized by a low concentration of phosphate in blood.

ICTP An antigen produced when type I collagen is digested by matrix metalloproteinases, yielding cross-linked carboxy-terminal telopeptide of type I collagen; a serum marker for bone resorption.

Mineralization The process by which the body uses minerals to build bone structure.

N-telopeptide (NTx) A biochemical marker of bone resorption.

Osteitis fibrosa A complication of hyperparathyroidism in which the bones are soft and often deformed; also called osteitis fibrosa cystica.

Osteoblasts Cells responsible for formation of bone, including synthesis of type I collagen and noncollagenous proteins and mineralization of osteoid.

Osteocalcin (OC) A protein found in the extracellular matrix of bone and dentin and involved in regulating mineralization in the bones and teeth.

Osteoclasts Large, multinuclear cells responsible for resorption of bone.

Osteomalacia Inadequate or delayed mineralization of osteoid; the adult equivalent of rickets (interruption in the development and mineralization of the growth plate in children).

Osteopenia A condition characterized by decreased bone density occurs that is often predecessor to osteoporosis. It is diagnosed with a bone density test.

Osteoporosis A condition characterized by reduction in bone mass, leading to fractures with minimal trauma; postmenopausal osteoporosis occurs in women after menopause; senile osteoporosis occurs in both men and women later in life.

Paget disease A localized, not metabolic bone disease characterized by osteoclastic bone resorption followed by replacement of bone in a chaotic fashion. Prevalance varies strongly between different countries.

Parathyroid hormone (PTH) A peptide hormone secreted by parathyroid glands in response to hypocalcemia that increases calcium in blood by increasing bone resorption, increasing renal reabsorption of calcium, and increasing the synthesis of 1,25-hydroxyvitamin D; the latter increases intestinal absorption of calcium and phosphate.

Parathyroid hormone–related protein (PTHrP) A protein that mimics many actions of PTH, but is a product of a different gene that is expressed in many normal tissues and overexpressed by tumors in most cases of humoral hypercalcemia of malignancy (HHM).

Procollagen type I carboxy-terminal propeptide (PICP) A biochemical marker of bone formation.

Procollagen type I N-terminal propeptide (PINP) A biochemical marker of bone formation.

Pyridium crosslinks A family of molecules that links collagen molecules to each other; the breakdown products are excreted in the urine with attached crosslinks including pyridinoline (PYD) and deoxypyridinoline (DPD).

Renal osteodystrophy Bone diseases associated with chronic renal failure, including high turnover (osteitis fibrosa or secondary hyperparathyroidism) and low turnover (osteomalacia and adynamic bone) diseases.

Rickets A disorder in children caused by a lack of vitamin D, calcium, or phosphate that leads to softening and weakening of the bones. In adults it is known as osteomalacia.

Secondary hyperparathyroidism Excessive secretion of parathyroid hormone (PTH) in response to low plasma calcium that, in turn, is caused by another condition; seen in patients with chronic renal failure and in people with inadequate vitamin D.

Tartrate-resistant acid phosphatase 5b (TRACP5b) An enzyme derived from osteoclasts; it is a marker of bone resorption.

Vitamin D Fat-soluble vitamin produced by skin upon exposure to sunlight (vitamin D_3, also called cholecalciferol) or adsorbed from foods that contain it (vitamin D_2 or ergocalciferol); deficiency causes rickets in children and osteomalacia in adults. Related tests with clinical utility include assays for 25-hydroxyvitamin D [25(OH)D] and 1,25 dihydroxyvitamin D (calcitriol).

The skeletal system is one of the largest organs in the body and the storehouse for 99% of the body's calcium. Bones are mineralized connective tissue in which type I collagen forms a network of flexible fibers. **Mineralization** of this network, or matrix, with calcium salts is required to produce the rigid skeleton. Bones are a living tissue that is constantly being remodeled by degradation of old tissue and its replacement with new bone matrix. Two bone cell types, **osteoclasts** and **osteoblasts**, are mainly responsible for remodeling. It is now possible to analyze both bone formation and resorption by clinical laboratory methods.

The metabolism of calcium is a tightly controlled processes in the body. Calcium has critical roles in intracellular signaling, at the plasma membrane of cells, and in control of function of extracellular proteins, such as those in the coagulation cascade. The body's handling of extracellular (1) calcium is closely intertwined with that of (2) phosphate and to a somewhat lesser extent of (3) magnesium. It is also intricately connected with the active cellular processes in bone, a metabolically and functionally important system in its own right.

After an overview of bone and mineral metabolism, this chapter presents the clinical chemistry of (1) calcium, (2) phosphate, (3) magnesium, (4) hormones regulating these minerals, (5) markers of bone formation and degradation, and (6) major disorders of bone.

Overview of Bone and Mineral Metabolism

The main functions of bone are (1) mechanical, (2) protective, and (3) metabolic. Bones are composed of cortical (about 80 % of mineral) and trabecular (about 20 % of mineral) bone. The function of cortical bone is primarily mechanical and protective, whereas trabecular bone is more metabolically active. Bone is composed primarily of an extracellular mineralized matrix with a smaller cellular fraction. The organic matrix is primarily type I collagen (about 90%) with lesser amounts of other proteins. The organic matrix is mineralized primarily by the deposition of inorganic calcium and phosphate. Osteoclasts and osteoblasts are the two main types of bone cells. Osteoclasts resorb bone, whereas osteoblasts synthesize new bone.

Turnover or remodeling of bone occurs continuously, enabling the bone to repair damage and adjust strength. Bone remodeling does not occur at random, but instead in discrete packets known as bone remodeling units (Figure 39-1). The remodeling cycle includes (1) activation, (2) resorption, (3) reversal, (4) formation, and (5) resting phases. Circulating osteoclast precursors are recruited, proliferate, and fuse to form osteoclasts. These giant multinucleated cells resorb bone by producing hydrogen ions to mobilize minerals and lysosomal enzymes to digest the organic matrix. After resorption ceases, a cement line is deposited in the resorption cavity, probably by mononucleated cells. Stromal lining cells differentiate to osteoblasts. Osteoblasts form bone by synthesizing the organic matrix, including type I collagen, and participating in the mineralization of the newly synthesized matrix. An estimated 10% to 30% of the skeleton is remodeled each year. Bone growth and turnover are influenced by the metabolism of calcium, phosphate, magnesium and by many hormones, especially **parathyroid hormone (PTH)**, 1,25-dihydroxyvitamin D ($1,25[OH]_2D$), and several cytokines.

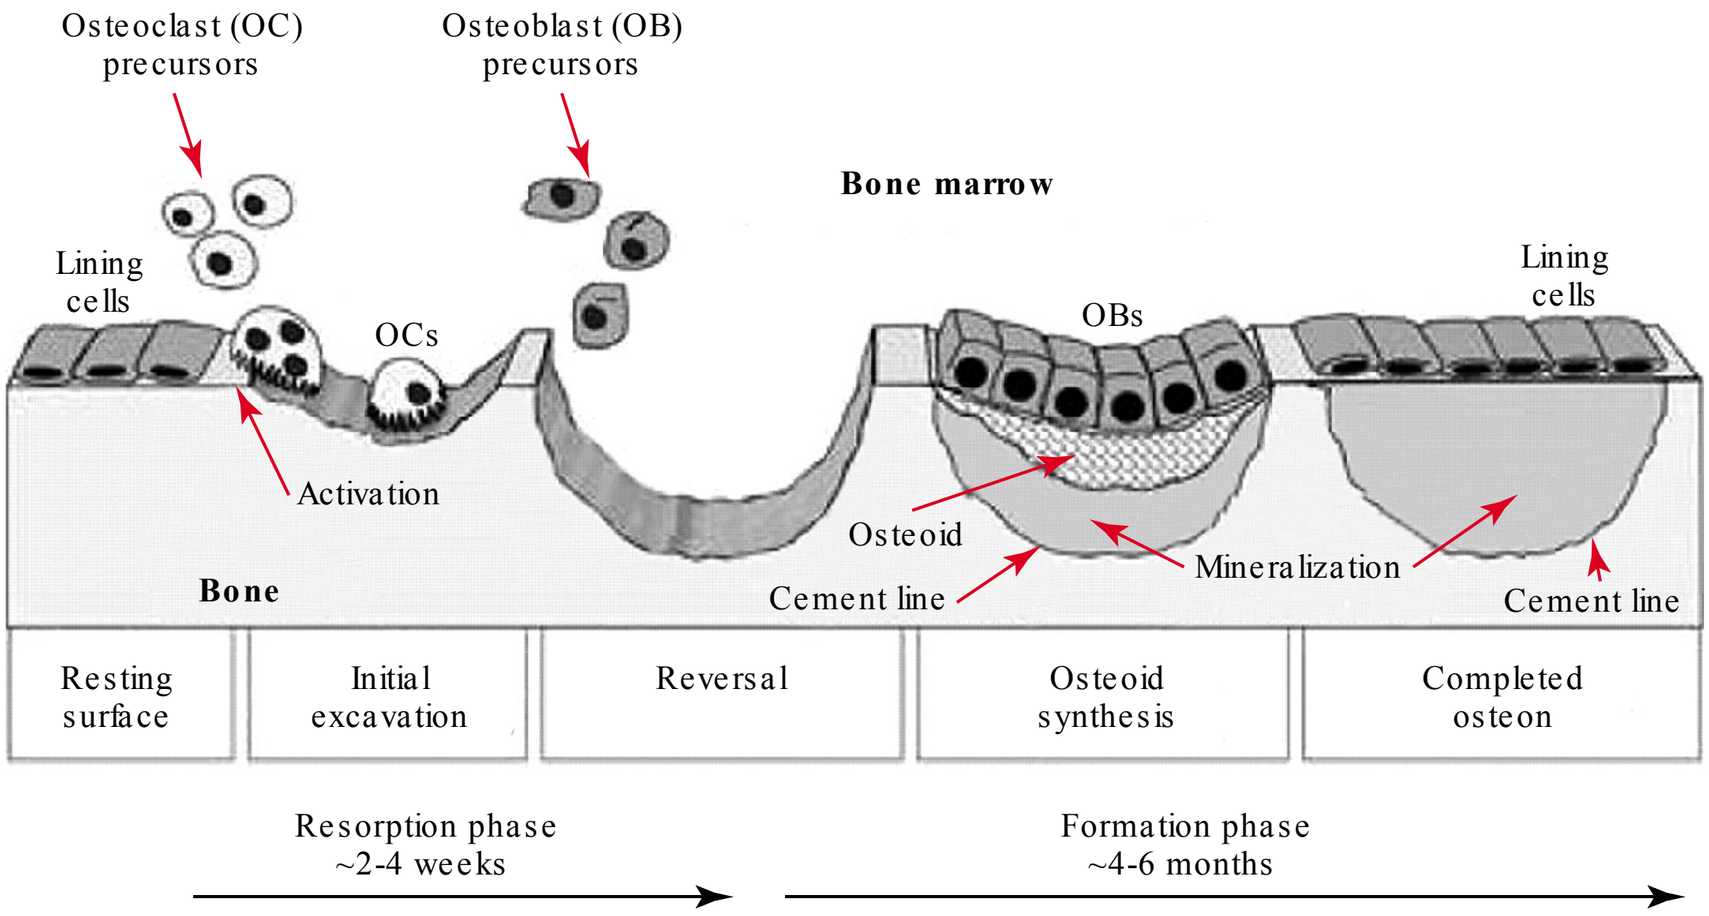

Figure 39-1 Bone remodeling sequence. A depiction of the sequential action of osteoclasts and osteoblasts in removing old bone and replacing it with new bone. For simplicity of illustration, the figure shows remodeling in only two dimensions, whereas in vivo, it occurs in three dimensions with osteoclasts continuing to enlarge the cavity at one end and osteoblasts beginning to fill it in at the other end. (From Riggs BL, Parfitt AM. Drugs used to treat osteoporosis: the critical need for a uniform nomenclature based on their action on bone remodeling. J Bone Miner Res 2005;20:177-84.)

Two products of the osteoblast appear to coordinate osteoblast and osteoclast activity. The first, receptor activator of nuclear factor-κB (RANK) ligand, binds to a receptor on osteoclast progenitor cells and increases osteoclast differentiation and activity. The second, osteoprotegerin (OPG), serves as a decoy receptor for RANK ligand. When OPG binds to RANK ligand, the osteoclast-stimulation activity is prevented. The relative ratios of these two molecules determine bone turnover.

Bone contains (1) nearly all of the calcium (99%), (2) most of the phosphate (85%), and (3) much of the magnesium (55%) of the body. Their concentrations in plasma depend on the net effect of (1) bone mineral deposition and resorption, (2) intestinal absorption, and (3) renal excretion. PTH and $1,25(OH)_2D$ are the principal hormones regulating these three processes.

Calcium

Calcium is the fifth most common element in the body and the most prevalent cation. The skeleton contains 99% of the body's calcium (Table 39-1), predominantly as extracellular crystals of unknown structure with a composition approaching that of hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$.

TABLE 39-1 Distribution of Calcium, Phosphate, and Magnesium in the Body

Tissue	Calcium	Phosphate	Magnesium
Skeleton	99%	85%	55%
Soft tissue	1%	15%	45%
Extracellular fluid	<0.2%	<0.1%	1%
Total	1000 g (25 mol)	600 g (19.4 mol)	25 g (1.0 mol)

Modified from Aurbach GD, Marx SJ, Speigel AM. Parathyroid hormone, calcitonin, and the calciferols. In: Wilson JD, Foster DW, eds. Williams textbook of endocrinology, 8th edition. Philadelphia: WB Saunders, 1992:1397-476.

Biochemistry and Physiology

In blood, virtually all of the calcium is in the plasma, which has a mean calcium concentration of approximately 9.5 mg/dL (2.38 mmol/L). Calcium exists in three physicochemical states in plasma (Figure 39-2) with approximately (1) 50% free (ionized), (2) 40% bound to plasma proteins, primarily albumin, and (3) 10% complexed with small anions (see Table 39-1). Calcium is redistributed among these three plasma pools, acutely or chronically, by (1) alterations in the concentration of protein and small anions, (2) changes in pH, or (3) changes in the quantities of free calcium and total calcium in the serum.

The free calcium fraction is the biologically active form. Its concentration in plasma is tightly regulated by the calcium-regulating hormones PTH and $1,25(OH)_2D$. Intracellular calcium has key roles in many important physiological functions, including (1) muscle contraction, (2) hormone secretion, (3) glycogen metabolism, and (4) cell division. The intracellular concentration of calcium in the cytosol of unstimulated cells is $<10^{-6}$ to 10^{-7} mol/L (1 to 0.1 μmol/L), which is less than one one-thousandth of that in the extracellular fluid (10^{-3} mol/L).

Extracellular calcium is needed for (1) bone mineralization, (2) blood coagulation, and (3) other functions. Calcium stabilizes the plasma membranes and influences permeability and excitability. A decrease in the serum free calcium concentration causes increased neuromuscular excitability and tetany. An increased concentration reduces neuromuscular excitability.

Clinical Significance

Disorders of calcium metabolism are separated into those causing **hypocalcemia** and **hypercalcemia**.[3,6,9,10]

Hypocalcemia

Low total serum calcium (hypocalcemia) may be due to a reduction in either the albumin-bound calcium or the free fraction of calcium, or both (Box 39-1). Hypoalbuminemia is the most common cause of decreased total calcium with

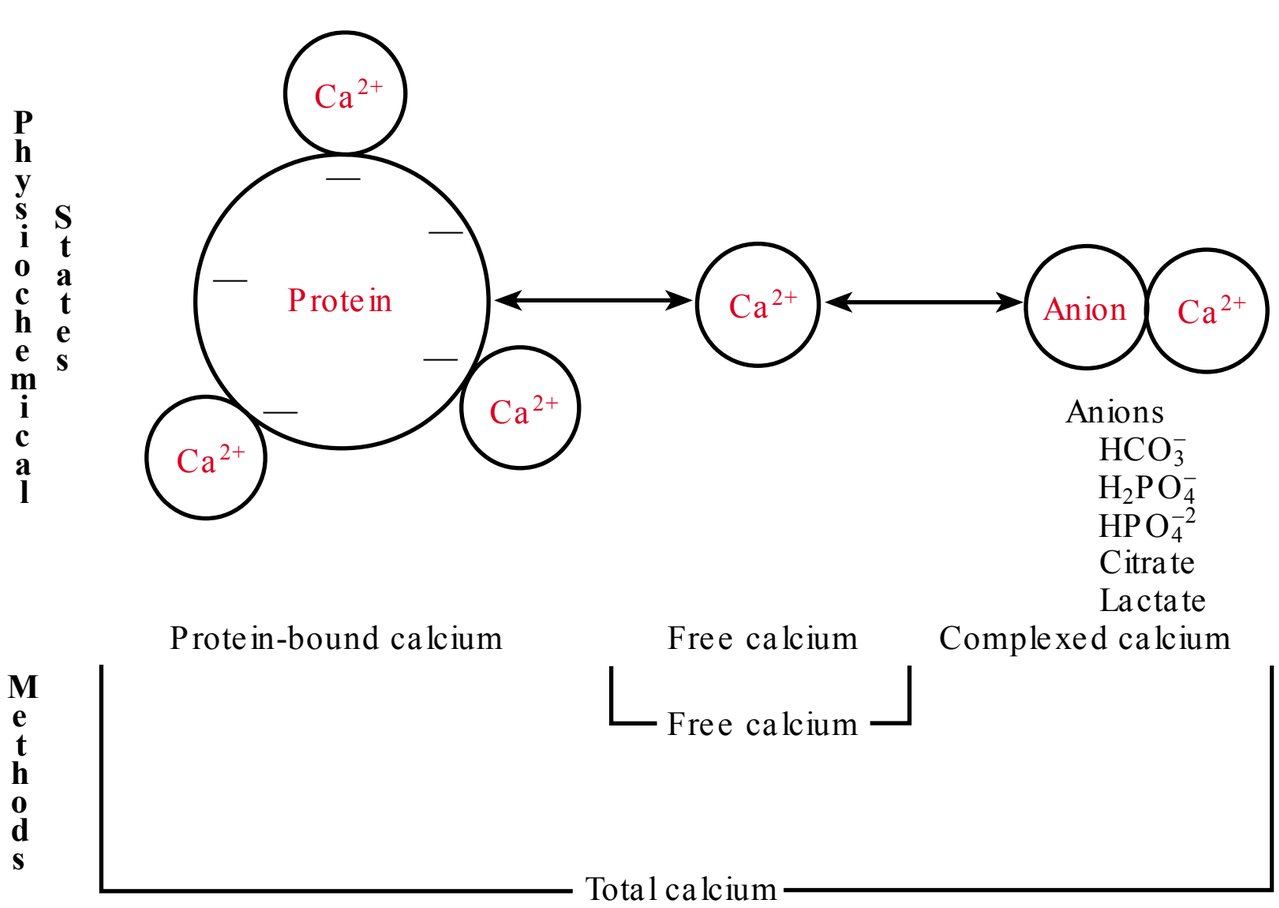

Figure 39-2 Equilibria and determinations of calcium in serum. Calcium moves among three physiochemical pools: (1) free calcium, (2) protein-bound calcium, and (3) calcium complexed with inorganic and organic anions. Methods for determining total calcium measure the calcium in all three pools, whereas methods for determining free calcium measure only that pool.

normal free calcium (sometimes called pseudohypocalcemia); serum calcium concentration is lower when serum albumin is low because 1 g/dL of albumin binds approximately 0.8 mg/dL of calcium. Common clinical conditions associated with low serum albumin include (1) chronic liver disease, (2) nephrotic syndrome, (3) congestive heart failure, and (4) malnutrition. In such states it is preferable to measure free calcium with a specific assay or, if such is not available, to use an adjustment calculation for the total calcium concentration (discussed later).

In chronic renal failure, (1) hypoproteinemia, (2) hyperphosphatemia, and (3) low serum $1,25(OH)_2D$ (caused by reduced renal synthesis) contribute to hypocalcemia. Magnesium deficiency, as discussed in a later section of this chapter, impairs PTH secretion and causes PTH end-organ resistance.

Hypoparathyroidism is caused most commonly by parathyroid gland destruction during neck surgery (90%). Pseudohypoparathyroidism is characterized by resistance to PTH and increased concentrations of PTH.

Rapid remineralization of bone after (1) surgery for primary hyperparathyroidism (hungry bone syndrome), (2) treatment for hyperthyroidism, or (3) treatment for hematological malignancy may result in hypocalcemia. Acute pancreatitis is frequently complicated by hypocalcemia. **Vitamin D** deficiency may also be associated with hypocalcemia because of impaired intestinal absorption of calcium.

Hypocalcemia most commonly presents with signs and symptoms of neuromuscular hyperexcitability, such as (1) tetany, (2) paresthesias, and (3) seizures. A rapid fall in the serum calcium may also be associated with hypotension and electrocardiographic abnormalities.

The initial laboratory evaluation includes assessment of renal function and measurement of serum albumin and magnesium concentrations. Serum intact PTH concentrations are low or inappropriately normal in hypoparathyroidism and elevated in pseudohypoparathyroidism. Vitamin D deficiency is characterized by low serum 25(OH)D, high PTH (**secondary hyperparathyroidism**), and high serum alkaline phosphatase (ALP).

For symptomatic hypocalcemia, calcium may be administered intravenously.

Hypercalcemia

Hypercalcemia is commonly encountered in clinical practice and results when the flux of calcium into the extracellular fluid compartment from the (1) skeleton, (2) intestine, or (3) kidney is greater than its efflux. Hypercalcemia is caused by (1) increased intestinal absorption, (2) increased renal retention, (3) increased skeletal resorption, or (4) a combination of mechanisms.

Common and many of the uncommon causes of hypercalcemia are listed in Box 39-2. Primary hyperparathyroidism is the most common cause in outpatients, whereas malignancy is the most common cause in hospitalized patients. Together, these two disorders account for 90% to 95% of all cases of hypercalcemia.

Primary hyperparathyroidism is most often caused by an adenoma, but may be caused by hyperplasia involving multiple parathyroid glands, or, rarely, by parathyroid carcinoma.

Greater than 80% of hyperparathyroid patients are relatively free of symptoms on presentation because of the early detection of this disorder by the widespread use of chemistry testing panels that include calcium. The most common signs and symptoms of hypercalcemia are nonspecific and related to the neuromuscular system. With mild hypercalcemia (calcium <12 mg/dL or <3 mmol/L) symptoms include (1) fatigue,

BOX 39-1 Causes of Hypocalcemia

- Hypoalbuminemia
- Chronic renal failure
- Magnesium deficiency
- Hypoparathyroidism
- Pseudohypoparathyroidism
- Osteomalacia and rickets due to vitamin D deficiency or resistance
- Acute hemorrhagic and edematous pancreatitis
- Healing phase of bone disease of treated hyperparathyroidism, hyperthyroidism, and hematological malignancies (hungry bone syndrome)

BOX 39-2 Causes of Hypercalcemia

- Primary hyperparathyroidism
  - Parathyroid adenoma, hyperplasia, carcinoma
  - Familial
    - Multiple endocrine neoplasia type I
    - Multiple endocrine neoplasia type II
- Malignancy
  - Skeletal metastases
  - Humoral hypercalcemia
    - Parathyroid hormone—related protein (PTHrP)
    - Growth factor(s) (e.g., epidermal and platelet-derived)
  - Hematological malignancy
    - Cytokines (interleukin-1, tumor necrosis factor, etc.)
    - 1,25-Dihydroxyvitamin D (lymphoma)
  - Coexistent primary hyperparathyroidism
- Other endocrine disorders
  - Hyperthyroidism
  - Hypothyroidism
  - Acromegaly
  - Acute adrenal insufficiency
  - Pheochromocytoma
- Familial hypocalciuric hypercalcemia
- Idiopathic hypercalcemia of infancy
- Vitamin overdose, vitamin D or A
- Granulomatous diseases (e.g., sarcoidosis, tuberculosis)
- Renal failure
  - Chronic, acute (diuretic phase) or after transplant
- Chlorothiazide diuretics
- Lithium therapy
- Milk-alkali syndrome
- Hyperalimentation regimens
- Immobilization
- Increased serum proteins
  - Hemoconcentration
  - Paraprotein

(2) malaise, and (3) weakness; at higher concentrations, (4) depression, (5) apathy, and (6) inability to concentrate may be present. Hypercalcemia may induce mild nephrogenic diabetes insipidus with increased thirst and increased urination. Chronic hypercalcemia with hypercalciuria has been known to lead to formation of calcium-containing kidney stones, which, in some cases, leads to slowly developing renal failure. The majority of patients with primary hyperparathyroidism (>60%) are postmenopausal women.

Primary hyperparathyroidism is diagnosed by laboratory investigations. Hypercalcemia should be documented by measuring total calcium and serum albumin, or ideally free calcium, on more than one occasion before initiating further testing. Measurement of intact PTH (with concomitant measurement of calcium) is the most sensitive and specific test for parathyroid function and is central to the differential diagnosis of hypercalcemia. In parathyroid-related hypercalcemia, plasma PTH is not suppressed (below its reference interval). In other causes of hypercalcemia, the high circulating calcium concentration suppresses PTH production by the parathyroid glands. Serum $1,25(OH)_2D$ concentration is usually above the middle of the reference interval in primary hyperparathyroidism, as PTH stimulates its production. By contrast, $1,25(OH)_2D$ (like PTH) is low-normal or suppressed in (1) nonparathyroid hypercalcemia, except in sarcoidosis, (2) other granulomatous diseases, and (3) certain lymphomas in which the pathological tissues contain the 25-hydroxyvitamin D-1α-hydroxylase required to produce $1,25(OH)_2D$.

PTH increases the renal clearance of bicarbonate and phosphate. In hyperparathyroidism, a mild hyperchloremic metabolic acidosis is often present, whereas in nonparathyroid hypercalcemia a mild hypochloremic metabolic alkalosis is likely. Although **hypophosphatemia** is often seen in hyperparathyroidism, the measurement of serum phosphate is of limited value, because hypophosphatemia is also found in hypercalcemic cancer patients.

Patients with primary hyperparathyroidism who have signs of adverse effects of the disorder, such as nephrolithiasis and **osteitis fibrosa**, should undergo parathyroid surgery. If the patient is asymptomatic, guidelines have been established recommending surgery over monitoring depending on the (1) serum calcium concentration, (2) creatinine clearance, (3) concentration of urine calcium, and (4) bone density (http://jcem.endojournals.org/content/87/12/5353.long/accessed November 14, 2013).

Hypercalcemia occurs in 5% to 30% of individuals with cancer. Tumors most commonly cause hypercalcemia by (1) producing **parathyroid hormone–related protein** (PTHrP), which is secreted into the circulation and stimulates bone resorption and/or (2) invasion of the bone by metastatic tumor, which produces local factors that stimulate bone resorption. PTHrP binds to the PTH receptor and is the principal mediator of **humoral hypercalcemia of malignancy** (HHM). Cytokines and PTHrP appear to mediate hypercalcemia in multiple myeloma and other hematological malignancies. Some lymphomas associated with acquired immunodeficiency syndrome or human T-lymphotrophic virus—1 (HTLV-1) infections cause hypercalcemia by producing $1,25(OH)_2D$. Some patients with cancer have coexisting primary hyperparathyroidism.

Signs and symptoms of hypercalcemia in patients with hypercalcemia due to malignancy include (1) rapid increase in serum calcium concentration, (2) lethargy, (3) obtundation, (4) nausea, and (6) vomiting.

Laboratory test selection is similar to that in suspected hyperparathyroidism. Measurement of PTHrP is rarely needed. In specific instances (e.g., sarcoidosis, lymphoma), measurement of $1,25(OH)_2D$ may be useful.

Therapies are directed toward (1) treating the malignancy, (2) decreasing the serum calcium concentration by saline diuresis, and (3) decreasing osteoclastic resorption (by treatment with bisphosphonate drugs). Glucocorticoids are effective in reducing intestinal adsorption of calcium.

Measurement of Calcium

The methods most widely used for quantifying calcium measure either free (ionized) calcium or total calcium. The term ionized calcium is a misnomer, because all plasma or serum calcium is ionized, whether or not it is associated with protein or small anions by ionic binding. Throughout this chapter, the term *free* calcium is used.

Free calcium is considered the best indicator of calcium status because it is biologically active and tightly regulated by PTH and $1,25(OH)_2D$.

Measurement of Total Calcium

Methods used to measure the total serum concentrationos calcium include (1) spectrophotometric methods, (2) ion-specific electrode (ISE) methods , and (3) atomic absorption methods.

Spectrophotometric Methods

These methods use metallochromic indicators that change color when they bind calcium. Although less accurate than atomic absorption spectrometry, they have been easier to automate.

o-Cresolphthalein Complexone Method. In alkaline solution, o-cresolphthalein complexone (CPC) forms a red chromophore with calcium, which is measured at a wavelength between 570 and 580 nm. The sample is diluted with acid to release protein-bound and complexed calcium. Interference by magnesium ions is reduced by (1) the addition of 8-hydroxyquinoline, (2) buffering the reaction mixture to near pH 12, and (3) measurement of the absorbance near 580 nm. Additives reduce the turbidity of lipemic specimens and enhance complex formation. Ethanol or other organic solvents may be included to reduce blank absorbance. Multipoint calibration is recommended, and linearity may be improved by adding sodium acetate. Temperature is controlled because the reaction is temperature-sensitive. The CPC and alkaline reagents are stable separately but have limited stability when combined.

Arsenazo III Method. Arsenazo III, at mildly acidic pH (approximately 6), has much higher affinity for calcium than

for magnesium. The solution must be thoroughly buffered, because the spectral properties of arsenazo III are dependent on pH. Binding of calcium to arsenazo III is influenced by buffer and sodium concentration. Interference from most biological pigments is reduced by measuring the calcium-dye complex near 650 nm. With the dry-slide technique, clinically significant interference may be noted in patients receiving citrated blood or blood products. Unlike CPC, arsenazo III is stable as a single reagent.

Ion-Specific Electrode Methods

With ISEs, the specimen is acidified to convert protein-bound and complexed calcium to free calcium before measurement of total calcium. Calcium ISEs are discussed later in this chapter.

Atomic Absorption Methods

Atomic absorption is described in detail in Chapter 9.

Specimen Requirements

Serum and heparinized plasma are the preferred specimens for the measurement of total calcium. Citrate, oxalate, and ethylenediaminetetraacetic acid (EDTA) anticoagulants should not be used because they interfere by forming complexes with calcium. Co-precipitation of calcium with fibrin in heparinized plasma or lipids has been reported with storage or freezing.

Urine specimens should be preserved by adding 20 to 30 mL of 6 mol/L HCl per 24-hour specimen (1 to 2 mL for a random specimen) to prevent calcium salt precipitation. Addition of acid after the collection may not completely dissolve precipitated calcium salts.

Interferences

Hemolysis, icterus, lipemia, paraproteins, magnesium, and gadolinium chelates in contrast agents have been reported to interfere with photometric methods. Many methods use (1) bichromatic analysis, (2) multiwavelength corrections, or (3) blanking to reduce interference. Although hemolysis causes a negative error because red blood cells contain lower concentrations of calcium than does serum, more significant errors may be caused by the spectral interference of hemoglobin. Depending on the method, hemoglobin has been reported to produce either negative or positive interference. In photometric methods, if hemolyzed specimens must be analyzed, blanking with ethylene glycol tetraacetic acid (EGTA) is suggested. Individual instruments and methods should be evaluated for their susceptibility to interferants. Gadolinium magnetic resonance contrast agents (gadodiamide [Omniscan] and gadoversetamide [OptiMARK]) cause a significant error (usually underestimation) in spectrophotometric methods.

How the patient is prepared and the specimen obtained affect both free and total calcium measurements as discussed later in this chapter.

Adjusted or Corrected Total Calcium

Various calculations have been used to adjust or correct total calcium for variations in protein concentration. The following equation is often seen in textbooks, but fails to consider the lack of harmonization of albumin and calcium methods, and differences in patient populations:

$$\text{Adjusted Total Calcium (mg/dL)} = \text{Total Calcium (mg/dL)} + 0.8\,[4 - \text{Albumin (g/dL)}]$$

$$\text{Adjusted Total Calcium (mmol/L)} = \text{Total Calcium (mmol/L)} + 0.02\,[40 - \text{Albumin (g/L)}]$$

Some factors limiting the ability of total and adjusted calcium to predict free calcium are listed in Box 39-3. When possible, mathematical adjustments or corrections should be replaced by direct determination of free calcium.

BOX 39-3 Factors Altering the Distribution of Calcium among the Protein-Bound, Complexed, and Free Pools

Factors Altering Protein Binding of Calcium	Factors Altering Complex Formation
Altered concentration of albumin or globulins	Citrate
Abnormal proteins	Bicarbonate
Heparin	Lactate
pH	Phosphate
Free fatty acids	Pyruvate and β-hydroxybutyrate
Bilirubin	Sulfate
Drugs	Anion gap
Temperature	

Measurement of Free Calcium

ISEs are widely used for the rapid measurement of free calcium, electrolytes, and blood gases (see Chapters 10 and 24). Calcium ISEs contain a calcium-selective membrane and an internal reference electrode.

Modern calcium ISEs use liquid membranes containing the ion-selective calcium sensor dissolved in an organic liquid trapped in a polymeric matrix. Neutral carriers (e.g., ETH 1001) are the most commonly used calcium sensors, followed by ion exchangers, such as organophosphate.

Temperature affects electrode response and the extent of calcium binding by protein and small anions. Most free calcium analyzers adjust and maintain samples at 37 °C, thereby ensuring that results are physiologically relevant for the majority of patients and allowing samples to be chilled before analysis (see discussion below).

Interferences

Because ISEs measure ion activity, they are affected by the ionic strength of a specimen. Free calcium analyzers and calibrators are optimized for specimens of (1) serum, (2) plasma, or (3) whole blood. Because the ionic strength of these fluids is primarily a result of Na^+ and Cl^- in the plasma or serum, calibrators are usually prepared in buffer and NaCl with a final ionic strength of 160 mmol/kg. Errors occur with specimens other than serum, plasma, or whole blood unless the matrices

and ionic strength of the calibrators and samples are matched closely.

Modern electrodes have a high selectivity for calcium over (1) Na^+, (2) K^+, (3) Mg^{2+}, (4) H^+, and (5) Li^+. At physiological concentrations, these cations have little effect on the measurement of free calcium. Wide variations, however, in the concentration of Na^+ and high concentrations of Mg^{2+} and Li^+ may influence the apparent concentration of free calcium.

Newer electrodes use a dialysis membrane or neutral carrier to reduce or eliminate the protein effect observed with earlier electrodes. With current electrodes, the effect is less than 0.02 mmol/L for 1 g/dL (10 g/L) of protein. Protein deposits on the electrode may also act as a divalent cation exchanger, resulting in positive interference with high concentrations of Mg^{2+} Regular instrument maintenance and protein removal are reported to minimize this interference.

A number of chemicals may interfere with calcium ISEs or alter free calcium concentrations. Anionic surfactants and ethanol affect the calcium-selective membrane. Physiological anions, including (1) protein, (2) phosphate, (3) citrate, (4) lactate, (5) sulfate, and (6) oxalate, and chemicals, such as (7) EDTA and (8) EGTA, form complexes with calcium and reduce free calcium.

Effect of pH

T e binding of calcium by protein and small anions is influenced by pH in vitro and in vivo. Albumin, with up to 30 binding sites for calcium, accounts for approximately 80% of the protein-bound calcium. Increasing the pH of a specimen in vitro increases the ionization and negative charge on albumin and other proteins, leading to an increase in protein-bound calcium and a decrease in free calcium. Decreasing pH in vitro decreases ionization and negative charge, decreasing protein-bound calcium and increasing free calcium. Free calcium changes by about 5% for each 0.1 unit change in pH.

Because of this inverse relationship between free calcium and pH, specimens should be analyzed at the patient's in vivo blood pH.

Specimen Requirements

Specimens for free calcium measurement must be collected and handled anaerobically and promptly to minimize alterations in pH and free calcium due to the loss of CO_2 and the metabolism of blood cells. Syringes and evacuated tubes should be filled completely and sealed to prevent the loss of CO_2 (increase in pH). Specimens should also be handled to prevent the production of lactic acid (decrease in pH) by erythrocytes or white blood cells during anaerobic metabolism or glycolysis. Unless the specimens can be analyzed or processed promptly, specimens should be (1) collected, (2) transported, and (3) maintained on ice to prevent anaerobic metabolism.

Free calcium is measured in (1) heparinized whole blood, (2) heparinized plasma, or (3) serum. For the majority of laboratories in which specimens are analyzed within 30 minutes, heparinized whole blood may be preferable because it reduces processing time and specimen volume requirements and avoids the alteration in pH associated with centrifugation at temperatures other than 37 ℃. Free calcium is reported to be stable in whole blood specimens for 1 hour at room temperature and for 4 hours at 4 ℃. If specimens are not promptly analyzed, they should be collected in an ice water slurry to minimize metabolism, but plasma K^+ concentrations may be significantly increased because of the inhibition of Na^+,K^+-ATPase. If analysis is not completed within 1 hour, serum collected in evacuated gel tubes may be the optimal specimen. T e tubes should be filled completely. Once centrifuged, specimens are stable for hours at 25 ℃ and for days at 4 ℃, provided the tube remains sealed. Free calcium has been reported to be less stable in specimens from both acidotic and nonacidotic patients with uremia.

T e free calcium concentration and the actual pH of the specimen should be reported on each specimen. T e pH is useful in verifying that the specimen has been properly handled. Aerobic handling of specimens and correction of the free calcium to pH 7.4 may be misleading in patients with alkalosis or acidosis and should be avoided.

Effects of Anticoagulants

Heparin is the only acceptable anticoagulant for free calcium determinations, but it lowers free calcium at the concentrations (30 to 100 U/mL or more) found in many conventional blood gas syringes. T e use of liquid heparin should be avoided; it may result in falsely low free calcium because of (1) dilution of the blood specimen with liquid heparin, and (2) binding of free calcium by high concentrations of heparin. Citrate, oxalate, and EDTA bind calcium and unacceptably decrease free calcium concentrations.

Several commercially-available syringes are suitable for free calcium determinations: (1) electrolyte-balanced or calcium-titrated heparin syringes (final concentration of 40 to 50 U/mL); (2) very low heparin syringes with heparin in an inert filler, providing a final heparin concentration of 2 to 3 U/mL; and (3) lithium-zinc heparin (50 U/ mL) syringes. With electrolyte-balanced or calcium-titrated heparin syringes, the heparin is titrated with calcium so that the plasma free calcium concentration is not appreciably altered at most observed concentrations (3.6 to 6.4 mg/dL, or 0.9 to 1.6 mmol/L); however, some bias may be apparent at very low and high free calcium concentrations. Unlike electrolyte-balanced or calcium-titrated heparin, lithium-zinc heparin does not alter total calcium concentration; magnesium, however, was increased by 0.19 mg/dL or 0.08 mmol/L.

Most evacuated collection tubes, when filled completely, contain concentrations of heparin (15 U/mL) that only slightly decrease free calcium. Specific brands or even batches of syringes, evacuated tubes, and heparin should be carefully evaluated.

Patient Preparation and Sources of Preanalytical Error for Total and Free Calcium Measurements

Patient preparation and specimen collection affect the results of total and free calcium measurements (Box 39-4).

A common and important source of preanalytical error is the increase in total, but not free, calcium associated with

tourniquet use and venous occlusion during sampling. Errors of 0.5 to 1.0 mg/dL or 0.12 to 0.25 mmol/L in total calcium may result because of the increase in protein-bound calcium caused by the efflux of water from the vascular compartment during stasis. If a tourniquet is required, it should be applied just before sampling and released within 1 minute.

Fist clenching or other forearm exercise should be avoided before phlebotomy because forearm exercise causes a decrease in pH (lactic acid production) and an increase in free calcium.

Changes in posture cause fluid shifts and alter the concentration of cells and large molecules, including albumin and total calcium (as part of it is protein-bound) in the vascular compartment. Postural changes of about 10% in the concentrations of albumin and other proteins are common, but usually not noticed. By contrast, the changes in calcium are noticed, because the reference interval for calcium is narrow and small differences in measured calcium concentrations move the results from within the reference interval outside it or vice versa. Standing decreases intravascular water and increases the total calcium concentration by 0.2 to 0.8 mg/dL or 0.05 to 0.20 mmol/L. The hemodilution caused by recumbency (along with hypoalbuminemia) contributes to the increased prevalence of hypocalcemia (total, but not free calcium) often observed in hospital patients.

Most other preanalytical factors are less likely to lead to confusion. In a few patients, prolonged immobilization and bed rest lead to bone resorption and increase total and free calcium in blood. Hyperventilation and exercise decrease and increase the concentration of free calcium, respectively, because of changes in serum pH. Both serum free calcium and calcium excretion are lower during the night. Food ingestion has been reported to have various effects, but usually causes a slight increase in serum calcium. Ingestion of calcium salts may increase serum calcium. Hemolysis can alter free calcium because of dilution and alterations in pH and its binding (see previous discussion under Interferences).

Reference Intervals

The reference interval for total calcium in adults is approximately 8.6 to 10.3 mg/dL or 2.15 to 2.57 mmol/L. The reference interval for free calcium in adults is about 4.6 to 5.3 mg/dL or 1.15 to 1.33 mmol/L.

Total calcium declines in parallel with serum albumin during pregnancy, whereas free calcium remains unchanged.

Healthy men and women excrete up to 300 mg or 7.5 mmol of calcium per day on a diet with unrestricted calcium content, and up to 200 mg/day or 5 mmol/day on a calcium-restricted diet (500 mg or 12.5 mmol dietary calcium per day or less for several days).

Because of the dependence of free calcium on pH, it is recommended that pH be measured and reported with all free calcium determinations. T is will assist the laboratory and physician in identifying specimens in which inappropriate preanalytical handling has led to an in vitro change in pH.

Whole blood specimens develop a liquid-junction potential different from that of serum or plasma because of the presence of cells. A positive bias in free calcium that is directly proportional to the hematocrit has been reported. In addition, free calcium values have been reported to differ among capillary blood, venous blood, and serum samples because of differences in pH.

The desirable analytical coefficients of variation, based on within-person biological variation, are 0.9% and 1.0% or less, respectively, for free and total calcium.

BOX 39-4 Preanalytical Factors in Measurement of Serum Total or Free Calcium

In Vivo	In Vitro
Tourniquet use and venous occlusion	Inappropriate anticoagulants
Changes in posture: 10% to 12% increase of total calcium and 5% to 6% increase of free calcium on standing	Dilution with liquid heparin
Exercise	Interfering concentrations of heparin
Hyperventilation	Contamination with calcium
Fist clenching	Corks, glassware, tubes
Alimentary status	Specimen handling
Alterations in protein binding	Alterations in pH (free calcium)
Alterations in complex formation	Adsorption or precipitation of calcium
	Spectrophotometric interference
	Hemolysis, icterus, lipemia

Phosphate

Phosphorus in the form of inorganic and organic phosphate is an important and widely distributed element in the human body (see Table 39-1 and Table 39-2). Inorganic phosphate is the fraction measured in serum and plasma by clinical laboratories.

Biochemistry and Physiology

Phosphate in plasma exists as both monovalent ($H_2PO_4^-$) and divalent (HPO_4^{2-}) phosphate anions. In blood, organic phosphate esters are located primarily within cells. Inorganic phosphate is a major component of hydroxyapatite in bone.

In the soft tissue, most phosphate is cellular. Most of the phosphate in cells is organic and incorporated into nucleic acids, phospholipids, phosphoproteins, and high-energy compounds, such as adenosine triphosphate (ATP). Phosphate is also an essential element of cyclic nucleotides (such as, cyclic adenosine monophosphate [cAMP]) and

TABLE 39-2 Physiochemical States of Calcium, Phosphate, and Magnesium in Normal Plasma

	Approximate Percent of Total		
State	Calcium	Phosphate	Magnesium
Free (ionized)	50	55	55
Protein-bound	40	10	30
Complexed	10	35	15
Total (mg/dL)	8.6-10.3	2.5-4.5	1.7-2.4
(mmol/L)	2.15-2.57	0.81-1.45	0.70-0.99

Modified from Marshall RW. Plasma fractions. In: Nordin BEC, ed. Calcium, phosphate, and magnesium metabolism. London: Churchill Livingstone, 1976:162-85.

nicotinamide-adenine dinucleotide phosphate (NADP). It is important for the activity of several enzymes.

Hypophosphatemia

Hypophosphatemia, defined as the concentration of inorganic phosphate in the serum below the reference interval, usually <2.5 mg/dL or <0.81 mmol/L, is relatively common in hospitalized patients (approximately 2%).

Hypophosphatemia may be present when cellular concentrations are within physiological reference intervals, and cellular phosphate depletion may exist when serum concentrations are within serum reference intervals or even elevated. Hypophosphatemia or phosphate depletion may be caused by (1) a shift of phosphate from extracellular to intracellular spaces, (2) renal phosphate wasting, (3) decreased intestinal absorption, and (4) loss from intracellular phosphate. Box 39-5 lists the commonly encountered causes of hypophosphatemia and phosphate depletion.

Injected insulin and carbohydrate-induced stimulation of insulin secretion increase the transport of phosphate and glucose into cells and thus are common causes of hypophosphatemia. Refeeding of malnourished individuals causes an intracellular shift of phosphate. Respiratory alkalosis leads to an increase in intracellular pH, which activates phosphofructokinase and accelerates glycolysis, causing a shift of phosphate into the cell.

In some instances, (1) excessive PTH secretion, (2) Fanconi syndrome, (3) X-linked hypophosphatemic **rickets**, and (4) tumor-induced **osteomalacia** will result in loss of phosphate in urine and may also cause hypophosphatemia or phosphate depletion.

Hypophosphatemia or phosphate depletion due to inadequate phosphate absorption is less common, given the abundance of phosphate in the diet, but may occur in individuals taking aluminum- or magnesium-containing antacids and in patients with malabsorption. The antacids bind phosphate, thus hindering its absorption. The hypophosphatemia and phosphate depletion in patients with malabsorption may be more closely related to their secondary hyperparathyroidism (and resulting loss of phosphorus in urine) than to malabsorption of phosphate.

Intracellular phosphate may be lost in acidosis as a result of the catabolism of organic compounds within the cell. Diabetic ketoacidosis is associated initially with high-normal to increased serum phosphate. Treatment of the ketosis and acidosis with insulin and intravenous fluids, however, results in a rapid decrease in the serum phosphate concentration. Consequently, patients being treated for diabetic ketoacidosis may have both intracellular phosphate depletion and hyperphosphatemia.

The clinical manifestations of serum phosphate depletion depend on the length and degree of the deficiency. Plasma concentrations <1.5 mg/dL or <0.48 mmol/L may produce clinical manifestations. Because phosphate is necessary for the formation of ATP, both glycolysis and cellular function are impaired by low intracellular phosphate concentrations. Other conditions that may occur in phosphate depletion include (1) muscle weakness, (2) acute respiratory failure, and (3) decreased cardiac output. At very low serum phosphate (<1 mg/dL or <0.32 mmol/L), rhabdomyolysis may occur. Phosphate depletion in erythrocytes decreases erythrocyte 2,3-diphosphoglycerate, which causes tissue hypoxia because of increased affinity of hemoglobin for oxygen. Severe hypophosphatemia (serum phosphate concentration <0.5 mg/dL or <0.16 mmol/L) may result in hemolysis of red blood cells. Mental confusion and frank coma also may be secondary to the low ATP and tissue hypoxia. If hypophosphatemia is chronic, rickets (in children) and osteomalacia (in adults) may develop.

BOX 39-5 Causes of Hypophosphatemia and Phosphate Depletion

- Intracellular shift
  - Glucose
    - Oral or intravenous
    - Hyperalimentation
  - Insulin
  - Respiratory alkalosis
- Lowered renal phosphate threshold
  - Primary or secondary hyperparathyroidism
  - Renal tubular defects
    - Familial hypophosphatemia
  - Fanconi syndrome
- Decreased net intestinal phosphate absorption
  - Increased loss
    - Vomiting
    - Diarrhea
    - Phosphate-binding antacids
  - Decreased absorption
    - Malabsorption syndrome
    - Vitamin D deficiency
- Intracellular phosphate loss
  - Acidosis
    - Ketoacidosis
    - Lactic acidosis

Treatment of hypophosphatemia depends on the degree of hypophosphatemia and the presence of symptoms. Patients with moderate hypophosphatemia may require only treatment of the underlying disorder or oral phosphate supplementation. In patients with severe symptoms of hypophosphatemia, particularly if respiratory muscle weakness is present, parenteral administration of phosphate may be indicated.

Hyperphosphatemia

Hyperphosphatemia is usually secondary to the inability of the kidneys to excrete phosphate, as in renal failure. Moderate increases of serum phosphate occur in individuals with (1) low PTH (hypoparathyroidism), (2) PTH resistance (pseudohypoparathyroidism), or (3) acromegaly (increased growth hormone), caused by an elevated renal phosphate threshold. Other common causes of hyperphosphatemia are listed in Box 39-6.

A rapid increase in serum phosphate may be associated with hypocalcemia. Therefore symptoms may include (1) tetany, (2) seizures, and (3) hypotension. Long-term hyperphosphatemia may be associated with (1) secondary hyperparathyroidism, (2) osteitis fibrosa, and (3) soft tissue calcification of the kidneys, blood vessels, cornea, skin, and periarticular tissue.

Therapy for hyperphosphatemia is directed toward correcting the cause of the high serum phosphate. In renal failure and in hypoparathyroidism, dietary restriction of phosphate and agents that bind phosphate in the intestine (calcium carbonate and others) are useful in lowering the serum phosphate concentrations.

BOX 39-6 Causes of Hyperphosphatemia

- Decreased renal phosphate excretion
  - Decreased glomerular filtration rate
    - Renal failure, chronic and acute
  - Increased tubular reabsorption
    - Hypoparathyroidism
    - Pseudohypoparathyroidism
    - Acromegaly
    - Disodium etidronate ingestion
- Increased phosphate intake
  - Oral or intravenous administration
  - Phosphate-containing laxatives or enemas
- Increased extracellular phosphate load
  - Transcellular shift
    - Lactic acidosis
    - Respiratory acidosis
    - Untreated diabetic ketoacidosis
  - Cell lysis
    - Rhabdomyolysis
    - Intravascular hemolysis
    - Cytotoxic therapy
    - Leukemia
    - Lymphoma

Measurement of Phosphate

All widely used methods for serum inorganic phosphate are based on the reaction of phosphate ions with ammonium molybdate to form a phosphomolybdate complex that is then measured spectrophotometrically. The colorless phosphomolybdate complex is measured directly by ultraviolet (UV) absorption (340 nm), or it is reduced to colored molybdenum blue (600 to 700 nm) by one of several reducing agents, such as aminonaphtholsulfonic acid (ANS). An acid pH is necessary for the formation of the complexes but must be controlled because both complex formation and reduction of molybdate are dependent on pH. Measurement of unreduced complexes has several advantages, including (1) simplicity, (2) speed, and (3) stability. One disadvantage is the greater interference of hemolysis, icterus, and lipemia at 340 nm.

Specimen Requirements

Serum and heparinized plasma are the preferred specimens for the measurement of phosphate. Concentrations of inorganic phosphate are about 0.2 to 0.3 mg/dL or 0.06 to 0.10 mmol/L lower in heparinized plasma than in serum. Anticoagulants (such as, citrate, oxalate, and EDTA) should not be used because they interfere with the formation of the phosphomolybdate complex.

Phosphate concentrations in plasma or serum are increased by prolonged storage with cells at room temperature or 37 °C. Hemolyzed specimens are unacceptable because erythrocytes contain high concentrations of organic phosphate esters, which hydrolyze to inorganic phosphate. Inorganic phosphate increases by 4 to 5 mg/dL or 1.29 to 1.61 mmol/L per day in hemolyzed specimens stored at 4 °C, more rapidly at room temperature or 37 °C.

Phosphate is stable in separated serum for days at 4 °C and for months when frozen, provided evaporation is prevented.

Interferences

Depending on the method used, positive or negative interference has been noted with (1) hemolyzed, (2) icteric, and (3) lipemic specimens. Mannitol, fluoride, and monoclonal immunoglobulins have also been reported to interfere. Phosphate is a common component of detergents.

Reference Intervals

In adults, the reference interval for serum phosphate is 2.5 to 4.5 milligram of phosphorus per deciliter or 0.81 to 1.45 mmol/L. In children it is higher, 4.0 to 7.0 milligram of phosphorus per deciliter or 1.29 to 2.26 mmol/L, because growth hormone increases the renal phosphate threshold. Serum phosphate is lower during pregnancy. Serum phosphate increases after meals and exercise and exhibits a diurnal variation with higher concentrations in the afternoon and evening.

Urinary phosphate varies with (1) age, (2) muscle mass, (3) renal function, (4) PTH activity, (5) time of day, and (6) other factors. Urinary excretion of phosphate varies widely with diet and is essentially equivalent to dietary intake. On a nonrestricted diet, the reference interval for urinary phosphate is 0.4 to 1.3 g/day or 12.9 to 42.0 mmol/day.

Urine should be collected in 6 mol/L HCl, 20 to 30 mL for a 24-hour specimen, to prevent precipitation of phosphate.

Magnesium

Magnesium is the fourth most abundant cation in the body. Approximately 55% of the total body magnesium is in the skeleton and 45% is intracellular; in cells it is the most prevalent cation (see Table 39-1).

Biochemistry and Physiology

The concentration of magnesium in cells is approximately 2.4 to 7.3 mg/dL or 1 to 3 mmol/L. Within the cell, most of the magnesium is bound to proteins and negatively charged molecules, notably ATP. Extracellular magnesium accounts for about 1% of the total body magnesium content. About 55% of plasma magnesium is free (see Table 39-2).

Magnesium is (1) a cofactor for more than 300 enzymes, (2) required for enzyme substrate complex formation (e.g., MgATP), and (3) an allosteric activator of many enzyme systems. Reducing the serum magnesium concentration results in increased neuromuscular excitability, because magnesium competitively inhibits the entry of calcium into neurons.

Hypomagnesemia/Magnesium Deficiency

Hypomagnesemia is common in hospitals. Ten percent of the patients admitted to city hospitals and as many as 65% of patients in intensive care units may be hypomagnesemic. In many cases, the hypomagnesemia appears to reflect a shift into cells because it resolves without magnesium replacement. The causes of magnesium deficiency are shown in Box 39-7. Moderate or severe magnesium deficiency is usually due to losses of magnesium from the gastrointestinal (GI) tract or kidneys.

Magnesium deficiency is commonly associated with losses from the lower intestine in diarrhea. Because magnesium is

BOX 39-7 Causes of Magnesium Deficiency

- Gastrointestinal disorders
  - Prolonged nasogastric suction
  - Malabsorption syndromes
  - Extensive bowel resection
  - Acute and chronic diarrhea
  - Intestinal and biliary fistulas
  - Protein-calorie malnutrition
  - Acute hemorrhagic pancreatitis
  - Primary hypomagnesemia (neonatal)
- Renal loss
  - Chronic parenteral fluid therapy
  - Osmotic diuresis
    - Glucose (diabetes mellitus)
    - Mannitol
    - Urea
  - Hypercalcemia
  - Alcohol
  - Drugs
    - Diuretics (furosemide, ethacrynic acid)
    - Aminoglycosides
    - Cisplatin
    - Cyclosporine
    - Amphotericin B
    - Cardiac glycosides
    - Pentamidine
    - Tacrolimus
  - Metabolic acidosis (starvation, ketoacidosis, alcoholism)
  - Renal diseases
    - Chronic pyelonephritis, interstitial nephritis, and glomerulonephritis
    - Diuretic phase of acute tubular necrosis
    - Postobstructive nephropathy
    - Renal tubular acidosis
    - Postrenal transplantation
  - Primary hypomagnesemia
  - Phosphate depletion

BOX 39-8 Causes of Hypermagnesemia

- Excessive intake
  - Orally (usually in the presence of chronic renal failure)
    - Antacids
    - Cathartic
  - Rectally
    - Purgation
  - Parenterally
    - Treatment of pregnancy-induced hypertension
    - Treatment of magnesium deficiency
- Renal failure
  - Chronic, usually with administration of magnesium:
    - Antacid
    - Cathartic
    - Enema
    - Infusion
    - Dialysis fluid
  - Acute
    - Rhabdomyolysis
- Familial hypocalciuric hypercalcemia
- Lithium ingestion

most efficiently absorbed from the distal small bowel, malabsorption and bypass surgery for obesity are also associated with magnesium malabsorption. Nasogastric suction or vomiting may deplete body stores of magnesium as upper GI fluids contain approximately 0.5 mmol/L of magnesium.

Excessive urinary losses of magnesium from the kidneys are important causes of magnesium deficiency in (1) in alcoholism, (2) in diabetes mellitus (osmotic diuresis), (3) with loop diuretics (furosemide) and (4) with aminoglycoside antibiotics. Increased sodium excretion (parenteral fluid therapy) and increased calcium excretion (hypercalcemia) also result in renal magnesium wasting.

Neuromuscular hyperexcitability with tetany and seizures may be present. Magnesium deficiency impairs PTH secretion and causes end-organ resistance to PTH, which may result in hypocalcemia. Cardiac arrhythmias have been associated with magnesium deficiency and are partly caused by the hypokalemia and intracellular potassium depletion that occur in magnesium deficiency.

Hypomagnesemia is not necessarily an indication of magnesium deficiency. Conversely, intracellular magnesium depletion and magnesium deficiency may exist despite a normal serum magnesium concentration.

Acute symptomatic magnesium deficiency is usually treated with parenteral magnesium; mild depletion may be treated with oral magnesium.

Hypermagnesemia

Magnesium intoxication is not common, although serum magnesium concentrations may be mildly or moderately increased in as many as 12% of hospital patients. Symptomatic **hypermagnesemia** is usually caused by excessive intake, resulting from the administration of (1) antacids, (2) enemas, and (3) parenteral fluids containing magnesium (Box 39-8). Most symptomatic patients have concomitant renal failure, which limits the ability of the kidneys to excrete excess magnesium. Magnesium is a standard therapy for pregnancy-induced hypertension (preeclampsia and eclampsia); magnesium intoxication may be seen in mothers and their neonates.

Depression of the neuromuscular system is the most common manifestation of magnesium intoxication. Deep tendon reflexes disappear at a serum magnesium concentration above 5 to 9 mg/dL or 2.06 to 3.70 mmol/L, whereas depressed respiration and apnea, caused by paralysis of voluntary muscles, may occur at serum magnesium concentrations >10 to 12 mg/dL (or >4.11 to 4.94 mmol/L) with cardiac arrest at even higher concentrations.

Because calcium acutely antagonizes the toxic effects of magnesium, patients with severe magnesium intoxication may be treated with intravenous calcium. If necessary, peritoneal dialysis or hemodialysis against a low-magnesium dialysis bath effectively lowers the serum magnesium concentration.

Measurement of Total Magnesium

Serum and plasma total magnesium are commonly measured by spectrophotometric methods and occasionally by atomic absorption methods.

Spectrophotometric Methods

Spectrophotometric methods are commonly used to measure magnesium. T ese methods are defined by the key reagents which include (1) calmagite and methylthymol blue, (2) formazan dye, (2), magon (xylidyl blue), (3) chlorophosphonazo III, and (4) arsenazol. T ese metallochromic indicators generally form a colored complex (red or blue) with

magnesium in alkaline solution, which is measured at around 600 nm. Specific calcium chelating agents (such as EGTA) are added to reduce interference by calcium.

Measurement of Free (Ionized) Magnesium

Free magnesium is determined in (1) whole blood, (2) plasma, or (3) serum by use of commercially-available instruments using ISEs with neutral carrier ionophores. Current ionophores and electrodes, however, have insufficient selectivity for magnesium over calcium. Free calcium is simultaneously determined and used with the signal from the magnesium electrode to calculate free magnesium concentrations.

Specimen Requirements

Serum and heparinized plasma are the preferred specimens for measuring magnesium. Anticoagulants such as (1) zinc heparin, (2) lithium-zinc heparin, and (3) some of the newer heparins developed for free calcium determinations should be avoided because they increase magnesium. Other anticoagulants such as (1) citrate, (2) oxalate, and (3) EDTA also should not be used as they form complexes with magnesium. Storage of serum for days at 4 °C and for months frozen does not affect measured concentrations of total magnesium, provided evaporation of the specimen is prevented.

Serum or plasma must be separated from the clot or red blood cells as soon as possible to prevent an increase in serum magnesium because of cell leakage. Because erythrocytes contain higher concentrations of magnesium than serum or plasma, hemolyzed specimens are unacceptable. Interference by icterus or lipemia depends on the method and can be decreased by use of bichromatic analysis or blanking with EDTA. Lipemic specimens should be ultracentrifuged.

Urine specimens should be collected in acid (e.g., HCl, 20 to 30 mL of 6 mol/L for a 24-hour specimen) to prevent precipitation of magnesium complexes.

Reference Intervals for Total Magnesium

For adults, the reference interval for serum magnesium is approximately 1.7 to 2.4 mg/dL (0.66 to 1.07 mmol/L). Erythrocytes have magnesium concentrations approximately three times those of serum. Care should be taken when interpreting magnesium concentrations, because results in mg/dL and mEq/L are not readily distinguishable unless the units are attached.

Hormones Regulating Mineral Metabolism

PTH and $1,25(OH)_2D$ are the primary hormones regulating bone and mineral metabolism.[1,3,9,10] **Calcitonin** has pharmacological actions, but a physiological role has not been established in adults. PTHrP is the principal mediator of HHM.

Parathyroid Hormone

Parathyroid hormone (PTH) is synthesized and secreted by the four parathyroid glands located bilaterally in the neck (two on the left and two on the right), on or near the thyroid gland capsule. The glands are composed of chief and oxyphil cells. These cells (1) synthesize, (2) store, and (3) secrete PTH. Ectopic parathyroid glands in the thorax are not uncommon.

Biochemistry and Physiology

The concentration of PTH in plasma is determined by its synthesis and secretion by the parathyroids and by its metabolism and clearance by the liver and kidneys. PTH acts directly on bone and kidney.

Synthesis and Secretion

PTH is synthesized as a precursor, pre-pro-PTH (Figure 39-3). Both the "pre" and "pro" sequences are cleaved off enzymatically within the cell. Intact PTH (84 amino acids, molecular mass of 9425 Da) is either secreted, stored, or degraded intracellularly.

The concentration of free calcium in blood or extracellular fluid is the primary physiological regulator of PTH synthesis and secretion. Free calcium is sensed by a calcium-sensing receptor in the plasma membrane of parathyroid cells. This receptor activates intracellular events that lead to (1) inhibition of PTH synthesis and secretion and (2) enhancement of PTH metabolism. A decrease of plasma calcium has the opposite effect.

Magnesium and $1,25(OH)_2D$ also influence the synthesis and secretion of PTH. The $1,25(OH)_2D$ interacts with vitamin D receptors in the parathyroid glands to chronically suppress PTH synthesis. Chronic severe hypomagnesemia, such as that occurring in alcoholism, has been associated with impaired PTH secretion, whereas acute hypomagnesemia may stimulate secretion. Hypomagnesemia has also been reported to impair the action of PTH on target cells.

Biological Actions

PTH influences both calcium and phosphate homeostasis, directly through its own actions on both bone and kidney and indirectly on the intestine through $1,25(OH)_2D$. Biological activity resides in the first third or N-terminal region of PTH. Synthetic PTH(1-34) is at least as potent as PTH(1-84) at stimulating (1) calcemic, (2) phosphaturic, and (3) other biological responses in kidney and bone. PTH exerts its actions by interacting with PTH/PTHrP receptors located in the plasma membrane of target cells; it increases cyclic AMP and initiates a cascade of intracellular events.

In the kidneys, PTH (1) increases calcium reabsorption in the distal convoluted tubule of the nephron, (2) decreases reabsorption of phosphate by the proximal tubule, and (3) inhibits Na^+-H^+ antiporter activity, which favors a mild hyperchloremic metabolic acidosis in hyperparathyroid states, and (4) induces 25-hydroxyvitamin D-1α-hydroxylase, increasing the production of $1,25(OH)_2D$, which stimulates intestinal absorption of both calcium and phosphate.

The effects of PTH on bone are complex, as evidenced by its stimulation of either bone resorption or bone formation, depending on the concentration of PTH and on the duration

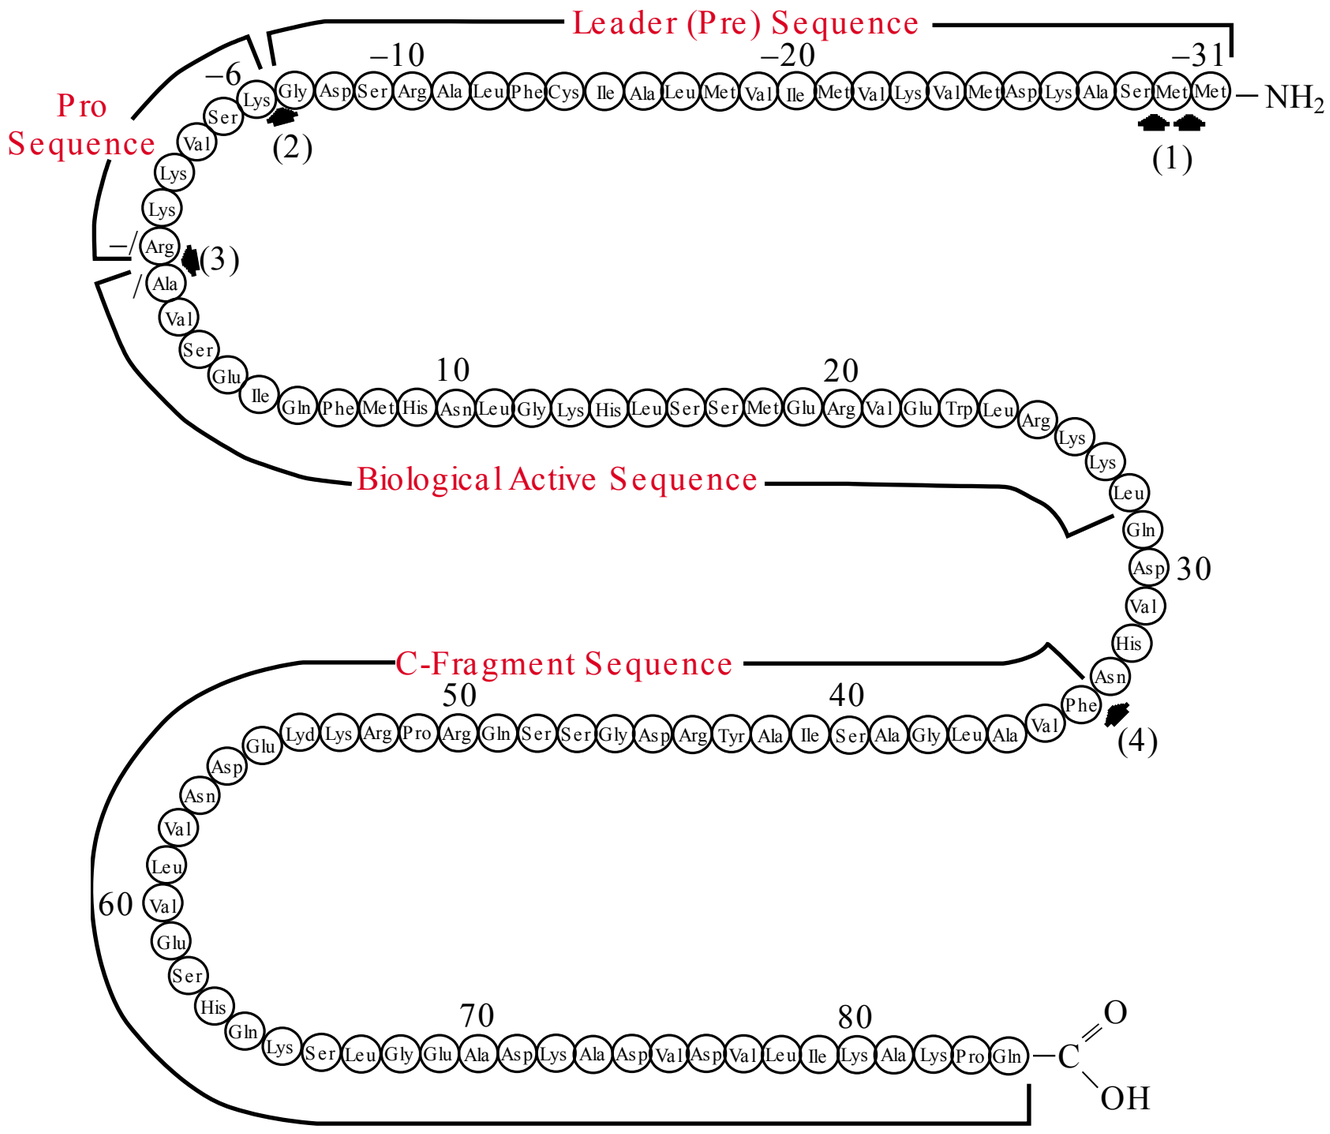

Figure 39-3 Amino acid sequence of pre-proparathyroid hormone. Arrows indicate the sites of cleavage by proteases to remove the N-terminal methionines (1), the leader (pre) sequence (2), and the pro sequence (3), producing intact parathyroid hormone (PTH) (1-84). Cleavage at position (4) produces inactive carboxyl (C)-terminal fragments. (From Habener JF, Rosenblatt M, Potts JT Jr. Parathyroid hormone: biochemical aspects of biosynthesis, secretion, action, and metabolism. Physiol Rev 1984;64:985-1053.)

of exposure. Bone resorption, a prompt effect, is important for the maintenance of calcium homeostasis, whereas delayed effects are important for extreme systemic needs and skeletal homeostasis.

PTH (1) increases total and free plasma calcium, (2) decreases plasma phosphate, and (3) increases urinary excretion of inorganic phosphate. Urinary calcium is usually increased, because the larger filtered load of calcium (deriving from bone resorption and intestinal calcium absorption) overrides the increased tubular reabsorption of calcium.

Metabolism and Circulating Heterogeneity

PTH circulates as intact hormone and inactive carboxyl (C)-terminal fragments. Its heterogeneity is a consequence of (1) the secretion of both intact and inactive hormone by the parathyroids, (2) peripheral metabolism of intact hormone by liver and kidney, and (3) renal clearance of intact hormone and inactive fragments. In the parathyroids, secretion of intact PTH is increased by hypocalcemia and greatly reduced or absent in hypercalcemia, whereas secretion of inactive fragments persists in hypercalcemia.

Biologically active intact PTH has a half-life in plasma of less than 5 minutes. It is metabolized to inactive fragments in the liver and kidneys. C-terminal fragments are cleared by glomerular filtration and normally have a half-life of less than 1 hour. T eir half-life and circulating concentration are increased in individuals with impaired renal function. Generally, 5% to 25% of the total immunoreactive PTH in blood is intact hormone, and 75% to 95% is C-terminal fragments. T e relative concentrations of intact hormone and fragments vary with physiology and pathology. More recently, evidence has been presented for circulating forms of PTH missing the first few N-terminal amino acids.[11]

Clinical Significance

Determination of PTH is useful (1) in the differential diagnosis of both hypercalcemia and hypocalcemia, (2) for assessing parathyroid function in renal failure, and (3) for evaluating parathyroid function in bone and mineral disorders. Free or total calcium is usually measured in the same specimen as the PTH because the measured PTH concentration should be interpreted in light of the concomitant calcium result.

PTH is the most important test for differential diagnosis of hypercalcemia. PTH is increased in most patients with primary hyperparathyroidism and below the reference interval in most patients with nonparathyroid hypercalcemia, including those with **hypercalcemia-associated malignancy (HAM)**, the most common cause of nonparathyroid hypercalcemia (Figure 39-4). Primary hyperparathyroidism is (1) most often caused by excessive secretion of PTH by a solitary adenoma, (2) less commonly by multiple hyperplastic glands and (3) uncommonly (<1%) by parathyroid carcinoma. Primary hyperparathyroidism is treated by surgical removal of the adenoma. Intraoperative determination of PTH is helpful in assessing the completeness of parathyroid surgery. A decline of 50% or more from the preoperative concentration is usually considered indicative of successful removal of hyperfunctioning tissue. HAM is usually associated with bone metastases and/or production of PTHrP. Of note, PTHrP does not cross-react in any intact PTH immunoassays that have been evaluated.

PTH is also useful in the differential diagnosis of hypocalcemia. In secondary hyperparathyroidism, PTH is increased before total or free calcium becomes abnormally low. Chronic renal failure is a common cause of hypocalcemia. Magnesium deficiency may impair PTH secretion resulting in unexpectedly low or normal concentrations of PTH. Patients with

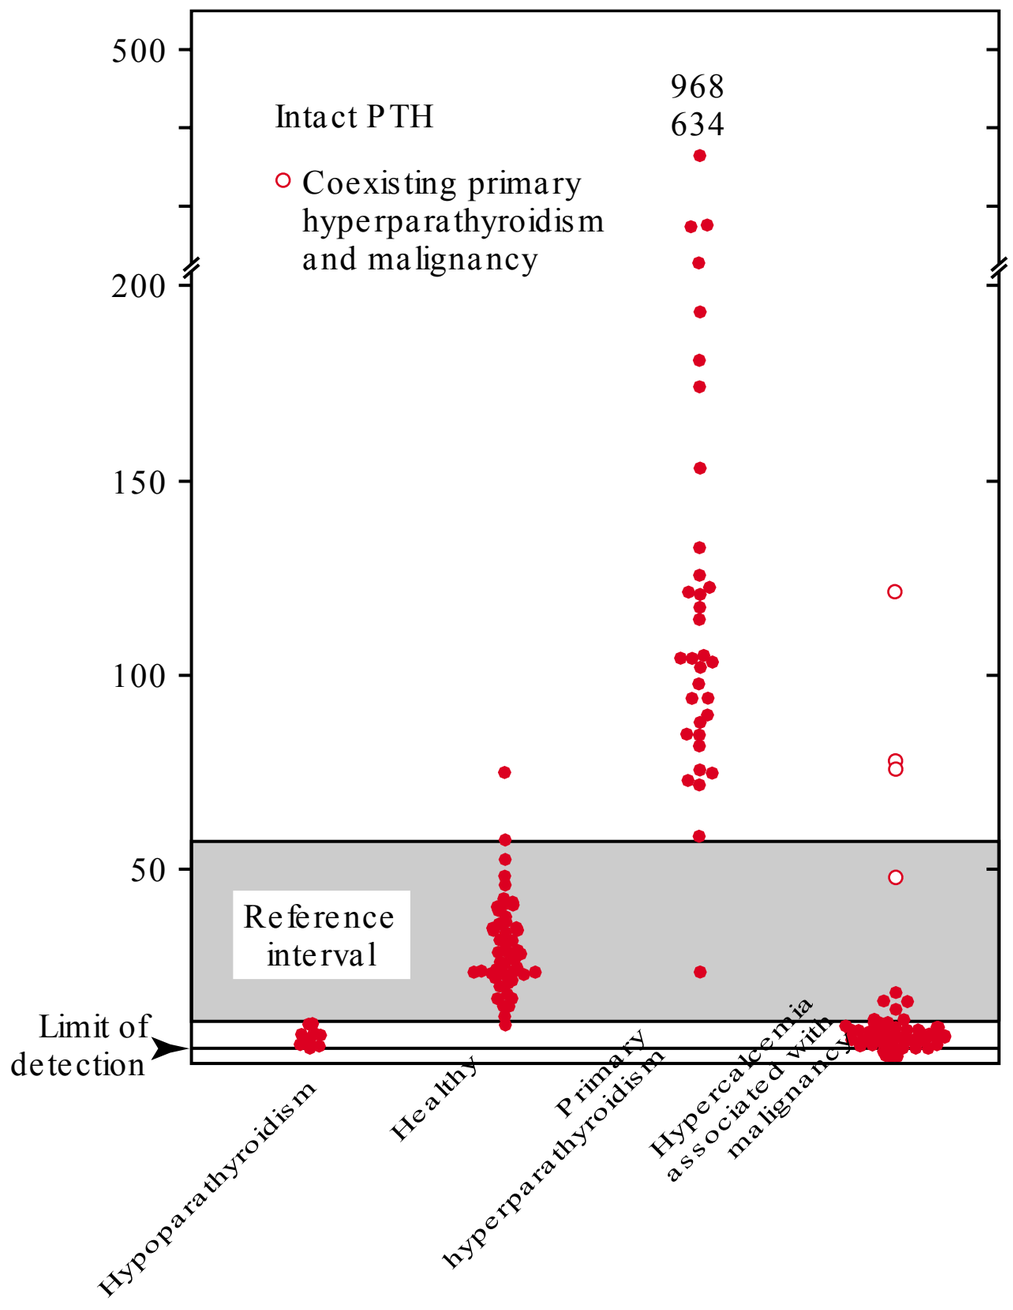

Figure 39-4 Intact parathyroid hormone (PTH) in healthy subjects and patients with primary hyperparathyroidism, hypercalcemia associated with malignancy, and hypoparathyroidism. (From Endres DB, Villanueva R, Sharp CF Jr, et al. Measurement of parathyroid hormone. Endocrinol Metab Clin North Am 1989;18:611-29.)

hypoparathyroidism have low concentrations of PTH, whereas PTH is increased in patients with pseudohypoparathyroidism.

In patients with end-stage renal disease, measurement of PTH is helpful in (1) assessing parathyroid function, (2) estimating bone turnover, and (3) improving management (see later section on Metabolic Bone Diseases). Patients with high-turnover bone disease (advanced osteitis fibrosa) have the highest concentration of PTH whereas patients with low-turnover **adynamic bone disease (ABD)**, including osteomalacia, have the lowest concentrations of PTH. A therapeutic goal for intact PTH (as measured with first generation assays) of two to four times the upper limit of the reference interval has been proposed to prevent bone diseases in these patients.

Measurement of Parathyroid Hormone

Two-site or sandwich immunoassays are used to measure intact PTH. These methods require two antibodies capable of simultaneously binding PTH: (1) a solid-phase capture antibody, often directed against the C-terminal region (e.g., amino acid sequences 39-84) and (2) a signal or labeled antibody, often directed against the N-terminal region (e.g., amino acid sequences 1-34). Both antibodies are added in excess to ensure that all PTH is measured. Excess labeled antibody is removed by washing prior to quantification of the labeled antibody attached to the PTH that is captured by the immobilized capture antibody.

A problem in most first-generation methods for intact PTH is that N-terminal—truncated fragment(s) cross-react. The degree of overestimation of intact PTH by first-generation intact PTH assays is method-dependent. Overestimation of intact PTH by 50% in patients with chronic renal failure or primary hyperparathyroidism and by 20% in healthy individuals is not unusual. Radioimmunoassays and other competitive immunoassays should not be used because they primarily measure inactive C-terminal fragments or are not sensitive enough to adequately measure intact PTH.

Specimen Requirements

Serum or EDTA plasma is generally preferred. After separation, the serum or plasma should be frozen if the analysis is delayed. Lower concentrations of PTH are observed in serum incubated at room temperature for more than a few hours or held a day or more at 4 ℃. PTH has been reported to be more stable in EDTA plasma.

Reference Intervals

Reference intervals for PTH are method dependent. Typical reference intervals are 10 to 65 pg/mL or 1.1 to 6.8 pmol/L for first-generation intact PTH and 6 to 40 pg/mL or 0.6 to 4.2 pmol/L for second-generation intact PTH assays. The reported upper limits of the reference intervals may be inappropriately high because of the high prevalence of vitamin D insufficiency, with mild secondary hyperparathyroidism, in the population. Intact PTH concentration is low or normal during pregnancy, but higher during the first few days of life. PTH increases with aging, a possible consequence of mild secondary hyperparathyroidism due to vitamin D insufficiency.

Vitamin D and Its Metabolites

Vitamin D is both produced endogenously by exposure of skin to sunlight and absorbed from foods. Vitamin D is first metabolized to its main circulating form, 25-hydroxyvitamin D [25(OH)D], and then to its biologically more active form, 1,25-dihydroxyvitamin D [1,25$(OH)_2$D], a hormone regulating calcium and phosphate metabolism. The circulating concentration of 25(OH)D reflects vitamin D nutritional status.[3,5,9,10] Deficiency of vitamin D results in impaired formation of bone, producing rickets in children and osteomalacia in adults.

Biochemistry and Physiology

Vitamin D and its metabolites may be categorized as either cholecalciferols or ergocalciferols (Figure 39-5). Cholecalciferol (vitamin D_3) is the parent compound of the naturally occurring family and is produced in the skin from 7-dehydrocholesterol on exposure to the UV B portion of sunlight. Factors that influence production of vitamin D_3 by the skin include (1) latitude, (2) season of the year, (3) aging, (4) sunscreen use, and (5) skin pigmentation. Vitamin D_2 (ergocalciferol), the parent compound of the other vitamin D family, is manufactured by irradiation of ergosterol produced by yeasts. Vitamin D_2 differs from vitamin D_3 by the presence of

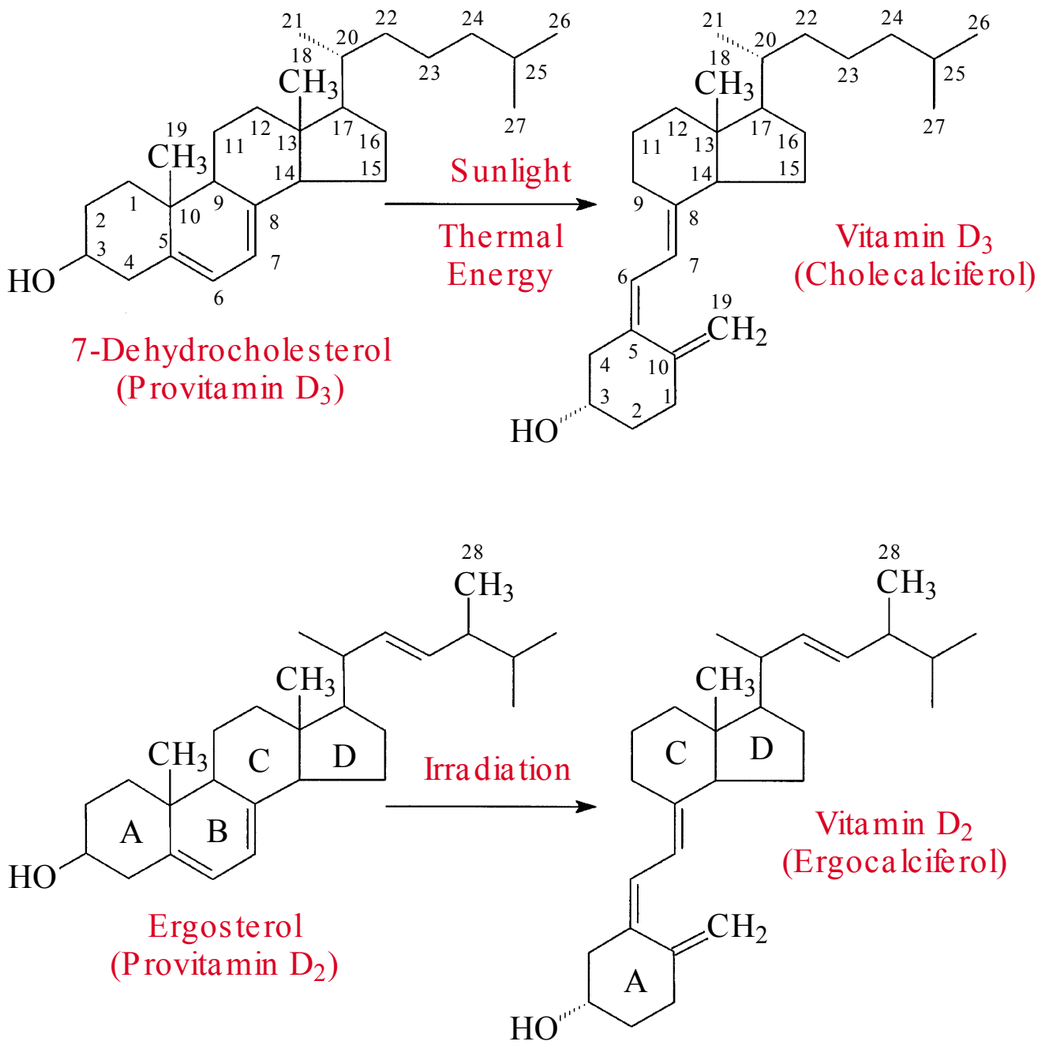

Figure 39-5 Structure of vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol) and their precursors. 7-Cholecalciferol is produced in the skin from exposure of 7-dehydrocholesterol to sunlight. Ergocalciferol is produced commercially by irradiation of ergosterol. (Modifed from Holick MF, Adams JS. Vitamin D metabolism and biological function. In: Avioli LV, Krane SM, eds. Metabolic bone disease, 2nd edition. Philadelphia: WB Saunders, 1990:155-95.)

a double bond between carbon 22 and carbon 23 and a methyl group on carbon 24. When vitamin D or its metabolites are written without a subscript, both families are included.

Vitamin D may be acquired by exposure of skin to sunlight or ingestion of foods containing vitamin D or its metabolites. Only a few foods, primarily (1) fish liver oils, (2) fatty fish, (3) egg yolks, and (4) liver, naturally contain significant amounts of vitamin D. Consequently, before foods were supplemented with vitamin D_2 or vitamin D_3, most vitamin D in the body was produced by synthesis in skin. In North America, a considerable fraction of vitamin D is acquired by ingestion of fortified foods such as (1) cereals, (2) bread products, (3) milk and (4) vitamin D supplements. The recommended daily allowance is 400 IU (10 μg), although higher requirements (800 to 1000 IU) may be needed in the elderly.

Metabolism, Regulation, and Transport

Vitamin D_2 and vitamin D_3 are metabolized to $25(OH)D_2$ and $25(OH)D_3$, respectively, in the liver by vitamin D-25-hydroxylase. These metabolites are then further metabolized to $1,25(OH)_2D_2$ and $1,25(OH)_2D_3$, respectively, in the kidneys (and also in the placenta in pregnant women) by 25(OH)D-1α-hydroxylase (Figure 39-6). The biologically most-active form of vitamin D is $1,25(OH)_2D$, whereas 25(OH)D is the main circulating form of vitamin D (Table 39-3). Circulating concentrations of $1,25(OH)_2D$ are approximately 15 to 60 pg/mL (36 to 144 pmol/L), and those of 25(OH)D are 10 to 65 ng/mL (25 to 162 nmol/L). The half-life of $1,25(OH)_2D$ in plasma is 4 to 6 hours, whereas the half-life of 25(OH)D is 2 to 3 weeks.

Circulating concentrations of $1,25(OH)_2D$ are tightly regulated, primarily by circulating concentrations of (1) PTH, (2) phosphate, (3) calcium, and (4) $1,25(OH)_2D$ itself. PTH and hypophosphatemia increase the synthesis of $1,25(OH)_2D$ by increasing 25(OH)D-1α-hydroxylase activity, whereas hypocalcemia acts indirectly by stimulating the secretion of PTH. Hypercalcemia, hyperphosphatemia, and $1,25(OH)_2D$ reduce 25(OH)D-1α-hydroxylase activity and production of $1,25(OH)_2D$. $1,25[OH]_2D$ also induces 25(OH)D-24-hydroxylase, an enzyme producing 24,25-dihydroxyvitamin D ($24,25[OH]_2D$), which is the most prevalent dihydroxylated vitamin D form in serum. The activity of this enzyme may reduce the formation of biologically active $1,25(OH)_2D$.

In the circulation, vitamin D, 25(OH)D, and $1,25(OH)_2D$ are bound to vitamin D—binding protein (DBP), a specific, high-affinity transport protein also known as group-specific component. DBP is synthesized by the liver and circulates in concentrations of approximately 400 mg/L, with fewer than 5% of its binding sites normally occupied. Vitamin D and its metabolites are bound with the following preference: $25(OH)D > 1,25(OH)_2D >>$ vitamin D. Only 0.03% of 25(OH)D and 0.4% of $1,25(OH)_2D$ are normally free in plasma (see Table 39-3). DBP concentrations are increased in pregnancy and with estrogen therapy and decreased in nephrotic syndrome.

Biological Actions of 1,25-Dihydroxyvitamin D

Calcium and phosphate concentrations in serum are maintained by the actions of $1,25(OH)_2D$ on (1) intestine, (2) bone, (3) kidney, and the (4) parathyroids. In the small intestine, $1,25(OH)_2D$ stimulates calcium absorption, primarily in the duodenum, and phosphate absorption in the jejunum and ileum. At high concentrations, it increases bone resorption by inducing monocytic stem cells in bone marrow to differentiate into osteoclasts and by stimulating osteoblasts to produce cytokines and other factors that influence osteoclast activity. By stimulating osteoblasts, $1,25(OH)_2D$ also increases the circulating concentration of **bone alkaline phosphatase (BALP)** and the noncollagenous bone protein **osteocalcin (OC)** (see section on Biochemical Markers of Bone Turnover). In the kidneys, $1,25(OH)_2D$ inhibits its own synthesis and stimulates its metabolism. It also acts directly on the parathyroids to inhibit the synthesis and secretion of PTH. $1,25(OH)_2D$ exerts its actions by associating with a specific nuclear vitamin D receptor.

Clinical Significance

The preferred method for determining vitamin D nutritional status is the measurement of 25(OH)D (Box 39-9), because (1) 25(OH)D is the main circulating form of vitamin D, (2) it has a long half-life, (3) its concentration varies less day-to-day with exposure to sunlight and with dietary intake, and (4) the measurement of 25(OH)D is relatively easy compared with the more technically complicated methods for vitamin D. Groups at higher risk for developing nutritional vitamin D

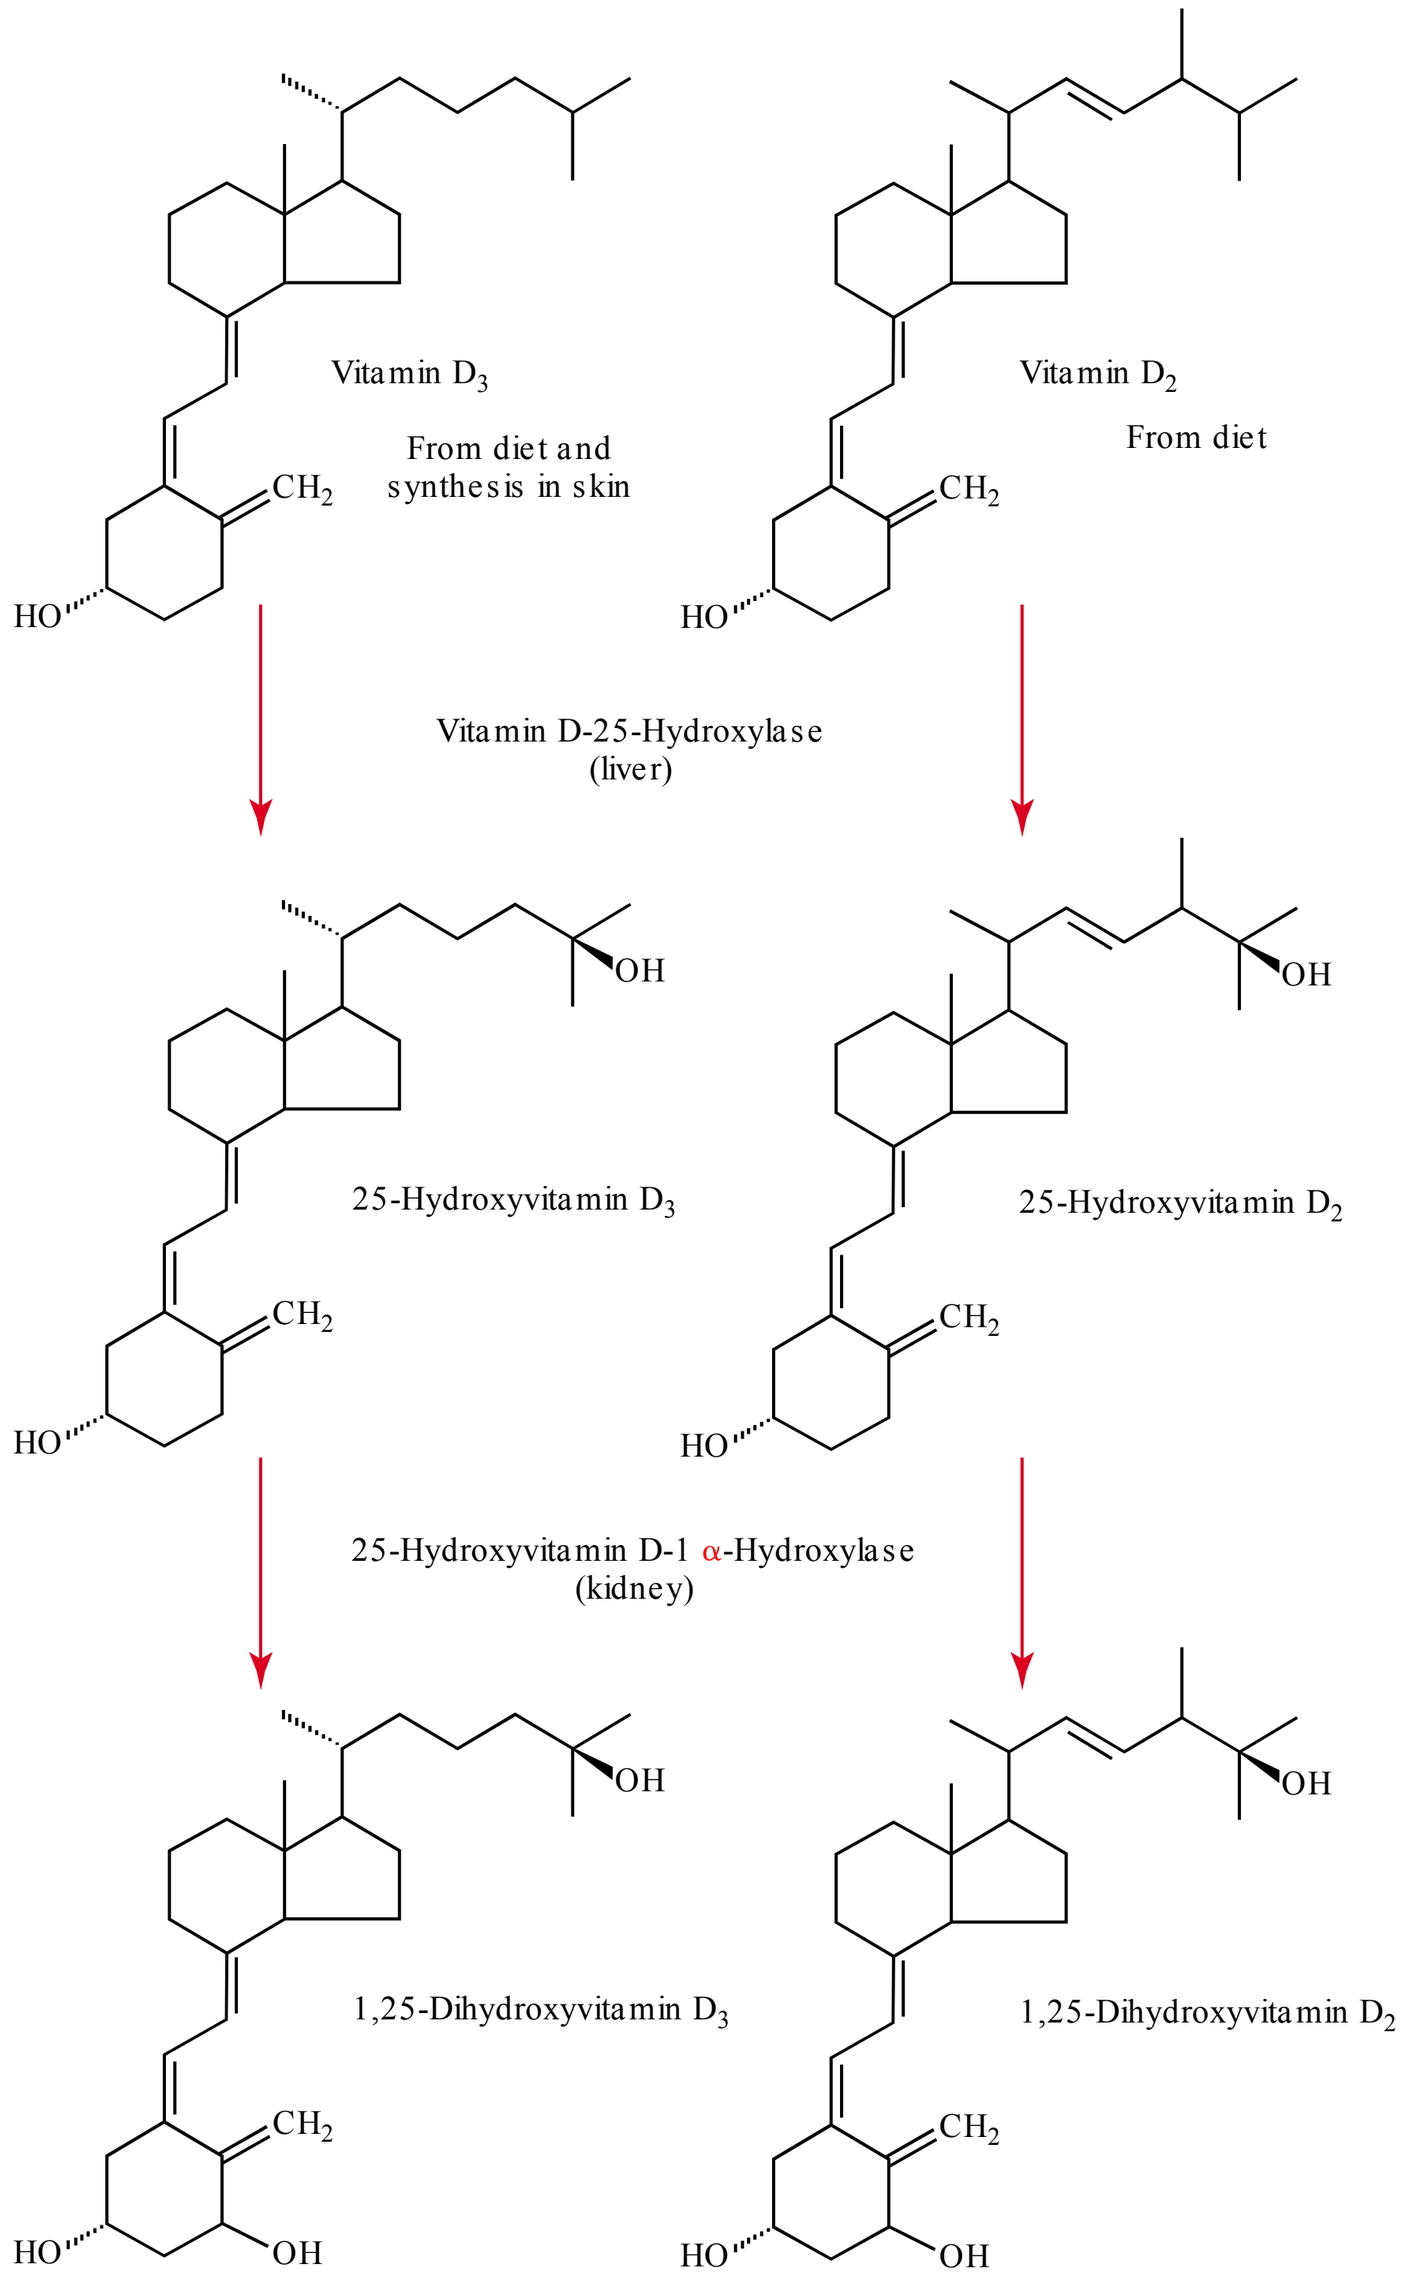

Figure 39-6 Metabolism of vitamin D. Vitamin D_2 and vitamin D_3 are enzymatically hydroxylated to 25-hydroxyvitamin D_2 and D_3 in the liver which are converted to the corresponding two forms of 1,25-dihydroxyvitamin D by the kidneys. 1,25-Dihydroxyvitamin D_2 and 1,25-dihydroxyvitamin D_3 are the most-biologically active forms of vitamin D.

TABLE 39-3 Vitamin D and Its Metabolites in Plasma

Compound	Concentration	Free (%)	Half-Life
Vitamin D	<0.2-20 ng/mL (µg/L) <0.5-52 nmol/L	—	1 to 2 days
25(OH)D	10-65 ng/mL (µg/L) 25-162 nmol/L	0.03	2 to 3 weeks
$1,25(OH)_2D$	15-60 pg/mL (ng/L) 36-144 pmol/L	0.4	4 to 6 hours

25(OH)D, 25-Hydroxyvitamin D; $1,25(OH)_2D$, 1,25-dihydroxyvitamin D.

BOX 39-9 Abnormal Circulating Concentrations of Total 25(OH)D

Decreased 25(OH)D
- Inadequate exposure to sunlight combined with inadaquate dietary
- Inadequate dietary vitamin D combined with inadequate sunlight
- Vitamin D malabsorption combined with inadequate sunlight
- Severe hepatocellular disease
- Increased catabolism (e.g., drugs, such as anticonvulsants)
- Increased loss (nephrotic syndrome)

Increased 25(OH)D
- Vitamin D or 25(OH)D intoxication

deficiency include (1) breast-fed infants, (2) strict vegetarians who abstain from eggs and milk, (3) individuals of color, and (4) the elderly.

Knowing the concentration of 25(OH)D is useful in evaluating (1) hypocalcemia, (2) vitamin D status, (3) bone disease, and (4) other disorders of mineral metabolism. Circulating concentrations of 25(OH)D may be decreased by (1) reduced availability of vitamin D, (2) inadequate conversion of vitamin D to 25(OH)D, (3) accelerated metabolism of 25(OH)D, and (4) urinary loss of 25(OH)D with its transport protein. Reduced availability of vitamin D occurs with (1) inadequate exposure to sunlight, (2) dietary deficiency, (3) malabsorption syndromes, or (4) gastric or small bowel resection. Severe hepatocellular disease has been associated with inadequate conversion of vitamin D to 25(OH)D. Drugs such as (1) phenytoin, (2) phenobarbital, and (3) rifampin induce drug-metabolizing enzymes that accelerate the metabolism of vitamin D and its metabolites. Serum 25(OH)D concentrations may be reduced in patients with nephrotic syndrome because of the urinary loss of DBP and 25(OH)D.

Measurement of 25(OH)D has limited value in hypercalcemia. Its most common use in hypercalcemia is in confirming intoxication after ingestion of large amounts of vitamin D or 25(OH)D. The concentration of the latter is typically greater than 100 ng/mL or 250 nmol/L in such patients.

Measurement of $1,25(OH)_2D$ is useful in detecting inadequate or excessive hormone production in the evaluation of (1) hypercalcemia, (2) hypercalciuria, (3) hypocalcemia, and (4) bone and mineral disorders (Box 39-10). Because activated macrophages convert 25(OH)D to $1,25(OH)_2D$, serum concentrations of $1,25(OH)_2D$ are often increased in (1) sarcoidosis, (2) tuberculosis, and (3) other granulomatous diseases. Lymphoma may also be associated with increased concentrations of $1,25(OH)_2D$. Concentrations of $1,25(OH)_2D$ are elevated in vitamin D—dependent rickets type II and in $1,25(OH)_2D$ intoxication, and may be elevated in primary hyperparathyroidism. Those patients with primary hyperparathyroidism who have high concentrations of $1,25(OH)_2D$ appear to be more prone to developing hypercalciuria and renal stones. Reduced concentrations of $1,25(OH)_2D$ are observed in patients with (1) renal failure, (2) hypercalcemia of malignancy, (3) hyperphosphatemia, (4) hypoparathyroidism, (5) pseudohypoparathyroidism, (6) type I vitamin D—dependent rickets, (7) hypomagnesemia, (8) nephrotic syndrome, and (9) severe hepatocellular disease. Measurement of $1,25(OH)_2D$, however, is not useful in confirming intoxication with vitamin D or 25(OH)D, because $1,25(OH)_2D$ concentrations may be (1) low, (2) within physiological limits, or (3) elevated.

BOX 39-10 Abnormal Concentrations of 1,25-Dihydroxyvitamin D

Decreased $1,25(OH)_2D$
Renal failure
Hyperphosphatemia
Hypomagnesemia
Hypoparathyroidism
Pseudohypoparathyroidism
Vitamin D—dependent rickets, type I
Hypercalcemia of malignancy
Increased $1,25(OH)_2D$
Granulomatous diseases such as sarcoidosis, tuberculosis
Primary hyperparathyroidism
Lymphoma
$1,25(OH)_2D$ intoxication
Vitamin D—dependent rickets, type II

Measurement of Vitamin D Metabolites

Specific and sensitive assays have been developed for 25(OH)D and $1,25(OH)_2D$. The assays for 25(OH)D and $1,25(OH)_2D$ should measure D_2 and D_3 metabolites equally (with equimolar reactivity), since both D_2 and D_3 are metabolized to produce biologically active $1,25(OH)_2D$. Separate measurement of the D_2 and D_3 forms does not necessarily distinguish between dietary and endogenous sources of vitamin D, as food is supplemented with D_2 and D_3.

Most assays for 25(OH)D and $1,25(OH)_2D$ require the following steps: (1) deproteinization or extraction, (2) purification, and (3) quantification. Deproteinization or extraction, usually with acetonitrile, frees the metabolites from DBP. The differences in their polarities because of the numbers of hydroxyl groups have been used to separate vitamin D and its metabolites. With three hydroxyl groups, $1,25(OH)_2D$ is more polar than 25(OH)D with two hydroxyls, which is more polar than vitamin D with only one hydroxyl group. Solid-phase extraction using octadecyl (C_{18})-silica was widely used for partially purifying $1,25(OH)_2D$. The most popular method used both a reversed-phase C_{18}-silica minicolumn and a normal-phase silica minicolumn to separate vitamin D metabolites. This method was modified by eliminating the silica cartridge and using "phase switching" with a single $C_{18}OH$ cartridge. The method of quantification depends on the metabolite being measured.

Serum 25(OH)D has been measured by (1) competitive protein binding assay (CPBA), (2) immunoassay, (3) UV absorbance after separation by high-performance liquid chromatography (HPLC), and (4) liquid chromatography-tandem mass spectrometry (LC-MS/MS). CPBAs based on DBP measure both $25(OH)D_2$ and $25(OH)D_3$. CPBAs that do not chromatographically separate 25(OH)D from other metabolites overestimate 25(OH)D concentrations by about 10% in healthy individuals. With immunoassays, samples and calibrators are deproteinized with acetonitrile and analyzed after chromatography or directly without chromatography. Although antisera also recognize $24,25(OH)_2D$, $25,26(OH)_2D$, and 25(OH)D-26,23-lactone, results are comparable with HPLC because of the much lower concentration of these other metabolites. In practice, HPLC and LC-MS/MS methods are being more used because of evidence that some immunoassays underestimate the vitamin D_2 form of 25(OH)D. HPLC and LC-MS/MS methods measure $25(OH)D_2$ and $25(OH)D_3$ separately. The sum of the two concentrations is used to determine whether a patient is deficient in vitamin D (or, also, whether a patient

has a vitamin D overdose). It is not appropriate to "treat" an increased or decreased concentration of 25(OH)D_2 or 25(OH)D_3 when the sum of the two concentrations is normal.

1,25$(OH)_2$D circulates at concentrations 1 X 10^{-3} lower than that of 25(OH)D and at significantly lower concentrations than other dihydroxylated metabolites, greatly complicating its specific determination in serum. The most widely used method requires (1) deproteinization with acetonitrile, (2) oxidation with sodium metaperiodate to eliminate interference from more abundant dihydroxylated metabolites, and (3) purification using a single C_{18}-OH cartridge followed by quantification by radioimmunoassay using a radioiodinated analogue of 1,25$(OH)_2$D. In a newer method, purification of 1,25$(OH)_2$D is carried out with immunocapsules containing a gel with immobilized monoclonal anti-1,25$OH)_2$D antibody, followed then by quantification with an automated chemiluminescent immunoassay.[11]

Specimen Requirements

Serum is typically used in the measurement of vitamin D metabolites. Once separated from the clot, metabolites are relatively stable at both room temperature and 4 °C; however, specimens should be frozen if the analysis is delayed. Vitamin D metabolites in serum do not appear to be sensitive to light and do not require special handling in the laboratory.

Reference Intervals

Reference intervals for vitamin D metabolites are method dependent, and the lower limit of 25(OH)D that is optimal for health is controversial. Representative reference intervals are:

25(OH)D: 20 to 65 ng/mL (50 to 162 nmol/L)
1,25$(OH)_2$D: 15 to 60 pg/mL (36 to 144 pmol/L)

Concentrations of <20 to 30 ng/mL (<50 to 75 nmol/L) are associated with increased circulating PTH and reduced calcium absorption. The National Health and Nutrition Examination Survey (NHANES) III study published in 2002 and 2003 reported an unexpectedly high prevalence of low 25(OH)D concentrations; during the winter in the southern United States, 25(OH)D was <20 ng/mL(<50 nmol/L) in 15% of adult Caucasian men and 30% of women with especially high rates in Blacks and intermediate rates in Hispanics.

Circulating concentrations of 25(OH)D are increased by exposure to sunlight and show seasonal variation with the highest concentrations in summer or fall and the lowest concentrations in winter or spring. Concentrations are influenced by latitude, sunscreen use, and skin pigmentation. Serum 25(OH)D concentrations of 100 ng/mL (250 nmol/)L are not uncommon in individuals highly exposed to sunlight, such as lifeguards.

Concentrations of vitamin D metabolites vary with age and are increased in pregnancy. Concentrations of 1,25$(OH)_2$D are higher in pregnancy and in children than adults with the highest concentrations occurring during periods of greatest growth. Although 25(OH)D and 1,25$(OH)_2$D concentrations have been reported to decrease with age, this decline may be a consequence of (1) poor nutrition, (2) reduced exposure to sunlight, and (3) declining health. Concentrations of these metabolites have been unchanged with age in studies limited to healthy and active subjects.

Calcitonin

Calcitonin is secreted by the parafollicular or C cells, which arise from the neural crest and are distributed throughout the thyroid gland. These cells are included in the APUD (amine precursor uptake and decarboxylation) family, which explains the association of medullary thyroid carcinoma (a tumor of the C cells) and other tumors of the APUD family in multiple endocrine neoplasia types 2A and 2B (MEN-2A and MEN-2B). Calcitonin as a tumor marker is discussed in Chapter 20. It is unclear whether calcitonin has any physiological role in mineral homeostasis in adult humans.

Parathyroid Hormone–Related Protein

Parathyroid hormone–related protein (PTHrP) was discovered by investigators studying the mechanism by which certain cancers produce HHM.

Biochemistry and Physiology

PTHrP is derived from a gene on chromosome 12 that is distinct from the PTH gene on chromosome 11. Three isoforms of (1) 139, (2) 141, and (3) 173 amino acids are predicted by alternative messenger RNA (mRNA) splicing. The PTH-like activity of PTHrP is contained within the 36 N-terminal amino acids. At the N-terminal end of the molecule, 8 of the first 13 amino acids are identical with those of PTH. PTHrP interacts with the PTH type 1 receptor, mimicking the biological actions of PTH in classic target tissues, including bone and kidney. Like PTH, PTHrP causes (1) hypercalcemia, (2) hypophosphatemia and (3) increased urinary cyclic AMP. When compared with patients with primary hyperparathyroidism, patients with PTHrP-induced hypercalcemia have lower concentrations of 1,25$(OH)_2$D and more typically have (1) metabolic alkalosis (instead of hyperchloremic metabolic acidosis), (2) less distal tubular calcium reabsorption, and (3) less (and uncoupled) bone formation.

Besides its endocrine role in the pathophysiology of HHM, PTHrP appears to participate in healthy physiology by acting locally on cells or tissue as an autocrine or paracrine factor. PTHrP is widely expressed in most healthy tissues of fetuses and adults. Although it is unlikely that the low circulating concentrations of PTHrP have a significant effect on calcium homeostasis in healthy adults, PTHrP may exert endocrine effects on calcium homeostasis during fetal life and lactation. Body fluids that contain high concentrations of PTHrP include breast milk and amniotic fluid.

Clinical Significance

Hypercalcemia-associated malignancy (HAM) is the second most common cause of hypercalcemia. This is frequent paraneoplastic syndrome occurs primarily through HHM and/or local osteolysis with the former accounting for the majority of cases of HAM. HHM is common in patients with (1) squamous (lung, head and neck, esophagus, cervix, vulva, skin, and other sites), (2) renal, (3) bladder, and (4) ovarian carcinomas.

Hypercalcemia due to skeletal metastases and local osteolysis is common in (1) breast cancer, (2) multiple myeloma, (3) lymphomas, and (4) other hematological malignancies. The hypercalcemia of a subset of lymphomas appears to be caused by HHM. Breast carcinomas may cause hypercalcemia by HHM and/or skeletal metastases with local osteolysis.

PTHrP is the principal mediator of HHM. After being secreted by tumors, PTHrP circulates and acts on its target tissues (skeleton and kidney) as an endocrine hormone causing hypercalcemia. PTHrP is increased in 50% to 90% of patients with HAM. PTHrP concentrations have been less frequently elevated in patients with hypercalcemia associated with hematological malignancies (e.g., multiple myeloma). PTHrP is undetectable or within the reference interval for healthy individuals in most, but not all, patients with malignancy not associated with hypercalcemia. Increased concentrations of PTHrP have been reported to precede hypercalcemia in some patients with malignancy.

PTHrP determinations are usually considered investigational, because HHM nearly always occurs in advanced disease when the diagnosis is obvious. The need for PTHrP determinations may increase if it becomes important in prognosis, selection of therapy, or monitoring.

Measurement of Parathyroid Hormone–Related Protein

A number of competitive and noncompetitive immunoassays have been used for measuring PTHrP in plasma from patients with HHM.

Specimen Requirements

PTHrP is unstable in serum and plasma at 4 °C and at room temperature unless collected in the presence of protease inhibitors. A combined mixture of (1) aprotinin, (2) leupeptin, (3) pepstatin, and (4) EDTA provides the greatest protection. In general, specimens should be collected with protease inhibitors and kept on ice. Serum or plasma should be promptly separated from the clot or cells and should be frozen.

Reference Intervals

Reference intervals for PTHrP are method dependent. One of the most widely used commercially-available noncompetitive immunoassays has a reference interval of 1.3 pmol/L or less. PTHrP is reported to be detectable in approximately 50% to 80% of healthy individuals with the most sensitive methods.

Integrated Control of Mineral Metabolism

The metabolism of calcium is linked intimately with that of phosphate (Figure 39-7). The homeostatic mechanisms are directed principally toward the maintenance of normal extracellular calcium and phosphate concentrations, which sustain extracellular and intracellular processes and provide substrates for skeletal mineralization. The parathyroid glands respond to a decrease in free calcium concentration within seconds. During a time of calcium deprivation, the increase in serum PTH rapidly alters both renal and skeletal metabolism.

Of the approximately 10 g (250 mmol) of calcium filtered by the kidneys each day, 65% is reabsorbed in the proximal tubule. Calcium reabsorption here is closely linked to sodium and is independent of PTH. Approximately 10% to 20% of calcium is reclaimed in the thick ascending loop of Henle and 5% to 10% in the distal convoluted tubule. PTH enhances calcium reabsorption at the distal tubule, presumably through a cyclic AMP-dependent mechanism. A small portion of filtered calcium, about 5%, is reabsorbed in the collecting duct via a PTH-independent mechanism.

In contrast to the calcium-conserving effect of PTH on the kidneys, PTH increases renal phosphate excretion at the proximal tubule by directly lowering the renal phosphate threshold. Approximately 6.5 g (210 mmol) of phosphate is filtered by the kidneys each day. Typically, 85% to 90% is reabsorbed by the renal tubules (proximal and distal convoluted tubule). PTH is one of the most important factors regulating the renal phosphate threshold and therefore the serum phosphate concentration.

PTH also increases intestinal calcium absorption by increasing $1,25(OH)_2D$. PTH is a major trophic factor for

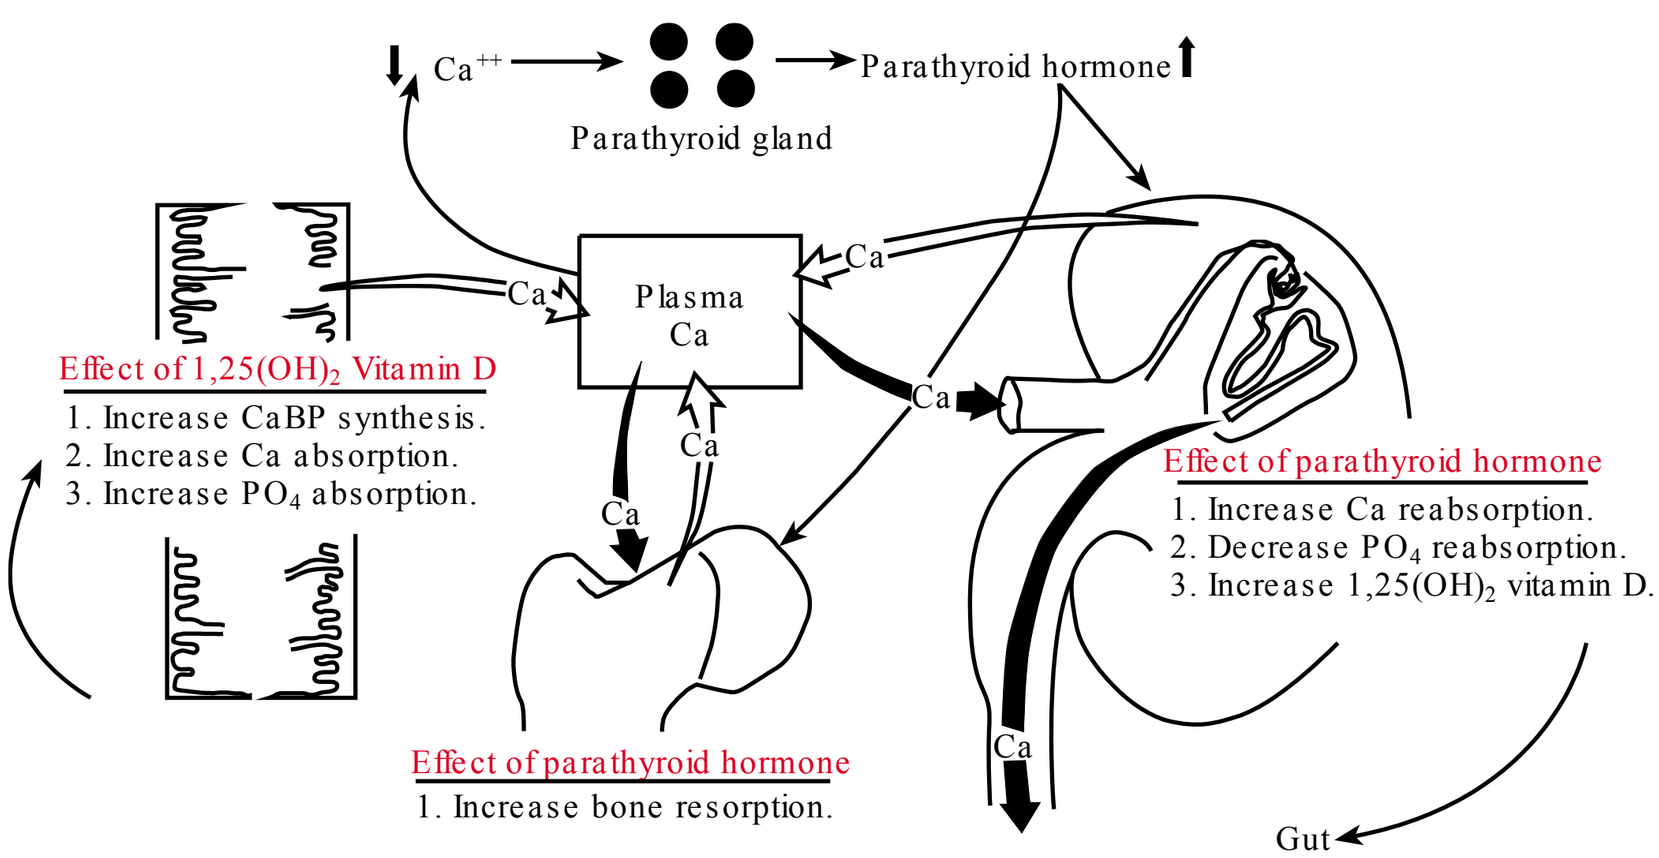

Figure 39-7 Integrated control of mineral metabolism. CaBP, Calcium-binding protein.

renal 25(OH)D-1α-hydroxylase. It thus increases the conversion of 25(OH)D to the active vitamin D metabolite, $1,25(OH)_2D$. Calcium is absorbed principally in the duodenum, although it also is absorbed by the distal small bowel and colon. About 30% of a daily calcium intake of 1 g (25 mmol) is absorbed. Approximately 100 mg (2.5 mmol) of calcium is secreted into gut lumen by intestinal secretion. Consequently, the net calcium absorption is 200 mg (5.0 mmol)/day. Calcium is absorbed by passive diffusion and by an active transport system. It is estimated that passive diffusion accounts for absorption of about 10% of ingested calcium per day. Active calcium absorption in the duodenum is increased by $1,25(OH)_2D$.

Dietary phosphate intake is usually 1.2 to 1.4 g (39 to 45 mmol) per day, nearly twice the recommended intake, of which approximately 60% to 70% is absorbed, principally in the jejunum. As with calcium, both passive and active transport systems exist, with $1,25(OH)_2D$ being the principal regulator of the active transport of phosphate. PTH-stimulated synthesis of $1,25(OH)_2D$ thus offsets the phosphaturic effect of PTH. T e prevailing serum phosphate concentration also modulates renal 25(OH)D-1α-hydroxylase. Phosphate depletion or hypophosphatemia stimulates formation of $1,25(OH)_2D$ by the kidneys. In general, at pharmacological concentrations, calcitonin has an effect that is opposite to that of PTH.

PTH also has an acute effect on the skeleton. PTH decreases osteoblastic collagen synthesis, but osteoclastic bone resorption increases with a net increase of mineral (calcium and phosphate) release from bone into the extracellular fluid. PTH is able to act directly on osteoblasts by interacting with their PTH receptors. T e effect of PTH on osteoclasts appears to be indirect, through local mediators produced by the osteoblast (e.g., RANK ligand and OPG) or released from the bone matrix (e.g., tissue growth factor beta [TGF-β]). Prolonged calcium deprivation results in enhanced recruitment of osteoclasts and an increased number of mature osteoclasts, which continue to resorb bone, releasing calcium and phosphate and degradation products of the organic bone matrix. Prolonged exposure to PTH eventually also increases osteoblast activity and bone formation.

Despite the critical importance of magnesium in physiology, no hormone or factor has been described as regulating magnesium homeostasis. Magnesium is absorbed efficiently in the intestinal tract (most efficiently in the distal small bowel). In the kidneys, about 25% to 35% of filtered magnesium is passively reabsorbed in the proximal convoluted tubule. T e major site of active absorption is the ascending loop of Henle, where 60% to 70% is reabsorbed. During times of magnesium deprivation, urinary magnesium excretion is less than 0.5 mmol/day. When magnesium intake is excessive, any amount greater than the renal threshold is excreted.

Biochemical Markers of Bone Turnover

Biochemical markers of bone turnover are classified as markers of bone formation or bone resorption.

T ese markers listed in (Table 39-4) have been used for (1) monitoring the effectiveness of therapy, (2) selection of patients for therapy, (3) prediction of bone loss, and (4) prediction of fracture risk. Of these indications, they are mostly used for monitoring the effectiveness of therapy.

Osteoporosis is often characterized by modest alterations in bone turnover, and thus only small changes may occur during therapy. Measurements of bone mass (for example, dual energy x-ray absorptiometry) will identify statistically significant changes in bone mass after 1 to 3 years of treatment. Measurements of bone markers provide earlier assessments than do measurements of bone mass.

In addition to their use in metabolic bone disease, markers of bone turnover are potentially useful tools in diagnosing and monitoring metastatic bone disease.

Preanalytical and Analytical Variables of Bone Turnover Markers

Controllable sources of preanalytical variability include (1) sampling time, (2) sample preservation procedures, and (3) food intake. Bone marker concentrations in urine and serum vary with the time of day because of the diurnal variation of bone resorption and formation. Because of the nocturnal peak in bone turnover, the concentrations of most bone markers peak in the early morning hours (0400 to 0800) and reach their lowest concentrations in the afternoon (1300 to 2300). T e amplitude of this variation is greatest for resorption markers with the afternoon values averaging 70% of peak values. Consequently, specimens should be collected at a standardized time of day to minimize the impact of diurnal variability. For urinary markers, collection of the second morning void is often recommended.

Concentrations of urinary resorption markers are usually standardized by dividing by the urinary creatinine concentration. Factors that contribute to the overall variability of urinary resorption markers include (1) the within- and between-method variation in creatinine measurements, (2) the within-subject biological variation in urinary creatinine excretion rates, and (3) the dependence of creatinine excretion rates on muscle mass.

TABLE 39-4 Biochemical Markers of Bone Formation and Resorption

Name	Abbreviation
Formation	
Propeptides of Type I Procollagen	PINP and PICP
Bone alkaline phosphatase	BALP
Osteocalcin	OC
Resorption	
Type I Collagen Telopeptides	
N-telopeptide	NTx
C-telopeptide (formed by cathepsin K)	CTx
C-telopeptide (formed by MMPs)	ICTP
Pyridinium Crosslinks	
Free deoxypyridinoline	fDPD
Free deoxypyridinoline and free pyridinoline	fDPD and fPYD
Total deoxypyridinoline and free pyridinoline	tDPD and tPYD
Tartrate-resistant acid phosphatase 5b	TRACP5b

Long-term, within-individual variability of urine markers is generally higher (15% to 60%) than that of serum markers (5% to 10%). Compared with other bone markers, BALP and TRACP5b do not demonstrate significant diurnal variation because of their long half-lives in serum. Food intake has a marked effect only on serum **CTx** concentration. T e variation of serum CTx during the day has a magnitude of about ±±40% around the 24 hour mean mainly due to fasting. With other bone markers, the clinical impact of feeding versus fasting is small. Collection of samples in the fasting state is advantageous for many other tests that are likely to be performed on samples collected for bone-marker testing.

Markers of Bone Formation

Markers of bone formation (Table 39-4) include (1) the amino- or carboxy-terminal propeptides of type I procollagen, (2) **procollagen type I N-terminal propeptide (PINP)**, (3) **procollagen type I carboxy-terminal propeptide (PICP)**, (4) BALP, and (5) OC.

Propeptides of Type I Procollagen (PINP and PICP)

Type I collagen accounts for about 90% of the organic matrix of bone, and is synthesized as a precursor, type I procollagen. Each end (the carboxy-terminal end and the amino-terminal end) of procollagen contains a large domain known as a propeptide.T e amino- or N-terminal propeptide and the carboxyl- (or C-) terminal propeptide are called PINP and PICP, respectively. To form collagen from procollagen, these propeptides are enzymatically cleaved from the procollagen molecule (in the extracellular space, by two different enzymes), leaving the rod-like collagen molecule in bone. T e propeptides are taken up from the circulation via two specific receptor-mediated pathways and degraded by the endothelial cells of the liver.

Clinical Signif cance

Serum PINP is recommended for use as a reference marker for osteoporosis studies. For example, during the first 2 days of teriparatide (a recombinant form of parathyroid hormone) treatment that induces bone formation, PINP and PICP increase rapidly and continue to increase until the end of 1 month of treatment to a net increase of 110%, whereas resorption markers initially decrease (Figure 39-8). By contrast, during effective antiresorptive therapy, markers of bone formation respond more slowly than resorption markers.

Measurement of N-Terminal Propeptide of Type I Procollagen

Assays for PINP are divided into two families (1) intact PINP and (2) total PINP. Intact PINP assays measure only the trimeric form of the propeptide, whereas total PINP measures, in addition, smaller forms, most likely degradation products of the propeptide.

Specimen Requirements

T e preferred sample for measuring PINP or PICP is serum where they are very stable. Storage of a serum sample at room temperature for 1 week does not change measurable concentrations.

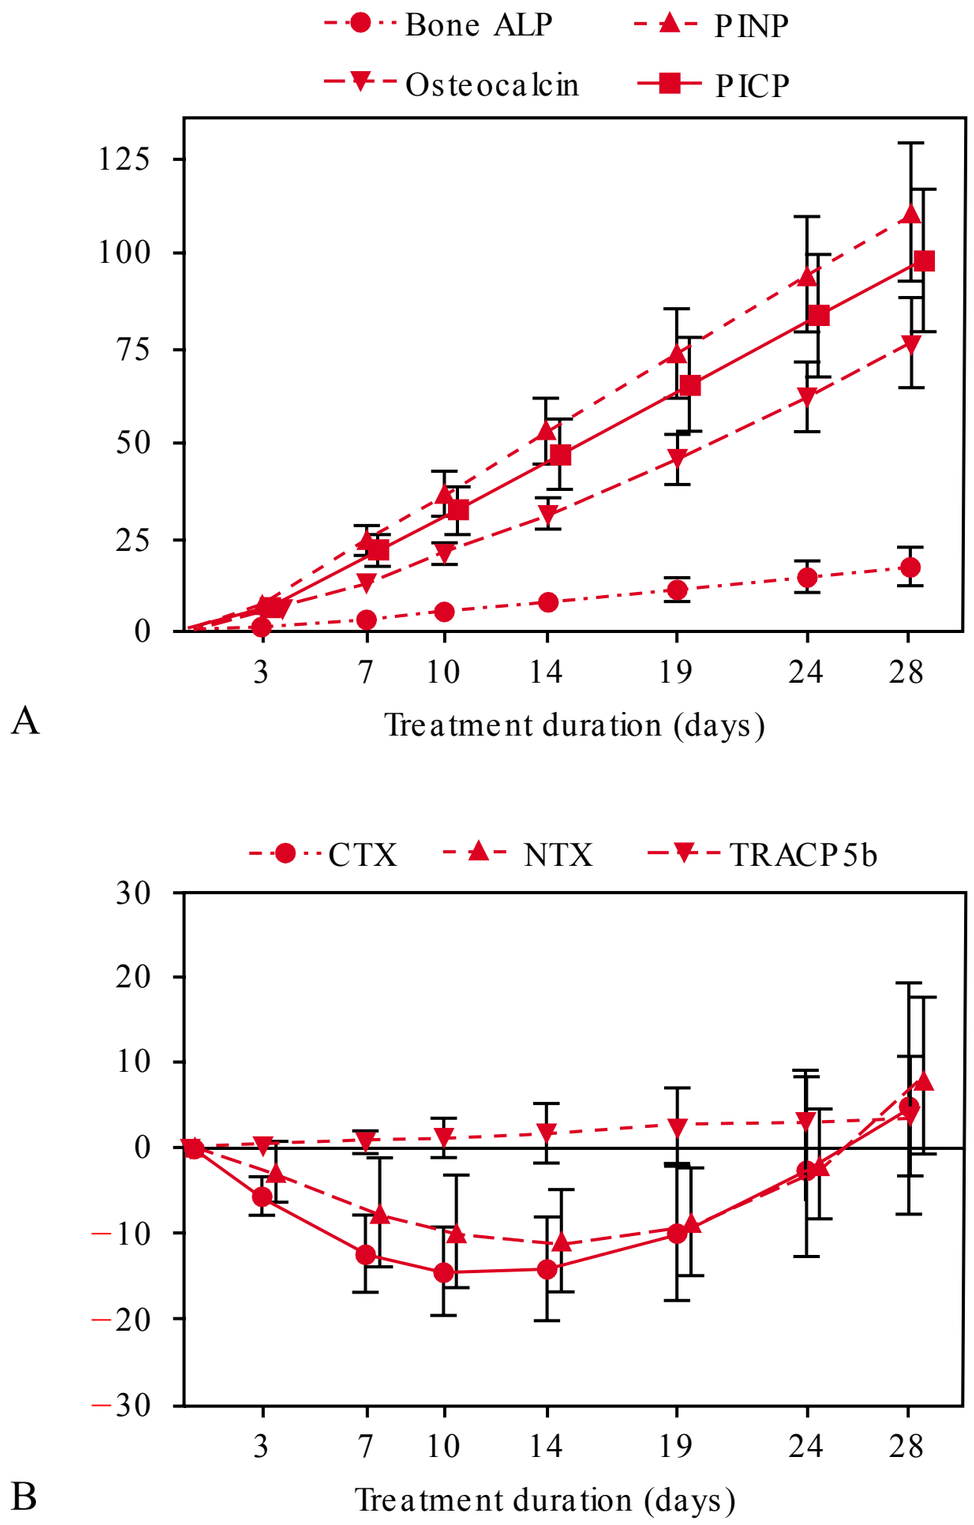

Figure 39-8 Changes in biochemical markers of bone metabolism during 28 days of teriparatide [PTH(1-34)] treatment of osteoporosis. Line plots show estimated mean and 90% confdence intervals for percentage change from baseline in (A) markers of bone formation and (B) markers of bone resorption. Bullet points at some time points have been slightly shifted horizontally to increase readability. For bone alkaline phosphatase (ALP), osteocalcin (OC), procollagen type I N-terminal propeptide (PINP), and procollagen type I carboxy-terminal propeptide (PICP), all changes from baseline are statistically signifcant ($P < 0.0001$). For CTx, all changes from baseline until day 19 are statistically signifcant ($P < 0.0004$). For N-telopeptide (NTx), all changes from baseline to days 7 to 10 are statistically signifcant ($P < 0.03$). For tartrate-resistant acid phosphatase 5b (TRACP5b), no changes are statistically signifcant. (From Glover SJ, Eastell R, McCloskey EV, Rogers A, Garnero P, Lowery J, et al. Rapid and robust response of biochemical markers of bone formation to teriparatide therapy. Bone 2009;45:1053-8.)

Reference Intervals

T e reference intervals for PICP are 38 to 202 µg/L in men and 50 to 170 µg/L in women. For intact PINP, the reference intervals in men are 20 to 78 µg/L and in women 19 to 84 µg/L. T e reference interval for total PINPI in young healthy premenopausal women (n = 637; age 30 to 39 years) is 16 to 72 µg/L and in men is 14 to 86 µg/L. Conentrations are higher in children, reflecting the child's growth rate. Concentrations increase during growth spurts.

Bone Alkaline Phosphatase

BALPs are membrane-bound ectoenzymes that are found in many tissues, including (1) bone, (2) liver, (3) kidney, (4) intestine, and (5) placenta. The ALP from the first three are isoforms of the same gene product. During mineralization of bone, the main function of BALP is to hydrolyze inorganic pyrophosphate (PPi) to generate phosphate (Pi). BALP is produced by the osteoblast during the matrix maturation phase, when the newly formed collagenous matrix is prepared for the deposition of mineral. Since BALP is firmly bound to the cell membrane, its release to plasma can be delayed. Because of its long half-life (≈≈40 hours), it is less sensitive than other markers of bone formation to acute changes and is relatively unaffected by diurnal variation.

Clinical Significance

BALP and total alkaline phosphatase (ALP) provide the highest clinical sensitivity and specificity in the diagnosis and monitoring of **Paget disease** of bone. Although total ALP is used most often, BALP is more sensitive than total ALP in mild disease. In severe osteomalacia, BALP may be markedly increased without an increase in bone mineralization because of a mineralizing defect. During teriparatide treatment, BALP is not increased as early or as much as PINP or OC (see Figure 39-8).

Measurement of Bone Alkaline Phosphatase

The activity assays of BALP tend to be technically complicated. A method using wheat germ agglutinin to precipitate BALP does not precipitate all forms from serum from Paget disease patients and fails to completely separate bone and liver activity. Several immunoassays have been reported for BALP, but none of the monoclonal antibodies are completely specific.[11] BALP is stable in serum and does not require special specimen handling.

Reference Intervals

Serum concentrations of BALP are influenced by age and sex. The reference interval of BALP with the IRMA is 5 to 20 µg/L. Children have much higher concentrations, especially during growth spurts.

Osteocalcin

Osteocalcin (OC) is a small protein of 49 amino acids which is the most abundant noncollagenous protein in bone. OC contains three glutamyl residues at amino acid positions 17, 21, and 24, which are formed by vitamin K—dependent enzymatic carboxylation. These carboxylated amino acids bind calcium ions and hydroxyapatite. The exact role of OC in bone formation is unknown. OC knockout mice have increased bone formation, but they also show decreased insulin and higher glucose concentrations in serum. Undercarboxylated OC (about 20% of total) is regarded as an osteoblast-secreted hormone regulating insulin secretion and sensitivity.

Serum OC is cleared by the kidneys and has a half-life of approximately 5 minutes. OC exhibits a diurnal variation with a nocturnal peak, dropping by as much as 50% to a morning nadir. Blood contains both the intact molecule and several proteolytic fragments.

Clinical Significance

The concentration of OC changes rapidly in situations that affect bone turnover. OC is not a pure marker of bone formation since freshly synthesized OC is either secreted into the bloodstream or incorporated into the bone matrix. OC is also released from the bone matrix during bone resorption. During teriparatide treatment, OC increases rapidly but less pronouncedly than PINP and continues to increase until the end of the first month of treatment (see Figure 39-8).

Measurement of Osteocalcin

Many immunoassay methods have been developed for OC. For most assays, specificities with respect to carboxylated and undercarboxylated forms of OC are not known. An immunoassay for the undercarboxylated form of OC uses recombinant human undercarboxylated OC for calibration and two monoclonal antibodies.

Specimen Requirements

OC is rapidly degraded in blood samples at room temperature or at 4 °C. Measured serum OC concentrations are more stable when assessed with methods measuring both intact OC and the N-terminal/midregion fragment (1-43).

Reference Intervals

OC concentrations are influenced by age and sex. In a commercially-available OC enzyme-linked immunosorbent assay (ELISA),[11] the reference interval is 9.6 to 40.0 µg/L in men, 8.4 to 33.9 µg/L in premenopausal women, and 12.8 to 55.0 µg/L in postmenopausal women. Concentrations are higher in children and the highest concentrations are observed during periods of rapid growth.

Markers of Bone Resorption

Except for **tartrate-resistant acid phosphatase 5b (TRACP5b)**, markers of bone resorption (see Table 39-4) are breakdown products of type I collagen.[2,4,9,12] These markers were initially measured in urine, but more recently serum-based methods have been developed.

Collagen Crosslinks

During synthesis, type I collagen molecules are modified extracellularly by formation of intramolecular and intermolecular covalent bonds or crosslinks. Intermolecular cross-linking sites have been located in short non—triple-helical domains at each end of the type I collagen molecule, called telopeptides. There are a series of divalent and later trivalent crosslinks (e.g., PYD and DPD). Trivalent crosslinks are also found in soft tissues and in collagen types other than type I (type II, III, etc.).

Degradation of Bone Collagen

Cathepsin K is the main enzyme that degrades bone collagen within the lacuna of the osteoclast. Osteoclasts also produce other proteases, including several matrix metalloproteinase

(MMP) enzymes. Cross-linked telopeptides are released from type I collagen during bone resorption. T is generates neoepitopes (such as, **N-telopeptide [NTx]**) that are measured by immunoassays. For C-terminal telopeptides, two distinct immunoassays, **ICTP** and CTx, reflect different enzymatic pathways of bone breakdown. Cathepsin K releases CTx antigen but destroys reactivity in the ICTP assay. ICTP antigen is stable after MMP digestion.

Excretion of hydroxyproline has been used to assess bone turnover or bone resorption because of the relatively high hydroxyproline content of bone proteins, but it is a poor test and is rarely used today.

Comparison of Urine and Serum Analyses

Urine has been used for measuring bone collagen degradation, but urine measurements needs to be corrected for creatinine excretion to adjust for effects of urine concentration or dilution. T is includes a second analyte, which has its own analytical variation that adds to the uncertainty of the result. During antiresorptive treatment, urinary telopeptide assessment may overestimate the decrease in bone resorption because the renal metabolism of these peptides can change them. T e response to antiresorptive therapy is generally greatest when measured with telopeptide assays, intermediate with total DPD assay, and lowest with free DPD assay.

Clinical Signif cance of Telopeptides and Crosslinks

Increased concentrations of urinary telopeptides and DPD have been reported in patients with (1) osteoporosis, (2) Paget disease of bone, (3) primary and secondary hyperparathyroidism, (4) hyperthyroidism, and (5) other diseases with increased bone resorption or osteolysis. Treatment of postmenopausal women or osteoporotic individuals with bisphosphonates or other antiresorptive drugs decreases bone resorption markers. Alternatively, teriparatide treatment induces minor changes in the serum concentration of telopeptides or tartrate-resistant acid phosphatase (see Figure 39-8).

Measurement of Telopeptides and Pyridinium Crosslinks

Several methods are commercially available. T e most commonly used are (1) serum and urine assays for NTx and CTx, (2) serum assay for ICTP, and a (3) urine assay for DPD.

N-Telopeptide Assay. NTx in urine is measured with a commercially-available ELISA that measures both pyridolines and pyrroles but not uncross-linked precursors. A serum NTx method is also available, but mostly for technical reasons, this assay has not become as widely used as the assay for NTx in urine.

C-Telopeptide CTx Assay. T e urinary CTx immunoassay is based on a synthetic peptide of the α_1(I) chain of type I collagen, which includes the cross-linking site. T is method recognizes mainly the β-isomer of aspartic acid induced in the sequence. Serum CTx is measured using two monoclonal antibodies. With two α_1(I) chain telopeptides in each collagen molecule, the use of two antibodies directed against the β-isomer ensures that only the β-forms are measured.

C-Telopeptide ICTP Assay. T e carboxy-terminal telopeptide of type I collagen (ICTP) assay detects collagen degradation fragments in serum. T e epitope measured is vulnerable to digestion by cathepsin K. However, the method is suitable for detecting the osteolytic processes taking place in multiple myeloma or metastatic bone disease, as well as the erosion process in rheumatoid arthritis.

Deoxypyridinoline and Pyridinoline Crosslinks. **Deoxypyridinoline (DPD)** and **Pyridinoline (PYD)** have been measured by HPLC or by immunoassay using automated analyzers or manual ELISA. HPLC methods measure total DPD and total PYD, whereas the immunoassays for DPD or DPD/PYD measure primarily free forms. In urine, approximately 40% of PYD and DPD are free, and 60% is protein bound.

Specimen Requirements

Serum is collected after overnight fasting. Tests using timed or random urine have been used for PYD and telopeptide measurements. Although early studies used 24-hour urine samples, timed or early-morning voided urine samples have also been used. A second morning void, collected by 1000, is most commonly recommended. For treatment monitoring, the specimens should be collected at the same time as the baseline specimen. Peak urinary excretion of PYDs occurs at about 0500 to 0800, reflecting the nocturnal peak in bone turnover. Urinary PYDs reach a nadir between 1400 and 2300.

Reference Intervals

Serum NTx reference intervals are 8.7 to 19.8 nmol BCE/L for premenopausal women and 10.7 to 22.9 nmol BCE/L for men. For urinary NTx the reference intervals are 10 to 110 µmol BCE/mol creatinine and 11 to 103, respectively, for premenopausal women and for men. Serum CTx upper limit is ≤573 ng/L for premenopausal women and ≤584 ng/L for men and the mean of urinary CTx concentration are 220 mg/mol creatinine and 249 mg/mol creatinine, respectively, for premenopausal women and men. T e reference interval for serum ICTP concentration is 1.5 to 5.0 µg/L for premenosausal women and men. T e reference intervals for free DPD concentration in urine are 3.0 to 7.4 µmol/mol creatinine for premenosausal women and 2.3 to 5.4 µmol/mol creatinine for men. Concentrations are higher in children, especially during periods of rapid bone growth.

Tartrate-Resistant Acid Phosphatase

During bone resorption osteoclasts produce and secrete two tartrate-resistant acid phosphatases. TRACP5b is produced by the osteoclasts and TRACP5a from other cells. Only about 10% of TRACP circulates in enzymatically active form, and the remaining 90% circulates as inactive fragments. Two commercial immunoassays are available for TRACP5b that show similar specificity and clinical performance.

Clinical Signif cance

Osteoclasts number can be increased in bone disorders and decreased by antiresorptive treatment. Reflecting these changes, In response to alendronate, TRACP5b decreased 39% in response to treatment with alendronate, compared with decreases of 49% to 69% for urinary telopeptides (CTx and NTx) and 75% for serum CTx.

Specimen Requirements

The preferred sample for measuring TRACP5b is serum. Diurnal variation is minor. TRACP5b may be relatively unstable on storage, although it has been shown that TRACP5b can be stored for up to 8 hours at room temperature and up to 3 days at 4 °C. For long-term storage, it is essential that samples be stored at—80 °C.

Reference Interval

An immunoassay for TRACP5b has upper limits of reference intervals of 4.15 U/L for women and 4.82 U/L for men.

Metabolic Bone Diseases

Metabolic bone diseases result from a partial uncoupling or imbalance between bone resorption and formation.[2,6,7,9,12] Decreased bone mass, or **osteopenia**, is more common than abnormal increases of bone mass. The most prevalent metabolic bone diseases are (1) osteoporosis, (2) osteomalacia and rickets, and (3) **renal osteodystrophy**. In addition to these three diseases that affect the skeleton in general, two diseases characterized by localized bone involvement are (1) Paget disease of bone and (2) bone metastases.

Osteoporosis

Osteoporosis, the most prevalent metabolic bone disease in developed countries, is characterized by (1) loss of bone mass, (2) microarchitectural deterioration of bone tissue, and (3) increased risk of fracture. Women have a lifetime fracture risk three times that of men. One third of women older than 65 suffer vertebral crush fractures. Lifetime risk of hip fracture is 15%. Vertebral fractures occur earlier than hip fractures. Peak bone mass is attained by 30 years of age and decreases after 35 to 45 years of age. Bone loss is approximately 1% per year, but accelerates to about 2% per year after menopause.[2,6,7,12]

After decreased bone mass is documented by bone mass measurements, the diagnostic work-up is directed at determining the cause (Box 39-11). Most often the cause is attributed to age (senile osteoporosis), postmenopausal osteoporosis, or both, but it may be secondary to chronic diseases, drug therapies, treatment with corticosteroids or thyroxine, or other causes.

BOX 39-11 Causes of Osteoporosis

- Failure to develop normal skeletal mass during growth and development
  - because of poor nutrition or inadequate exercise
- Endocrine deficiency or excess
  - Estrogen or testosterone deficiency
  - Cushing syndrome
  - Hyperthyroidism
  - Hyperparathyroidism
- Immobilization or weightlessness
- Hematological malignancies (multiple myeloma)
- Inherited defects of collagen synthesis (osteogenesis imperfecta)
- Systemic mastocytosis
- Heparin therapy
- Rheumatoid arthritis
- Idiopathic juvenile osteoporosis

In practice, bone markers are measured to assess bone turnover in patients with osteoporosis. The rate of bone turnover (spontaneous or modified by the therapy) is considered an important determinant of bone fragility in postmenopausal and older women. Elevated markers of bone turnover indicate increased bone turnover but are not diagnostic for osteoporosis. Because of the coupling between bone formation and resorption, markers for both bone resorption and bone formation are useful in monitoring the effects of antiresorptive therapy. Teriparatide treatment is best monitored by the measurement of PINP or OC, but resorption markers may change later during therapy (see Figure 39-8).

Of note, the International Osteoporosis Foundation (IOF/ http://www.iof onehealth.org/accessed November 18, 2013) and International Federation of Clinical Chemistry and Laboratory Medicine (IFCC/ http://www.ifcc.org/accessed November 18, 2013) have recommended for osteoporosis studies one formation marker (serum PINP) and one resorption marker (serum CTx) to be used as reference markers.

Efforts are aimed at prevention of osteoporosis by (1) adequate nutrition, (2) calcium and vitamin D supplementation, and (3) exercise. Treatment of osteoporosis depends on the cause. In secondary osteoporosis, treatment is directed at the underlying condition. Most therapies for the treatment of postmenopausal osteoporosis are directed at decreasing osteoclastic bone resorption. Antiresorptive therapies include administration of (1) bisphosphonates (such as, alendronate and risedronate), (2) estrogen, (3) selective estrogen receptor modulators (raloxifene), and (4) calcitonin (nasal spray or injection). Treatment with teriparatide is the first approved therapy for stimulating bone formation.

Osteomalacia and Rickets

Osteomalacia and rickets are caused by a mineralization defect during bone formation, resulting in an increase in osteoid, the unmineralized organic matrix of bone. Defective mineralization produces rickets in children and osteomalacia in adults. Osteomalacia or rickets is usually due to either vitamin D deficiency or phosphate depletion.

The causes of decreased 25(OH)D and $1,25(OH)_2D$ are listed in Boxes 39-9 and 39-10, respectively. Breast-fed infants, the elderly, strict vegetarians, and individuals with darker skin pigmentation are at increased risk of vitamin D insufficiency. Clinical osteomalacia caused by vitamin D deficiency is uncommon in the United States, but the prevalence of subclinical or mild osteomalacia is unknown. Subclinical osteomalacia may coexist with osteoporosis in elderly patients with poor diets and little exposure to sunlight. Vitamin D deficiency may develop in patients with malabsorption caused by (1) postgastrectomy syndrome, (2) small bowel disease (e.g., celiac sprue), (3) hepatobiliary disease, or (4) pancreatic insufficiency.

Vitamin D resistance is rare. Vitamin D—dependent rickets type I is an inherited defect in 25(OH)D-1α-hydroxylase causing impaired formation of $1,25(OH)_2D$. The disease is manifested in infancy and is treated with physiological doses

of $1,25(OH)_2D$. Vitamin D—dependent rickets type II is an inherited disorder characterized by very high serum concentrations of $1,25(OH)_2D$. This syndrome is due to resistance to $1,25(OH)_2D$, secondary to defects in the $1,25(OH)_2D$ receptor.

Osteomalacia and rickets may also occur because of phosphate depletion. The most common cause of rickets in the United States is hypophosphatemic osteomalacia (also known as hypophosphatemic vitamin D—resistant rickets and vitamin D—resistant rickets). This disorder is an X-linked dominant inherited trait characterized by renal phosphate wasting. Tubular phosphate wasting also has been known to occur sporadically in adults and as part of Fanconi syndrome. Certain rare mesenchymal tumors may also produce a phosphaturic factor (phosphatonin or fibroblast growth factor [FGF]-23), resulting in renal phosphate wasting and osteomalacia. In developing countries, dietary calcium deprivation may lead to the clinical picture of rickets, without clear vitamin D or phosphate deficiency.

Drugs have also been associated with osteomalacia. Anticonvulsants increase the hepatic catabolism of vitamin D metabolites, and produce end-organ resistance. Phosphate-binding antacids used for treatment of peptic ulcer disease cause osteomalacia by preventing the intestinal absorption of phosphate. Etidronate treatment (of, for example, Paget disease, osteoporosis, or hypercalcemia of malignancy) can cause a mineralization defect and result in osteomalacia.

Clinical manifestations of rickets include bowing of the extremities and short stature. In adults with osteomalacia, bone pain is the most common symptom, and stress fractures and frank skeletal fractures occur in some patients. X-rays show classic findings in rickets, and pseudofractures are common in adults.

In rickets and osteomalacia, the activity of ALP is typically increased because of the increased osteoblastic activity associated with producing unmineralized osteoid. Calcium concentrations may be low or within the reference interval in vitamin D deficiency. Phosphate may be within the healthy reference interval or low, but falls with the development of secondary hyperparathyroidism. Vitamin D nutrition is best assessed by the determination of serum 25(OH)D.

In renal tubular defects of phosphate transport, the serum calcium and PTH concentrations are usually within the healthy reference interval. Renal phosphate defects can be best assessed by studies of renal phosphate handling.

Nutritional rickets and osteomalacia are healed by treatment with physiological doses of vitamin D, whereas higher doses may be required in malabsorption. Adequate dietary intakes of calcium and phosphorus are critical during therapy. Renal phosphate-wasting syndromes require frequent pharmacological administration of oral phosphate.

Disorders of Bone and Mineral in Chronic Kidney Disease (Renal Osteodystrophy)

Renal osteodystrophy is a complex condition that develops in response to abnormalities of the endocrine and excretory functions of the kidneys. It includes all the disorders of bone and mineral metabolism associated with chronic renal failure.[2,8] These renal bone diseases include both high-turnover bone disease (osteitis fibrosa or secondary hyperparathyroidism) and low-turnover bone diseases (osteomalacia and adynamic bone disease).

Osteitis fibrosa (hyperparathyroid bone disease) is the most common high-turnover bone disease. This disorder is caused by the high concentrations of serum PTH in secondary hyperparathyroidism. Secondary hyperparathyroidism is a consequence of the hypocalcemia associated with hyperphosphatemia and $1,25(OH)_2D$ deficiency. Hyperphosphatemia is a result of the kidneys' inability to excrete phosphate. $1,25(OH)_2D$ deficiency results from the decreased renal synthesis of $1,25(OH)_2D$ because of decreased renal mass and suppression of 25(OH)D-1α-hydroxylase activity by high concentrations of phosphate. Deficiency of $1,25(OH)_2D$ leads to reduced intestinal absorption of calcium and reduced inhibition of PTH secretion by $1,25(OH)_2D$. Skeletal resistance to PTH also contributes to the hypocalcemia and secondary hyperparathyroidism.

Low-turnover bone diseases include osteomalacia and adynamic (also known as aplastic) bone diseases. Osteomalacia and adynamic bone disease are distinguished by the extent of unmineralized bone matrix or osteoid that is increased in osteomalacia but low or unchanged in adynamic bone disease. Osteomalacia in chronic renal failure may reflect vitamin D deficiency because of the decreased renal synthesis of $1,25(OH)_2D$. In the 1970s and 1980s, aluminum intoxication, from the therapeutic use of aluminum-containing antacids to reduce intestinal phosphate absorption, was a significant contributing factor to the development of osteomalacia and adynamic bone disease. Other causes of adynamic renal bone disease include (1) calcium supplementation, (2) excessive vitamin D administration, (3) treatment of hyperparathyroidism, (4) advanced age and osteoporosis, (5) diabetes, (6) corticosteroid therapy, and (7) immobilization. Today, oversuppression of parathyroid function (by calcium carbonate pills, vitamin D, and dialysate solutions with high calcium) is believed to be the main cause of adynamic renal bone disease.

Bone pain is the most common complaint of patients with renal osteodystrophy. Biochemical findings in chronic renal failure include hyperphosphatemia and hypocalcemia. PTH concentrations typically are increased and $1,25(OH)_2D$ decreased. Serum ALP is increased in patients with either hyperparathyroidism or osteomalacia. Management includes restriction of dietary phosphate, use of (aluminum-free) phosphate-binding agents, treatment with $1,25(OH)_2D$ or other active forms of vitamin D, dialysis, and ultimately, transplantation.

Paget Disease of Bone

Paget disease is a localized disease of bone characterized by osteoclastic bone resorption, followed by replacement of bone in a chaotic fashion. It may affect one or several bones. The disease has a restricted geographical distribution, being most common in (1) Europe, (2) North America, (3) Australia, and (4) New Zealand, where it can affect up to 4% of people

of Anglo-Saxon descent over 40 years of age. The cause is unknown. A family history of Paget disease is reported by 20% to 30% of patients.

The (1) skull, (2) femur, (3) pelvis, and (4) vertebrae are affected most commonly. In the United States, the disease is most often diagnosed from radiographs or abnormal laboratory tests such as ALP that have been performed for another reason. Bone pain and increased warmth may occur in or over the affected bone. Advanced disease has been known to produce deformities, such as skull enlargement and bowing of the weight-bearing bones such as the femur and tibia. Complications of deformed bone include (1) arthritic symptoms, (2) nerve compression, and in rare cases (3) osteogenic sarcoma.

The most common finding leading to the diagnosis of Paget disease is increased serum activity of ALP (up to tenfold). Increases in markers of bone resorption reflect the osteoclastic nature of this disease. Bone markers may be useful in diagnosis and therapeutic monitoring. Radiological examination demonstrates characteristic findings. The bone scan is the most sensitive test for detecting small, early lesions.

Therapy is directed at decreasing osteoclastic bone resorption by administration of bisphosphonates or calcitonin. Surgery is used to treat skeletal deformities that limit mobility or compress nerves.

Involvement of Bone in Malignancies

Bone metastases are the most common skeletal complication of malignancy, occurring in up to 70% of patients with advanced breast or prostate cancer, and to a smaller extent in other carcinomas. Metastases can be (1) markedly osteolytic (as in breast cancer) or (2) predominantly osteoblastic (as in prostate cancer), but often they are (3) mixed. The lesions of multiple myeloma are purely osteolytic as the tumor cells secrete factors that suppress bone formation. Generalized osteoporosis is also a feature of the disease. Many biochemical bone markers, reflecting bone formation or bone resorption, have been investigated for use in early detection or treatment monitoring of bone metastases and myeloma.

Review Questions

1. In regard to calcium and phosphate regulation, the function of $1,25(OH)_2D$ in the small intestine is to
   a. increase bone resorption by inducing the formation of osteoclasts.
   b. stimulate calcium absorption in the duodenum and phosphate absorption in the jejunum.
   c. increase synthesis of alkaline phosphatase (ALP).
   d. inhibit the synthesis and secretion of parathyroid hormone (PTH) by the parathyroid gland.
2. The most important laboratory test for the differential diagnosis of hypercalcemia is
   a. calcium.
   b. phosphate.
   c. calcitonin.
   d. parathyroid hormone (PTH).
3. Which one of the following anticoagulants is acceptable for use when collecting a blood sample for magnesium measurement?
   a. Heparin
   b. Ethylenediaminetetraacetic acid (EDTA)
   c. Sodium citrate
   d. Oxalate
4. Increased transport of phosphate and glucose into cells that is induced by stimulation of insulin secretion will cause
   a. hyperphosphatemia.
   b. hypocalcemia.
   c. pseudohypoparathyroidism.
   d. hypophosphatemia.
5. The protein to which approximately 80% of protein-bound calcium is attached is
   a. calcitonin.
   b. albumin.
   c. immunoglobulin M (IgM).
   d. vitamin D.
6. Hypoparathyroidism is most commonly caused by
   a. chronic renal failure.
   b. decreased dietary intake.
   c. parathyroid gland destruction.
   d. bone tumors.
7. A disease of bone that is characterized by osteoclastic bone resorption followed by chaotic replacement of the bone of, for example, the femur and vertebrae, is
   a. osteomalacia.
   b. osteoporosis.
   c. rickets.
   d. Paget disease.
8. A mineralization defect during bone formation will result in an increase in osteoid. In adults, this will produce
   a. rickets.
   b. osteomalacia.
   c. Paget disease.
   d. osteoporosis.
9. Chronic liver disease will cause hypoproteinemia, particularly of albumin. How will this affect the total serum calcium concentration?
   a. Decrease
   b. Increase
   c. There will be no change.
10. In regard to biochemical markers of bone resorption, most markers reflect which one of the following?
    a. Osteoblast mineralization phase
    b. The amount of vitamin D activity
    c. Some aspect of the degradation of type I collagen
    d. Kidney ability to excrete calcium and phosphate

CHAPTER 40

Disorders of the Pituitary*

Ishwarlal Jialal, M.D., Ph.D., William E. Winter, M.D., and Roger L. Bertholf, Ph.D.

Objectives

1. Define the following:
   - Adenohypophysis
   - Diabetes insipidus
   - Gonadotropin
   - Hypophysis
   - Hypothalamus
   - Neurohypophysis
   - Pituitary adenoma
   - Pituitary gland
   - Syndrome of inappropriate antidiuretic hormone secretion (SIADH)
2. Describe the structure and function of the pituitary gland including lobes, vascular supply, target endocrine glands, and involvement in the regulation of the endocrine system.
3. List and describe the stimulating and inhibiting hormones synthesized and released by the hypothalamus, including the neurotransmitters involved and feedback loops regulate release.
4. For each of the following hormones, describe their site of synthesis and secretion, biochemistry, regulation, physiological actions, disorders caused by hyper- and hyposecretion (if any), and analytical methods used to assess:
   - Adrenocorticotropic hormone (ACTH)
   - Antidiuretic hormone (ADH, arginine vasovasopressin)
   - Follicle-stimulating hormone (FSH)
   - Growth hormone (GH)
   - Insulin-like growth factor (IGF)
   - Luteinizing hormone (LH)
   - Oxytocin
   - Prolactin (PRL)
   - Thyrotropin
5. Discuss diabetes insipidus (DI), including causes, symptoms, comparison of these to diabetes mellitus, and the water-deprivation test.
6. State the need for the cosyntropin stimulation test and the insulin tolerance test, including hormones tested, hypothalamic-pituitary axis involved, and expected results.
7. Analyze and solve case studies related to pituitary gland disease and laboratory investigations of them.

Key Words and Definitions

Acromegaly A chronic disease of adults caused by hypersecretion of pituitary growth hormone and characterized by enlargement of many organs and parts of the skeleton and soft tissues.

Adenoma A benign epithelial tumor in which the cells form recognizable glandular structures or in which the cells are derived from glandular epithelium.

Adrenocorticotropic hormone (ACTH, corticotropin) A 39–amino acid peptide hormone secreted by the anterior pituitary gland that stimulates the adrenal cortex to secrete corticosteroids.

Antidiuretic hormone (ADH) A peptide hormone synthesized in the hypothalamus, but stored and released from the posterior pituitary lobe (also known as arginine vasopressin and vasopressin).

Arginine vasopressin (AVP) A peptide hormone also known as antidiuretic hormone (ADH) and vasopressin (VP) that is synthesized in the hypothalamus, but released from the posterior pituitary lobe.

beta-lipotropin (β-LPH) An 89–amino acid polypeptide hormone synthesized by the anterior pituitary; it exerts a mild peripheral lipolytic action and serves as a precursor of several hormones.

Corticotropin-releasing hormone (CRH) A neuropeptide released by the hypothalamus that stimulates release of ACTH (corticotropin) by the anterior pituitary gland.

Cushing disease A condition characterized by hyperadrenocorticism that is secondary to excessive anterior pituitary secretion of corticotropin by the pituitary.

Cushing syndrome A complex of symptoms caused by hyperadrenocorticism due either to a neoplasm of the adrenal cortex or adenohypophysis, or to excessive intake of glucocorticoids. When secondary to excessive pituitary secretion of corticotropin, it is known as Cushing disease.

*The authors gratefully acknowledge the contributions of Laurence Demers, Wayne Meikle, Nelson B. Watts, Ronald J. Whitley, and Mary Lee Vance on which portions of this chapter are based.

Key Words and Definitions—cont'd

Diabetes insipidus A form of diabetes in which the kidney tubules do not reabsorb sufficient water. Caused by either a deficiency of ADH or defective receptor action.

Follicle-stimulating hormone (FSH) A glycopeptide hormone secreted by the anterior pituitary gland; it has important effects on the ovaries and testes.

Ghrelin A peptide hormone, expressed primarily by the stomach, that stimulates the secretion of growth hormone and is considered a hunger-stimulating hormone.

Gonadotropin-releasing hormone (Gn-RH) Any hypothalamic factor that stimulates the release of both follicle-stimulating hormone and luteinizing hormone.

Growth hormone (GH) A polypeptide of 191 amino acids that is produced by the anterior pituitary and affects the metabolism of carbohydrates, lipids and proteins; it increases IGF-I.

Growth hormone–releasing hormone (GHRH) A hypothalamic hormone that regulates the release of growth hormone.

Hyperprolactinemia A condition characterized by increased levels of prolactin in the blood; in women it is associated with amenorrhea and galactorrhea, and in men it has been reported to cause hypogonadism, impotence, and in some cases gynecomastia.

Insulin-like growth factor (IGF) IGFs I and II (IGF-I and IGF-II) are polypeptides with considerable sequence similarity to insulin; IGF-I mediates some of the effects of growth hormone.

Kallmann syndrome A type of hypogonadotropic hypogonadism caused by failure of fetal gonadotropin-releasing hormone neurons to migrate to the hypothalamus.

Laron syndrome An autosomal recessive syndrome of skeletal growth retardation due to impaired inability to synthesize insulin-like growth factor I, usually because of growth hormone receptor defects. Also called Laron dwarfism.

Luteinizing hormone (LH) A glycoprotein gonadotropic hormone secreted by the anterior pituitary.

Oxytocin A nonapeptide hormone synthesized in the hypothalamus and stored in the posterior lobe of the pituitary.

Pituitary dwarfism Short stature caused by decreased synthesis or action of growth hormone.

Pituitary gigantism Excessive growth caused by increased synthesis of growth hormone before the epiphyses have fused.

Pituitary gland An elliptical body located at the base of the brain and attached by a stalk to the hypothalamus, from which it receives important neural and vascular outflow. It is divided into the anterior (adenohypophysis) and posterior (neurohypophysis) pituitary with each responsible for the production of its own unique hormones.

Polydipsia Chronic excessive intake of water as in diabetes mellitus or diabetes insipidus.

Polyuria The passage of a large volume of urine in a given period, which is a characteristic of diabetes mellitus and diabetes insipidus.

Prolactin (PRL) A lactogenic hormone synthesized by the anterior pituitary gland.

Prolactin-inhibiting hormone (PIH) A hormone released by the hypothalamus that inhibits secretion of prolactin by the adenohypophysis. Also known as prolactin-inhibiting factor and prolactostatin.

Pro-opiomelanocortin (POMC) The 31,000 dalton prohormone that is the precursor of corticotropin, the lipotropins, the melanocyte-stimulating hormones, and the endorphins, all of which are produced by posttranslational proteolytic cleavage of POMC in cell types that produce these hormones.

Somatostatin Any of several cyclic tetradecapeptides produced in the hypothalamus that inhibit release of several hormones of the pituitary.

Syndrome of inappropriate antidiuretic hormone (SIADH) A condition in which inappropriate antidiuretic hormone secretion produces dilutional hyponatremia, and increased extracellular fluid volume with an elevated urine osmolality.

Thyroid-stimulating hormone (TSH) A glycoprotein hormone synthesized by the anterior pituitary gland; also called thyrotropin.

Thyrotropin A glycoprotein hormone synthesized by the anterior pituitary gland that promotes the growth of the thyroid gland and stimulates the hormonal secretion by the gland. Also called thyroid-stimulating hormone.

Thyrotropin-releasing hormone (TRH) A tripeptide produced in the hypothalamus that stimulates the release of TSH from the anterior pituitary.

The **pituitary gland** (also known as the hypophysis) is located at the base of the skull (Figure 40-1)[10] in a bone cavity called the sella turcica (Turkish saddle). The gland is small—1 cm or less in height and width—and weighs approximately 500 mg. It is anatomically divided into the anterior (adenohypophysis) and the posterior (neurohypophysis) lobes. A third lobe (the intermediate lobe) is present in most vertebrates and in the human fetus; this lobe is rudimentary in the adult human.

Arterial blood reaches the pituitary gland via the superior hypophyseal artery. Venous blood, carrying neurosecretory hormones from the hypothalamus, reaches the pituitary through the hypothalamic hypophyseal portal system. These hypothalamic factors stimulate or inhibit the release of hormones from the adenohypophysis.

The pituitary gland regulates the endocrine system by integrating chemical signals from the brain with regulatory feedback from the concentration of hormones in the circulation to stimulate intermittent hormone release from target endocrine glands.[2,4,5,8] Historically the pituitary gland has been called the master endocrine organ, because it is intimately involved in the regulation of (1) growth, (2) development, (3) thyroid function, (4) adrenal function, (5) gonadal function, and (6) water and salt homeostasis.

The adenohypophysis secretes (1) **growth hormone (GH)**, (2) **prolactin (PRL)**, (3) **thyroid-stimulating hormone (TSH)**, (also known as **thyrotropin**), (4) **adrenocorticotropic hormone (ACTH)**, (5) **follicle-stimulating hormone (FSH)**, and (6) **luteinizing hormone (LH)**. TSH, LH, and FSH are glycoprotein hormones that possess a common alpha subunit and a distinct beta subunit that confers biologic specificity. ACTH, PRL, and GH are polypeptide hormones (Table 40-1).[10] The adenohypophysis also secretes **beta-lipotropin (β-LPH)** and a number of smaller peptides of undetermined significance. **Arginine vasopressin** (also known as antidiuretic hormone) and oxytocin are produced in the hypothalamus and are carried through the neurohypophyseal nerve axons to the neurohypophysis. Thus the neurohypophysis is not a discrete endocrine organ, but rather functions as a reservoir for these two hormones.

Of the six major hormones from the adenohypophysis, GH and PRL act primarily on diffuse target tissues with TSH, ACTH, and the gonadotropins (LH and FSH) acting primarily on specific target endocrine glands, specifically the (1) thyroid gland, (2) adrenal cortex, and (3) gonads, respectively (Table 40-2).[10] These peptide hormones originating from the pituitary and related hormones elaborated by the placenta during pregnancy have been classified based on their molecular structure and biochemical evolution.

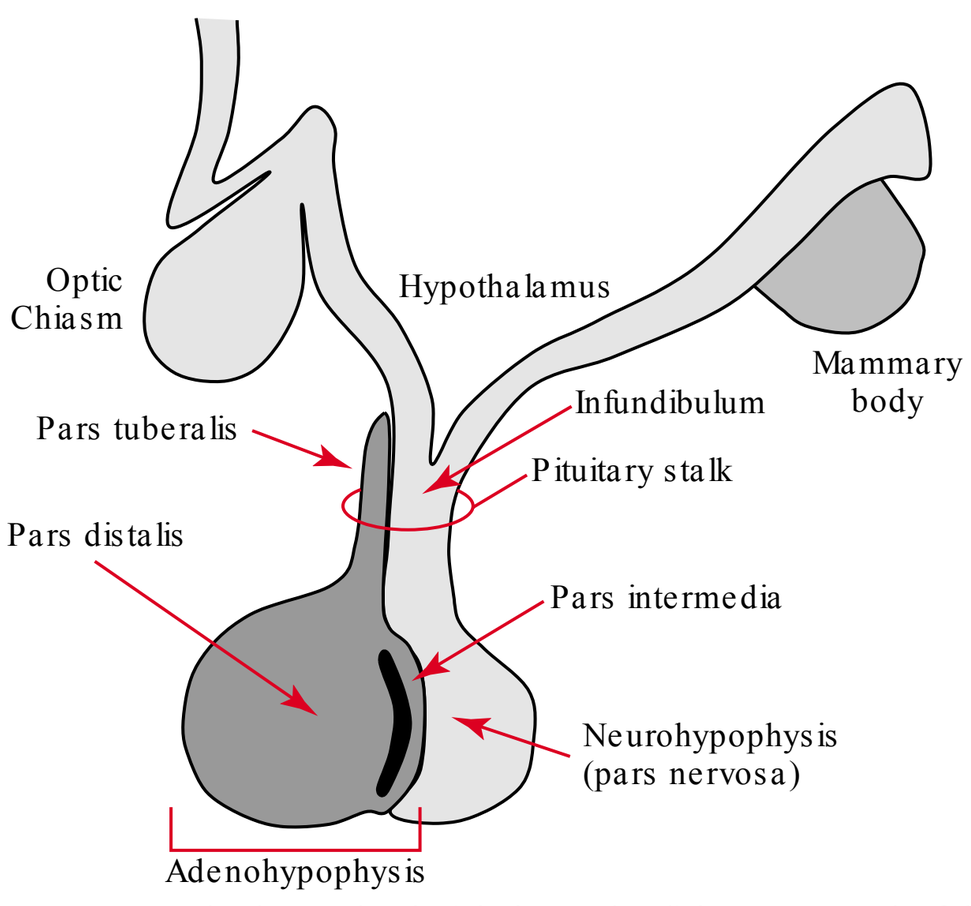

Figure 40-1 The hypophysis (pituitary gland) is composed of the adenohypophysis (the anterior lobe of the pituitary) and the neurohypophysis (the posterior lobe of the pituitary; pars nervosa). The adenohypophysis has three parts: the pars distalis, where most of the hormone-producing cells are located; the pars tuberalis, which is part of the pituitary stalk; and the pars intermedia.

TABLE 40-2 Hypothalamic Hormones and the Anterior Pituitary Hormones That They Regulate, Target Organ or Tissues Regulated by the Anterior Pituitary Hormone, and Hormonal Product of the Target Organ or Tissues

Hypothalamic Hormone(s)	Anterior Pituitary Hormone	Target Organ/Tissue	Target Hormone
CRH	ACTH	Adrenal cortex: zona fasciculata and zona reticularis	Cortisol
TRH	TSH	Thyroid follicular cell	T_4 and T_3
GHRH and Somatostatin	GH	Liver and many tissues of the body	IGF-I, IGHBP-3, and ALS
GnRH	LH, FSH	Gonad	Sex steroids and inhibins
PRIH	PRL	Breast	Not applicable

ACTH, Adrenocorticotropic hormone; ALS, acid-labile subunit; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; IGF-I, insulin-like growth factor I; IGHBP-3, IGF binding protein-3; LH, luteinizing hormone; PRIH, prolactin release-inhibiting hormone; PRL, prolactin; T_3, 3, 5, 3′-triiodothyronine; T_4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

TABLE 40-1 Hypothalamic Releasing or Inhibiting Hormones, Their Target Cells, and the Hormone That Is Regulated

Hypothalamic Hormone/Abbreviation	Amino Acids	Anterior Pituitary Target Cell	Hormone Regulated	Amino Acids	Molecular Weight
Corticotropin-releasing hormone (CRH)	41	Corticotroph	ACTH	39	4.5 kDa
Thyrotropin-releasing hormone (TRH)	3	Thyrotroph	TSH*	alpha: 92 beta: 118	28 kDa
Growth hormone-releasing hormone (GHRH)	44	Somatotroph	GH	191 176	22 kDa 20 kDa
Somatotrophin release-inhibiting hormone†	14	Somatotroph	GH	See above	see above
Gonadotropin-releasing hormone (GnRH)	10	Gonadotroph	LH* FSH*	alpha: 92 beta: 121 alpha: 92 beta: 111	32 kDa 30 kDa
Prolactin release-inhibiting hormone (PRIH)	1	Lactotroph	PRL	199	22 kDa

*All alpha glycoprotein chains are identical, including the alpha chain of human chorionic gonadotropin (hCG).
†Also known as somatostatin.
ACTH, Adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; PRL, prolactin; TSH, thyroid-stimulating hormone.

Hypothalamic Regulation[2-5,8]

Secretion of hormones from the anterior lobe of the pituitary gland is controlled by the hypothalamus, which synthesizes small peptide hormones known as releasing or inhibitory hormones (Figure 40-2).[2,5,8-10] Several have been characterized including: (1) **corticotropin-releasing hormone (CRH)**, (2) **thyrotropin-releasing hormone (TRH)**, (3) **growth hormone–releasing hormone (GHRH)**, (4) **somatostatin**, (5) **gonadotropin-releasing hormone (GnRH)**, (also called luteinizing hormone–releasing hormone), and (6) **prolactin-inhibiting hormone (PIH)** that is actually the neurotransmitter dopamine. In addition, GnRH stimulates the secretion of FSH and LH. However, a separate and distinct releasing factor for FSH has not yet been established, although negative feedback control of this gonadotropin is effected by inhibin, a peptide of gonadal origin.

Hormones that have been used to test for pituitary hormone reserve include (1) CRH, (2) TRH, (3) GHRH, and (4) GnRH In addition, pulsatile GnRH administration is used to initiate puberty and to induce ovulation or spermatogenesis. Alternately, GnRH antagonists that inhibit the action of endogenous GnRH are used to treat patients with (1) precocious puberty, (2) endometriosis, (3) uterine fibroids, and (4) prostate carcinoma. GHRH is yet another hypothalamic peptide that is used to treat patients with GH deficiency caused by hypothalamic disease.

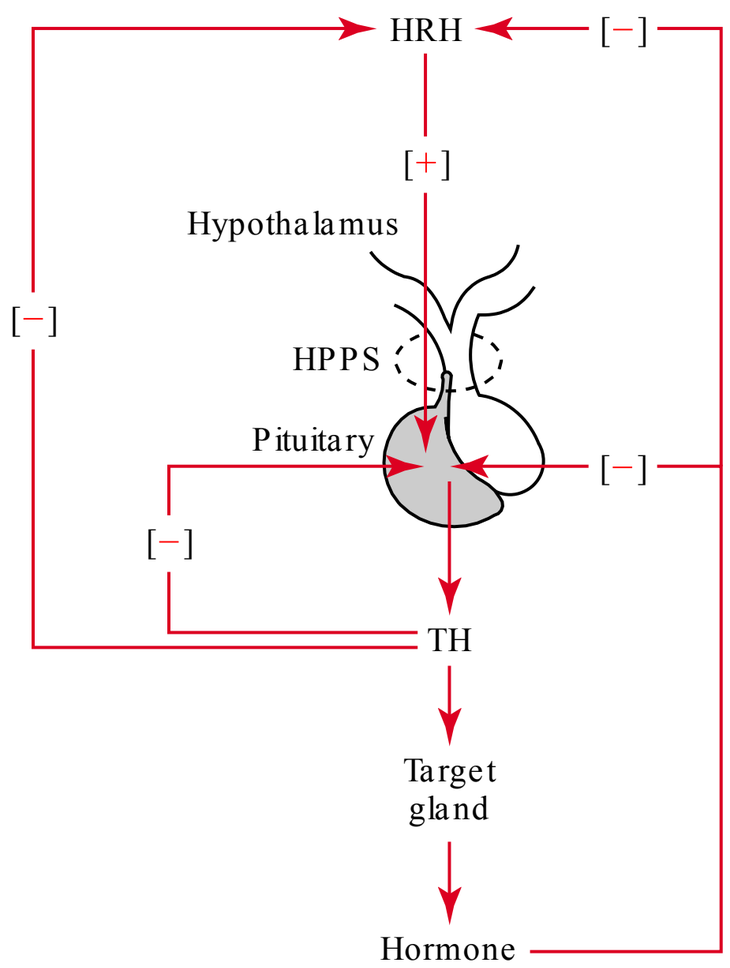

Figure 40-2 Many anterior pituitary trophic hormones (THs) (e.g., ACTH, TSH, GH, LH, and FSH) are regulated by hypothalamic releasing hormones (HRHs). Releasing hormones secreted by the hypothalamus reach the pituitary via the hypothalamic-pituitary portal system (HPPS). Long feedback loops involve negative feedback of the target cell hormone at the pituitary gland and hypothalamus. The short feedback loop involves the anterior pituitary trophic hormone feeding back at the hypothalamus, whereas the ultra-short feedback loop involves the anterior pituitary hormone feeding back at the anterior pituitary. [+], Stimulation; [−], suppression.

T e neurons that elaborate hypophysiotropic hormones are themselves influenced by hypothalamic neurotransmitters, such as (1) dopamine, (2) norepinephrine, (3) serotonin, (4) acetylcholine, and (5) endorphins. T ese neurotransmitters also modify the secretory activity of anterior pituitary hormones. For example, (1) basal and episodic secretion, (2) diurnal rhythm, and (3) nocturnal release of pituitary hormones are all considered to be secondary to central nervous system events that are mediated through hypothalamic hormones.

In addition to higher center regulation of the hypothalamic-pituitary axis by classic neurotransmitters, chemical mediators released by inflammatory cells (cytokines) have been discovered that participate in altering the control mechanisms associated with the neuroendocrine axis. For example, modulation of the feedback loop between the hypothalamic-pituitary-adrenal axis by cytokines, such as interleukin 1 (IL-1) and interleukin 6 (IL-6), released as a result of infection or stress, has been shown to diminish the immune system via release of ACTH which then raises cortisol concentrations.

Control of the functional relationship between the pituitary gland and its target organs is based on the principle of feedback control. T is feedback is a primarily negative one between the blood concentration of circulating hormones and the pituitary gland and hypothalamus. T e effect of negative feedback is typically opposite to that of the initial stimulus. For example, an elevated concentration of cortisol (initial stimulus) reduces the synthesis and the release of CRH, resulting in decreased secretion of ACTH and, ultimately, reduced secretion of cortisol (final response). Such feedback control maintains an optimal concentration of hormone in the blood under a variety of circumstances.

Hormones of the Adenohypophysis[2-5,8]

Hormones of the adenohypophysis are listed in Table 40-2[10] and discussed below.

Growth Hormone and Insulin-Like Growth Factors

T e most abundant hormone produced by the adenohypophysis is GH. **Insulin-like growth factor (IGF)** I is a polypeptide synthesized and released by the liver in response to GH. IGF-I (and IGF-II) have considerable amino acid sequence and functional similarity to insulin.

Biochemistry

GH is a single-chain polypeptide with a molecular mass of 21,500 Da that contains 191 amino acids and two intramolecular disulfide bridges. It is structurally similar to PRL and to the placental hormone chorionic somatomammotropin (hCS, placental lactogen), with which it has overlapping biological effects.

GH is synthesized by the somatotropic (acidophilic) cells of the adenohypophysis and is stored within intracellular granules. During the daytime hours, the plasma concentration of GH in healthy adults remains stable and relatively low (<2 ng/mL) with several secretory "spikes" occurring approximately

3 hours after meals and after exercise. In contrast during the evening hours, adults and children show a marked rise in GH secretory activity approximately 90 minutes after the onset of sleep; GH concentrations reach a peak value during the period of deepest sleep. This is pulsatile pattern of GH secretion may be important to anabolic and repair processes and for proper skeletal growth.

IGFs are polypeptides with high sequence similarity to insulin. Unlike most other peptide hormones, IGFs circulate in blood complexed to specific plasma-binding proteins. Six major IGF-binding proteins have been identified in human plasma. Insulin-like growth *f*actor binding protein (IGFBP)-3, a glycosylated binding protein, complexes more than 75% of the circulating IGF-I. The concentration of this binding protein is GH dependent and provides for a circulating reserve pool of IGF-I. Dissociation of the IGFs from the binding proteins occurs before passage through capillary membranes and entrance into tissue, such as cartilage.

Regulation of Release

The release of GH is thought to be controlled by hypothalamic GHRH and somatostatin. The former stimulates GH release and the latter inhibits GH release. Somatostatin is also found in the delta cells of the pancreatic islets and in many other sites in the digestive tract. It has important effects on the secretion of gastrointestinal hormones and causes inhibition of insulin and glucagon release. The hypothalamic influence on GH release appears to be primarily stimulatory through the action of GHRH. Release of these two hypothalamic factors is in turn influenced by higher centers of the brain. Thus different stimuli, such as (1) exercise, (2) physical and emotional stress, (3) hypoglycemia, (4) increased circulating amino acid concentrations (particularly arginine), and (5) hormones (such as, testosterone, estrogens, and thyroxine) evoke an increase in GH secretion. In the presence of abnormally high concentrations of glucocorticoids, GH secretion is suppressed. Other hypothalamic hormones (such as, TRH and GnRH) do not affect GH release in healthy subjects,[6] but may provoke GH release in patients with **acromegaly**.

Isolation and discovery of **ghrelin** revealed the existence of another control system for GH. Ghrelin is a small 28–amino acid peptide released from neuroendocrine cells in the gastric mucosa that binds to the GH secretagogue receptor to induce the secretion of both GHRH and GH itself. Ghrelin also induces food intake.

Physiological Actions

The overall physiological effect of GH is to promote growth in (1) soft tissue, (2) cartilage, and (3) bone. This action results from stimulation of protein synthesis that is partly induced by an increase in amino acid transport through cell membranes. The effects of GH on bone and muscle are exerted both directly and through the effects of IGF-I that is produced in the liver and other tissues under the influence of GH (e.g., bone). The increased growth of soft tissue and the skeleton is accompanied by changes in electrolyte metabolism, including a (1) positive nitrogen and phosphorus balance, (2) rise in plasma phosphorus concentrations, and (3) fall in blood urea and amino acid concentrations. Additional responses to GH include increased intestinal absorption of calcium and decreased urinary excretion of sodium and potassium. The metabolic changes are thought to result from the increased uptake of these ions by growing tissue. GH has other effects on intermediary metabolism. For example, GH stimulates the uptake of nonesterified fatty acids by muscle and accelerates the mobilization and metabolism of fat from adipose tissue to the liver. Chronic GH excess stimulates hepatic glycogenolysis and antagonizes the effect of insulin on glucose uptake by peripheral cells leading to an increase in blood glucose concentrations. GH and insulin induce growth in a similar manner because both have protein anabolic effects and stimulate the transport of amino acids into peripheral cells. Their respective effects on glucose homeostasis, however, oppose each other. Most growth-promoting GH effects are delayed rather than immediate and are exerted primarily through IGF-I.

The most important of the IGFs is IGF-I. In addition to its growth-promoting effects on cartilage, IGF-I also shows insulin-like activity in other tissue. IGF-I increases glucose oxidation in adipose tissue and stimulates glucose and amino acid transport into diaphragmatic muscle and heart muscle. Synthesis of collagen and proteoglycans is enhanced by IGF-I, which also has positive effects on (1) calcium, (2) magnesium, and (3) potassium homeostasis.

Plasma concentrations of immunoreactive IGF-I rise during childhood and achieve adult concentrations by the time of puberty. During puberty IGF-I concentrations have been observed to be two to three times the adult concentration. Following adolescence, IGF-I concentrations show a gradual decline, reaching a steady state in the third decade of life. IGF-I concentrations are increased as expected in patients with acromegaly and are reduced in GH-deficiency states and in many other conditions including (1) growth retardation, (2) hypothyroidism, (3) chronic illness, (4) nutritional deficiency, and (5) liver disease.

Clinical Significance[2-5,8]

Clinically important states of GH excess or deficiency are relatively uncommon and often difficult to diagnose. GH concentrations vary widely under normal circumstances, so the measurement of GH under random conditions is not generally considered useful. A single GH measurement should not be used to distinguish normal fluctuations from the low or high concentrations that are seen in various disease states. GH measurements are best determined as part of dynamic testing that involves the use of pharmacological or physiological stimuli to increase or suppress GH release.

In contrast to GH, a single measurement of IGF-I is considered an accurate reflection of IGF-I production. Serum concentrations of IGF-I are influenced by nonpathological factors such as (1) age, (2) degree of sexual maturation, and (3) nutritional status. As mentioned previously, IGF-I concentrations are low in states of GH deficiency, but also in patients with

acute or chronic protein or caloric deprivation as well as in hypothyroidism.

Growth Hormone Excess

Excess GH production is associated with an eosinophilic or chromophobe **adenoma** of the pituitary gland. T ese tumors are usually macroadenomas, that is, >10 mm in diameter. Prolonged exposure to GH excess causes an overgrowth of the skeleton and soft tissue. T e acral (pertaining to or affecting a limb or other extremity) overgrowth is recognized by increasing (1) ring, (2) shoe, or (3) glove size. T is occurs most commonly in adults and is known as acromegaly. When GH excess is seen before long-bone growth is complete (i.e., before epiphyseal fusion), the condition is called **pituitary gigantism**. With pituitary gigantism, in addition to the overgrowth of bone and soft tissue particularly evident in the face and extremities, there is a striking acceleration of linear growth. In severe or advanced cases of GH excess, the diagnosis is made on the basis of physical appearance alone. T e physical changes are often subtle and gradual so that a high degree of clinical suspicion is needed to make an early diagnosis. T e reversibility of the tissue changes depends largely on the duration of the disease. In addition to the soft-tissue changes, acromegaly may cause severe disability or death from (1) cardiac, (2) respiratory, or (3) neurological sequelae. T e most important requirement for the diagnosis of acromegaly is the demonstration of inappropriate and excessive GH secretion.

GH-secreting pituitary tumors account for most of the cases of acromegaly.[3,6] Patients who have pituitary tumors that produce GH are frequently shown to release GH in response to other hypothalamic peptides (TRH and GnRH) that under normal circumstances do not elicit a release of GH. On occasion, pituitary tumors that produce excess amounts of both GH and PRL are observed in around 25% of patients with acromegaly. Few cases of acromegaly, however, are due to GHRH hypersecretion by tumors.

As many as 10% of patients with active acromegaly have random serum GH concentrations that are within the healthy reference interval. T e test of choice for the diagnosis of acromegaly is a glucose tolerance test. Healthy individuals suppress their GH to very low concentrations at 60 to 120 minutes after a 75-gram oral glucose challenge. Essentially, all patients with acromegaly have an abnormal response to oral glucose. Patients with acromegaly typically show either no change in their basal concentration of GH or sometimes demonstrate a paradoxical increase in GH.

Serum IGF-I concentrations are elevated in active acromegaly. IGF-I concentrations often correlate better with the clinical severity of acromegaly than with glucose-suppressed or basal GH concentrations. In healthy nourished persons without liver or kidney disease, IGF-I concentrations reflect the integrated effect of GH at the tissue concentration and correlate with 24-hour GH concentrations. Other biochemical abnormalities in acromegaly include (1) hyperphosphatemia, (2) impaired glucose tolerance, and (3) frank diabetes.

Growth Hormone Deficiency States and Growth Retardation[2-5,8]

Children who have inadequate GH production or a GH receptor defect do not grow normally. GH deficiency may be (1) congenital or acquired, (2) idiopathic or caused by anatomical damage to the pituitary gland or hypothalamus, or (3) caused by isolated GH deficiency or associated deficiencies of other pituitary hormones. In one reversible GH deficiency state known as psychosocial dwarf sm, environmental stress has been shown to inhibit pituitary and hypothalamic function, leading to GH suppression and growth retardation. Children with this disorder show clinical and chemical evidence of growth deficiency when first evaluated, but usually have healthy pituitary function after a few days of hospital stay. GH deficiency is not a common cause of growth retardation. About one half of the children evaluated for growth retardation have no specific organic cause. Approximately, 15% of children with growth retardation have endocrine problems, and approximately one half of these children (about 8% of all children with short stature) have GH deficiency. However, children with growth retardation or **pituitary dwarf sm** with no clear explanation (including exclusion of hypothyroidism) should at least be screened for GH deficiency. With the availability of recombinant GH for therapeutic use, many children with short stature are now being selectively treated with GH to advance their growth pattern to more closely achieve their genetic potential.

GH deficiency in adults is probably the most common demonstrable abnormality in patients with large pituitary adenomas or patients who have undergone pituitary irradiation. In adults it has been known to lead to (1) premature mortality, (2) abnormal body composition, (3) impaired serum lipids, (4) decreased bone density with an increase in fracture risk, and (5) overall an impaired quality of life. T us GH replacement therapy is an important clinical intervention in GH-deficient adults and considered the standard of care.

Resistance to GH results in growth failure despite normal or increased serum GH concentrations and decreased plasma IGF-1 concentrations as in **Laron syndrome**. Patients who have familial short stature and high serum GH concentrations represent many different defects in genetic coding for the GH receptor that result in the absence of or defective GH receptors. In affected individuals, exogenous GH fails to produce any appreciable metabolic changes or to promote growth.

In healthy individuals, the basal concentration of GH is usually low, and the half-life of circulating GH is approximately 20 minutes. Moreover, GH is secreted by the pituitary gland in short pulses or bursts. T us assays of GH performed on a single random or fasting specimen may not distinguish patients with abnormally low concentrations from healthy subjects who have GH values at the low end of the reference interval. When evaluating GH reserve, provocative tests are frequently used to diagnose true deficiency. Although a physiological GH response to a provocative test is a strong indication for the absence of GH deficiency, no single test is considered diagnostic in this situation. For example, as many as 30% of subjects with physiological GH secretion fail to show

the expected elevation in serum GH in response to a specific provocative stimulus at any given time. Consequently, to diagnose GH deficiency as a cause of growth retardation, it is necessary to demonstrate that the serum concentration of GH remains low after the use of at least two different provocative stimuli. The definition of subnormal responses, however, is arbitrarily defined and assay dependent. However, in general a GH response of 7 ng/mL or more after stimulation is considered healthy.

A number of physiological and pharmacological stimuli provoke GH release as depicted in Table 40-3.[10] In one simple screening test, the patient performs 20 minutes of vigorous exercise, and then a sample is obtained for a GH measurement. Taking advantage of the known rise in the concentration of GH that occurs with deep sleep, a sample may be obtained 60 to 90 minutes after the onset of sleep. The obvious limitation of this approach is that the patient must be in the hospital or a clinical research center for testing. Insulin-induced hypoglycemia and arginine are the standard pharmacological stimuli used to test for GH release; protocols for their use are well established and standardized (see Table 40-3).[10] Other medications used to stimulate GH release include glucagon and clonidine. GHRH administration (1.0 μg/kg) in combination with arginine has also been used to test for pituitary GH reserve directly.[5]

As expected, IGF-I concentrations are low in patients with GH deficiency and growth failure. Patients with growth failure caused by other endocrine diseases or by nonendocrine diseases often have low circulating concentrations of IGF-I; thus a low concentration of IGF-I is not specific for diagnosing a GH deficiency. The presence of a physiological concentration of IGF-I, however, does rule out severe GH deficiency.

Analytical Methodology

Immunoassays are the usual methods to measure GH and IGFs, but mass spectrometric methods have been described.[10]

Measurement of Growth Hormone

Immunoassays are used to measure GH with specific GH antibodies available commercially as part of an immunoassay kit or on automated immunoassay instruments.

With the use of highly-specific monoclonal antibodies and recombinant-derived GH, some of these assays are able to discriminate GH variants. Most immunoassays for GH use recombinant-derived GH for tracer and calibration material. The latter is usually prepared gravimetrically and verified by comparison with an international reference preparation (IRP), such as the World Health Organization's (WHO's) international standard, IRP 80/505 human growth hormone recombinant (hGHr), which has a potency of 3.3 IU/mg of hGHr, or other standard preparations, such as WHO IRP 66/217 or 88/624.

The measurement of a single basal or random concentration of GH provides little diagnostic information. Secretion of GH by the pituitary gland is both episodic and pulsatile, and transient concentrations of as much as 40 ng/mL have been observed in healthy, healthy subjects. Serum concentrations are rather low between pulses in healthy individuals, and some immunoassays may not be able to distinguish patients with abnormally low values from healthy subjects who have values that happen to fall in the low-to physiological reference interval. In some individuals, spontaneous GH secretion is best monitored by drawing specimens for GH assay every 20 to 30 minutes over a 12- to 24-hour period although cost would likely preclude such testing on a routine basis.

A number of provocative tests have been established to stimulate or suppress GH release. The insulin tolerance test, which produces a transient hypoglycemia to provoke GH release, is the most common stimulation test used to assess adequacy of GH secretion. In addition it also allows for an adequate assessment of the hypothalamic-pituitary–adrenal axis; cortisol concentrations 20 μg/dL or greater exclude any derangement of this axis. Whilst this test is considered by many as the gold standard and it allows assessment of both GH and ACTH reserve, it is important to remember that it is

TABLE 40-3 Growth Hormone Stimuli

Growth Hormone Stimulus	Dose	Growth Hormone Sampling Minutes*
Glucogen	0.03-0.1 mg/kg, IM, max 1 mg	0, 30, 60, 90, 120, 150, 180, ±240 (maximum response ≈2 to 3 hours)
L-dopa	500 mg/M² (15 mg/kg) max 500 mg (or) <15 kg: 125 mg 15-30 kg: 250 mg >30 kg: 500 mg	0, 40, 60, 90, 120
Clonidine	0.15 mg/M² <30 lbs: 0.05 mg >30 lbs: 0.1 mg (0.1 mg/tab)	0, 30, 60, 90
Arginine HCl (synthetic arginine)	0.5 g/kg, max 30 (10% solution IV over 30 min)	0, ±15, 30, 60, 90, ±120
Insulin tolerance test (ITT)	0.1 U/kg (0.05-0.15) IV push insulin	0, 10, 20, ±30, 40, 60, ±75, ±90, ±120
Arginine-insulin tolerance test (AITT)	Arginine: begin at time zero, give insulin at +60 minutes	0, 30, 60, 70, 80, 100, 120

*Experts may differ on the best interval of growth hormone (GH) measurements; ± indicates an optional time point.
IM, intramuscular; IV, intravenous.

contraindicated in patients with cardiovascular disease, cerebrovascular disease, and seizure disorders due to the stress of the induced hypoglycemia.

Measurement of Insulin-Like Growth Factors

IGFs and IGF-binding proteins are measured in plasma or serum by immunoassays, typically immunometric assays, with use of recombinant standards and specific monoclonal antibodies. It is important to emphasize that reference intervals vary by age and sex, and it is important to use the reference interval reported for that specific assay. At least one mass spectrometric assay is used routinely for IGF-I; the reference intervals for this assay are similar to those found by immunoassays.

Prolactin[2,4,5,8]

PRL is a hormone secreted by specialized cells within the adenohypophysis termed lactotrophs. PRL's primary role is to stimulate and sustain lactation in postpartum mammals. PRL has many other effects, including essential roles in the maintenance of the immune system and an important role in ovarian steroidogenesis. PRL is also known as (1) lactogen, (2) lactotropin, (3) luteotropin, (4) mammotropin, or (5) galactopoietic, lactation, lactogenic, or luteotropic hormone.

Biochemistry

PRL contains 199 amino acids and has three intramolecular disulfide bridges. It is secreted by the pituitary lactotroph cells, which are acidophilic. PRL circulates in the blood in different forms including (1) monomeric PRL, 23 kDa (referred to as little PRL), (2) dimeric PRL, 48 to 56 kDa (big PRL), and (3) polymeric forms of PRL >100 kDa ("big-big" PRL). The monomeric form is considered the most bioactive of the different forms found in the circulation and demonstrates the greatest response to TRH, the hypothalamic releasing hormone that stimulates the pituitary to release PRL when TRH is present in high concentrations. TRH is not typically a major regulator of PRL secretion by the pituitary. The relative number and PRL content of lactotroph cells are increased in women during pregnancy, which is also the case in fetal pituitary glands.

Secretion of PRL, as for other hormones released by the anterior lobe of the pituitary gland, falls under hypothalamic control. PRL is unique, however, among the adenohypophyseal hormones in that the primary control of its secretion is inhibitory via dopamine.

Physiological Action

PRL is the principal hormone that controls the initiation and maintenance of lactation. However, for an appropriate expression of PRL action, breast tissue requires priming by (1) estrogens, (2) progestins, (3) corticosteroids, (4) thyroid hormone, and (5) insulin. PRL also (1) induces ductal growth, 2) development of the breast lobular alveolar system, and (3) the synthesis of specific milk proteins, including casein and γ-lactalbumin. PRL has effects on the immune system and is important in the control of osmolality and various metabolic events, including (1) the metabolism of subcutaneous fat, (2) carbohydrate metabolism, (3) calcium and vitamin D metabolism, (4) fetal lung development, and (5) steroidogenesis. The last function may be related to its antigonadotropic effect.

PRL, like other pituitary hormones, binds to a specific receptor on the cell membrane of its target organs such as (1) breast, (2) adrenal, (3) ovaries, (4) testes, (5) prostate, (6) kidney, and (7) liver.

Clinical Significance[2,4,5,8]

Hyperprolactinemia is the most common hypothalamic-pituitary disorder encountered in clinical endocrinology, and prolactinomas are the most common secretory tumors of the pituitary gland. PRL concentrations also may be increased in women who have only subtle alterations of fertility, such as (1) anovulation with or without menstrual irregularity, (2) amenorrhea and galactorrhea, or (3) galactorrhea alone. PRL excess in men is frequently manifested as oligospermia or impotence, or both. In addition, men with PRL-secreting pituitary adenomas more often have macroadenomas along with visual field disturbances as a result of a larger tumor pressing on the optic chiasm. Men do not have the subtle reminder of an irregular menstrual period that frequently exposes a microadenoma in women. In both men and women, increased PRL can result in infertility. Elevated PRL concentrations are observed in as many as 30% of women with polycystic ovarian syndrome and patients with clinically silent pituitary adenomas. Other causes of PRL elevation are shown in Table 40-4[10] and should be kept in mind when evaluating patients who have an elevated concentration of PRL. There is no reliable stimulation or suppression test as with other pituitary hormones to distinguish tumor from other causes of PRL elevation.

Basal gonadotropin concentrations are low in most patients with hyperprolactinemia; most studies suggest that PRL inhibits the release of GnRH, resulting in a state of functional hypogonadotropism. Other pituitary function tests are usually normal in patients with hyperprolactinemia, except in individuals with very large macroadenomas where the tumor is pressing on normal anterior pituitary cells.

TABLE 40-4 Differential Diagnosis of Hyperprolactinemia

PRIH (dopamine) deficiency	Hypothalamic disease
	Interruption in the hypothalamic pituitary portal system
Drugs	Dopamine antagonists
	Cholinergic antagonists
	Serotonergic antagonists
Hormones	Estrogen, pregnancy
Neurogenic	Nursing (nipple stimulation)
	Chest wall disease
	Spinal cord injury
Other diseases	Hyperthyroidism (pathologically elevated TRH can release PRL)
	Chronic renal disease
	Cirrhosis

PRIH, Prolactin release-inhibiting hormone; PRL, prolactin; TRH, thyrotropin-releasing hormone.

Clinically, medications that stimulate PRL release are probably the most common cause of hyperprolactinemia. When a significant elevation of PRL is confirmed, a careful history must be recorded to rule out the possibility that medications are not the cause for the elevation in PRL.

Invariably, serial PRL concentrations higher than 200 ng/mL are sufficient evidence to support a diagnosis of a PRL-secreting adenoma especially if imaging studies demonstrate an adenoma. Rarely, "pseudoprolactinomas" do occur and are large nonsecretory tumors (such as meningiomas) that press on the pituitary stalk, disrupting the normal inhibitory flow of dopamine from the hypothalamus, resulting in modest elevations in PRL concentrations (typically between 50 and 200 μg/L). Thus imaging studies coupled with serial basal prolactin concentrations are most useful in making a diagnosis of prolactinoma. Serum prolactin concentrations can be increased also by a macroprolactin, which can be (1) a complex of PRL with immunoglobulins or (2) aggregates of monomeric PRL. The presence of macroprolactin explains a significant proportion of cases of increased serum PRL and should be considered when a pathological explanation for an increased serum PRL is not found.

Analytical Methodology

Human PRL is measured in serum by use of immunoassays. Two-site immunometric ("sandwich") assays that make use of two or more antibodies directed at different parts of the PRL molecule are used on automated instruments. The signal antibody is labeled with a detection molecule such as an (1) enzyme, (2) fluorophore, or (3) chemiluminescent tag. PRL calibrators have values assigned by use of reference materials with known international unit potency, such as the WHO first IRP 75/504, the second international standard (IS) 83/562, or the third IS 84/500 (http://www.nibsc.ac.uk/accessed November 20, 2013). One of the concerns with PRL immunoassays is a "hook effect" with very high prolactin concentrations that affect certain immunoassay methods, particularly one-step assays in which no washing step is included between addition of the capture and detection antibodies. When suspected, samples need to be diluted and reanalyzed.

Adrenocorticotropic Hormone and Related Peptides[2-5,8]

Adrenocorticotropic hormone (ACTH) is a peptide hormone secreted by the adenohypophysis as one of the derivatives of **pro-opiomelanocortin (POMC)**. It acts primarily on the adrenal cortex, stimulating its growth and the synthesis and secretion of corticosteroids, most importantly, cortisol. ACTH production is increased during times of stress. It is also known as corticotropin, corticotrophin, adrenocorticotrophin, and adrenocorticotropin.

Biochemistry

ACTH and related peptides originate from POMC, a large precursor molecule with a molecular weight of 31 kDa (Figure 40-3). Enzymatic cleavage of POMC to smaller peptides takes place in both the anterior and intermediate lobes of the pituitary gland. In the anterior lobe of the pituitary gland, enzymes hydrolyze POMC to β-LPH and a 22-kDa fragment known as pro-ACTH. This latter peptide is further processed to ACTH (a peptide consisting of 39 amino acids) and to a 16-kDa peptide, pro-γ-melanotropin (γ-MSH). In turn, β-LPH is cleaved to two smaller peptides, β-endorphin and γ-LPH. Both γ-LPH and β-endorphin are released with ACTH from the anterior lobe of the pituitary gland, but only about one third of the β-LPH is converted to β-endorphin. In contrast the intermediate lobe (when present) fully processes β-LPH to β-endorphin, cleaving pro-α-melanotropin (α-MSH) to α-melanotropin (α-MSH), and splitting ACTH to α-MSH and a corticotropin-like intermediate-lobe peptide. These smaller peptides are found in the human fetus, but only trace amounts exist in the adult human pituitary gland. The changes observed in skin pigmentation in several endocrine diseases (e.g., with adrenal insufficiency) are most likely due to the α-MSH activity of excess ACTH.

In addition to β-endorphin, β-LPH contains the amino acid sequence of another endogenous opioid, met-enkephalin.

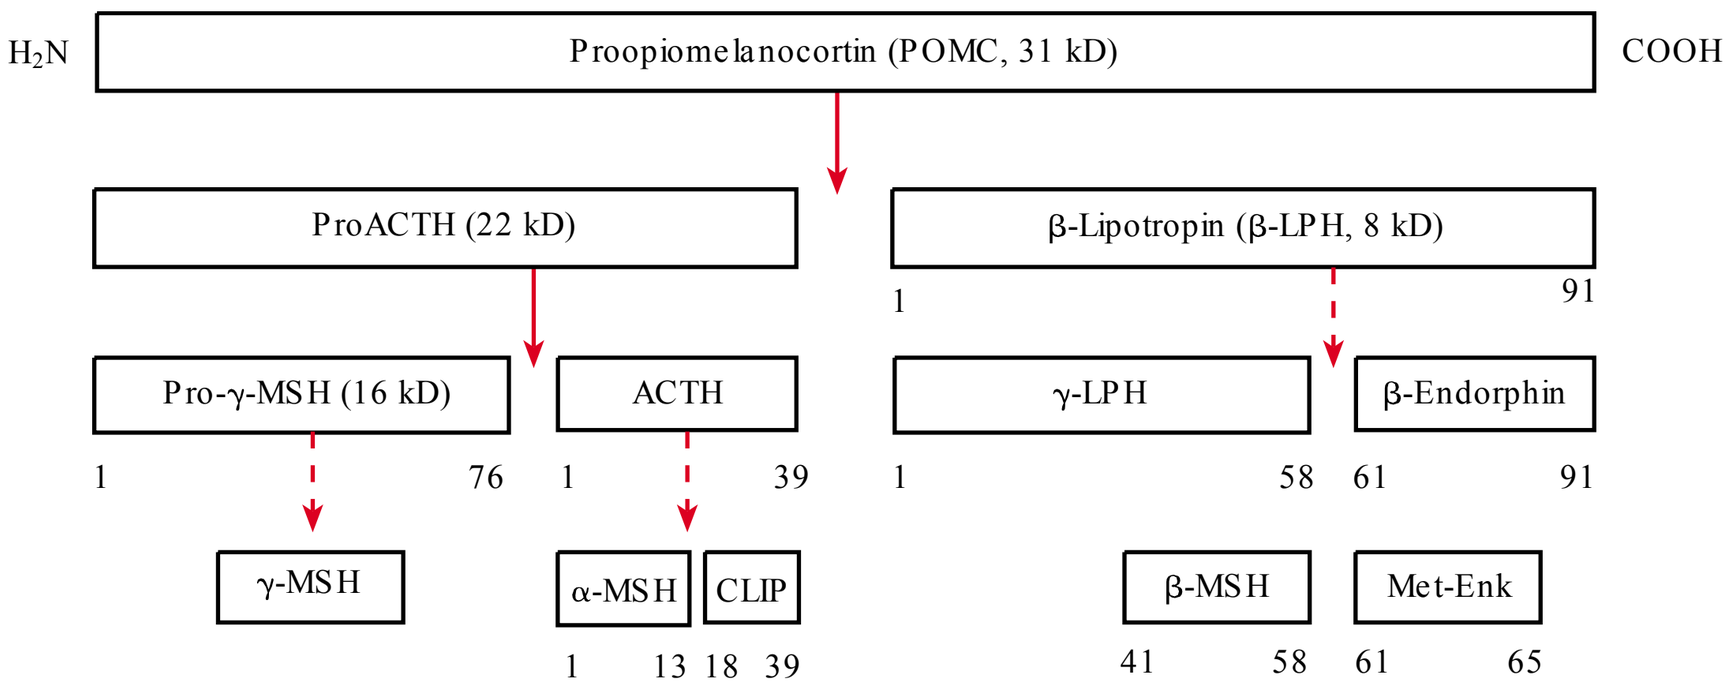

Figure 40-3 Diagrammatic representation of pro-opiomelanocortin (POMC) and its precursor relationship to adrenocorticotropic hormone (ACTH), beta-lipotropin (β-LPH), α- and β-melanotropin (MSH), and the endorphins.

However, this peptide is not the product of β-LPH breakdown, but rather arises from a precursor molecule known as pro-enkephalin. Pro-enkephalin is widely distributed in neurons throughout the brain and spinal cord. Some pro-enkephalin is found in the pituitary gland, but most is localized in the catecholamine-synthesizing cells of the adrenal medulla and is co-released with epinephrine and norepinephrine. A third family of endogenous opioid peptides is derived from pro-dynorphin, a prohormone stored primarily in the posterior lobe of the pituitary gland where it is co-released with vasopressin.

Regulation of Adrenocorticotropic Hormone Secretion

Regulation of the secretion of ACTH is described in Chapter 41.

Clinical Significance[2-5,8]

The major disorders of the pituitary gland with respect to ACTH include ACTH deficiency or secondary hypoadrenalism and excess ACTH secretion resulting in **Cushing disease** the commonest cause of **Cushing syndrome** (see Chapter 41). Briefly, for the diagnosis of Cushing syndrome/disease, useful tests include measurement of (1) the 24-hour excretion of urinary-free cortisol, (2) the dexamethasone suppression tests (both overnight with 1 mg and 48 hours with 2 mg/d), and (3) demonstration of loss of the diurnal variation with inappropriately increased cortisol concentrations in the evening as assayed by plasma or salivary cortisol. Useful tests for the diagnosis of secondary adrenal insufficiency due to CRH-ACTH deficiency include the (1) cosyntropin test, (2) overnight metyrapone test, (3) insulin tolerance tests—and, if necessary, (4) cosyntropin infusion test over several days. In the short metyrapone test a morning plasma 11-deoxycortisol >7 μg/dL excludes secondary adrenal insufficiency. Also during an insulin tolerance test if the concentration of plasma cortisol meets or exceeds a concentration of 20 μg/dL, secondary hypoadrenalism is excluded.

Gonadotropins (Follicle-Stimulating Hormone, Luteinizing Hormone)

FSH is synthesized in the adenohypophysis and (1) stimulates the growth and maturation of ovarian follicles, (2) stimulates estrogen secretion, (3) promotes the endometrial changes characteristic of the first phase (proliferative phase) of the mammalian menstrual cycle, and (4) stimulates spermatogenesis in the male. It is also called *f*ollitropin.

LH is also synthesized in the adenohypophysis and acts with FSH to promote ovulation and secretion of androgens and progesterone. It initiates and maintains the second (secretory) phase of the mammalian estrus and menstrual cycle. In females it is concerned with corpus luteum formation, and in males it stimulates the development and functional activity of testicular Leydig cells and testosterone production. LH is also called interstitial cell–stimulating hormone and lutropin.

Biochemistry

The glycoprotein hormones of the pituitary (LH, FSH, and TSH) and of the placenta (chorionic gonadotropin [CG]) are composed of two peptide chains (usually referred to as α- and β-subunits), each with carbohydrate substituent groups attached. The carbohydrate moiety, which accounts for 15% to 31% of the molecular weight, includes (1) fucose, (2) mannose, (3) galactose, (4) glucosamine, (5) galactosamine, and (6) sialic acid. The α-subunits of these hormones are similar to one another and are interchangeable. The β-subunits display greater differences in amino acid sequences among the various hormones that confer hormonal and immunological specificity. Isolated α-subunits are devoid of biological activity. Isolated β-subunits may have slight intrinsic biological activity, but full activity is attained when α- and β-subunits are recombined. This suggests that the presence of both subunits is important for specific receptor recognition and that the β-subunit is responsible for eliciting the specific biological response.

The gonadotropic cells of the anterior lobe of the pituitary gland secrete FSH (molecular weight 30 kDa) and LH (molecular weight 32 kDa). Because these two hormones control the functional activity of gonads, they are grouped together under the generic term gonadotropins.

Physiological Action

In females, FSH stimulates the growth and maturation of the ovarian follicles and, in the presence of LH, promotes secretion of estrogens by the maturing follicles. The LH surge (or "peak") in females in mid-cycle causes ovulation and release of the ovum from the ovarian follicle, which has previously ripened under the influence of FSH, and causes luteinization of the ruptured follicle to form the corpus luteum. The corpus luteum then secretes both progesterone and estradiol under the influence of pulsatile LH release. In males FSH stimulates spermatogenesis by the germ cells in the testes, and LH is responsible for the production of testosterone by the Leydig cells of the testes.

Regulation and Clinical Significance

Regulation of LH and FSH secretion and its clinical significance in reproductive endocrinology are discussed in Chapter 43. In women, a regular menstrual cycle is supportive of a normal functioning hypothalamic-pituitary-gonadal axis.

Briefly, the major clinical syndrome is deficiency of the gonadotropins LH and FSH. When there is deficiency of the gonadotropins resulting in hypogonadism, it is referred to as hypogonadotropic hypogonadism. These patients have low or normal concentrations of LH, FSH, and low concentrations of testosterone in males and estradiol in females. This can present as an isolated deficiency, monohypopituitarism, or part of multiple hormone deficiencies, panhypopituitarism. The best characterized isolated hormone deficiency is **Kallmann syndrome** due to a deficiency of GnRH, which is associated with impairment in smell, anosmia, or hyposmia and midline defects. In this disorder, priming with GnRH restores gonadotropin secretion and fertility. Hypogonadotropic hypogonadism can occur with (1) severe mental and physical stress, (2) anorexia nervosa, and (3) can be observed in the overtrained athlete.

Very rarely does hypogonadism result from a pituitary tumor, usually a large chromophobe adenoma.

Analytical Methodology

A number of different immunoassay methods have been developed for determining FSH and LH in blood and urine, and reliable commercial kits are widely available either for manual testing or with automated immunoassay instruments.

Currently, most immunoassays for FSH and LH show <1% cross-reactivity with TSH or human CG (hCG) or with their free α- or β-chains. For example, hCG interference in LH assays has essentially been eliminated (<0.008% cross-reactivity), and the immunometric assays found on automated instruments show precision (between-assay coef cients of variation [CVs]) of about 10% or less and limits of quantification <0.2 IU/L. T e latter is especially important for use in the evaluation of prepubertal children and patients with hypothalamic disorders when LH concentrations are barely detectable.

Thyroid-Stimulating Hormone[2-5,8]

TSH is a glycoprotein hormone synthesized by the thyrotroph cells of the adenohypophysis that promotes the growth and uptake of iodine by the thyroid gland and stimulates the synthesis and secretion of thyroid hormones from the thyroid gland. It is also called thyrotropin. It is a peptide with a molecular weight of 26.6 kDa. A molecule of TSH consists of two noncovalently linked α- and β-subunits with the α-subunit chemically similar to the α-subunits of LH, FSH, and hCG. TSH (1) stimulates the growth and vascularity of the thyroid gland, (2) stimulates the growth of thyroid follicular cells, and (3) promotes a number of the steps involved in thyroid hormone synthesis. T ese include the (1) uptake of iodine, (2) organification of iodine onto tyrosine, (3) coupling of tyrosines, and (4) proteolytic release of stored thyroid hormone from thyroglobulin stores.

Regulation and Clinical Signif cance

T e regulation of TSH secretion, its clinical significance, and methods for determining TSH are discussed in in Chapter 42. Briefly, two major clinical syndromes arise from TSH deficiency or TSH excess. TSH deficiency results in secondary hypothyroidism with low concentrations of T_4 and TSH. It needs to be emphasized that the T_4 concentrations are more reliable than TSH in the diagnosis of hypothyroidism as a result of hypothalamic-pituitary diseases, and TSH concentrations may be within the reference interval (although that is abnormal in the face of a low T_4 which should lead to TSH secretion normally and thus increased circulating TSH). A rare form of hyperthyroidism is caused by a TSH-producing tumor of the pituitary gland. Patients have clinical features of hyperthyroidism with elevated concentrations of T_4 and increased or inappropriately normal TSH concentrations.

Hormones of the Neurohypophysis[2,7-10]

T e neurohypophyseal system comprises neural tissue and neurons of the supraoptic and paraventricular nuclei of the hypothalamus. T ese neurons are located in and travel through the median eminence and pituitary stalk with the nerve endings projecting to the posterior lobe of the pituitary gland. T e cell bodies of these neurons synthesize and secrete (1) antidiuretic hormone (also known as arginine vasopressin and vasopressin) and (2) oxytocin. Both of these hormones are nonapeptides (molecular weight 1080 Da) consisting of a cyclic hexapeptide and a three–amino acid side chain. T e structure of oxytocin is similar to that of **antidiuretic hormone (ADH)** but with isoleucine rather than phenylalanine at position 3 and with leucine instead of arginine at position 8.

Antidiuretic Hormone[7,9,10]

ADH is formed by neuronal cells of hypothalamic nuclei and stored in the neurohypophysis. In humans it contains arginine at position 8. (In the pig and hippopotamus, lysine is found at position 8.) ADH functions to (1) stimulate contraction of the muscles of capillaries and arterioles, raising blood pressure; (2) promote contraction of the intestinal musculature, increasing peristalsis; (3) exert contractile influence on the uterus; and (4) have a specific effect on the epithelial cells of renal collecting tubules, augmenting resorption of water independently of solutes to cause concentration of urine and dilution of blood serum. T is action on the kidney is mediated by ADH binding to V2 receptors and stimulating cyclic AMP resulting in increased cell membrane expression of aquaporin-2 water channels with an increase in the reabsorption of water. ADH's rate of secretion is regulated chiefly by the osmolality of the plasma. Also a decrease in plasma volume sometimes evokes release of ADH.

Biochemistry

ADH is synthesized as part of a large precursor molecule (preprovasopressin) and ADH travels down axons in conjunction with a specific neurophysin-binding protein. T e latter serves as a carrier protein for ADH during axonal transport and storage. Oxytocin is also synthesized as part of a preprohormone along with a separate neurophysin-binding protein. T ese molecular complexes are packaged into secretory granules that migrate down the nerve axons for 12 to 14 hours before reaching the posterior pituitary lobe for storage. Release of the neurohypophyseal hormones into the portal circulation occurs via calcium-dependent exocytosis on nerve cell stimulation. At the physiological pH of plasma, ADH and oxytocin circulate mainly in unbound forms.

Regulation of Secretion

Osmolality of the blood is the main regulator of ADH secretion. Osmoreceptors in the brain respond to changes in plasma osmolality. As little as a 2% increase in extracellular fluid osmolality causes shrinkage of osmoreceptor cells with stimulation of ADH release from the posterior pituitary lobe. A plasma osmolality >280 mOsm/kg is considered the osmotic threshold for ADH release.

Besides the osmoreceptor mechanism, the physiological regulation of ADH secretion also involves a pressure-volume mechanism that is distinct from the osmotic sensor. In this second process, ADH release is regulated by baroreceptors that respond to alterations in blood volume. For example, a reduction in plasma volume or arterial pressure, or both,

stimulates ADH secretion. Other nonosmotic stimuli for ADH release include pain, stress, hypoglycemia, exercise, and chemical agents, such as (1) catecholamines, (2) angiotensin II, (3) opiates, (4) prostaglandins, (5) anesthetics, (6) nicotine, and (7) barbiturates. Agents such as alcohol, phenytoin, and glucocorticoids are known to inhibit ADH release, leading to a water diuresis.

The thirst center is regulated by many of the same factors that determine ADH release. This center has a higher set-point than the osmoreceptors and responds to osmolalities >290 mOsm/kg. Responses involving ADH, thirst, and the kidney are coordinated in a complex scheme to maintain plasma osmolality in healthy individuals within a narrow range (284 to 295 mOsm/kg).

Physiological Actions

The major physiological function of ADH is the control of water homeostasis, which allows the kidney to reabsorb water and concentrate urine. When released in sufficient quantity, ADH also induces a generalized vasoconstriction that leads to a rise in arterial blood pressure. ADH is believed to play an important role in the maintenance of arterial blood pressure during blood loss. Release of ADH into the pituitary portal system also augments the action of CRH in stimulating the release of ACTH from the adenohypophysis. However, ADH does not appear to affect the release of other anterior pituitary hormones.

Clinical Significance[2,7-10]

Disorders of ADH activity have been divided into hypofunction (**diabetes insipidus [DI]**) and hyperfunction (**syndrome of inappropriate antidiuretic hormone secretion [SIADH]**).

Diabetes Insipidus

Deficient production or action of ADH results in **polyuria** caused by the failure of the renal tubules to reabsorb solute-free water. Under normal circumstances, urine output is largely dependent on fluid intake. Thus an arbitrary limit for normal urine output is difficult to define. When urine output is >2.5 L/day, an investigation is usually indicated; with complete deficiency of ADH, urine output may approach 1 L/hr. If the thirst response is normal, increased ingestion of fluid (**polydipsia**) follows. If access to water is not restricted, plasma osmolality and serum electrolytes usually remain normal.

Polyuric states are divided into three main categories: (1) deficient ADH production (hypothalamic diabetes insipidus [HDI]), (2) deficient ADH action on the kidney (nephrogenic diabetes insipidus [NDI]), and (3) excessive water intake (psychogenic polydipsia). An osmotic diuresis may also produce polyuria and polydipsia. Uncontrolled diabetes mellitus with a high glucose load to the kidney is a common cause of an osmotic diuresis.

Hypothalamic Diabetes Insipidus. HDI is also called neurogenic, central, or cranial diabetes insipidus. It is caused by a failure of the pituitary gland to secrete normal amounts of ADH in response to osmoregulatory factors. The incidence of HDI is about 1 in 25,000 people. In 30% of patients, HDI occurs without apparent cause; other cases are associated with (1) tumors (pituitary area or metastatic), (2) trauma (surgery, head injury), (3) granulomatous disease (sarcoidosis, histiocytosis), (4) infections (meningitis, encephalitis), (5) vascular causes (infarction, aneurysm) and (6) inflammation (lymphocytic hypophysitis). During pregnancy, DI can result from an increase degradation of ADH by the placental cysteine aminopeptidase.

Nephrogenic Diabetes Insipidus. NDI results from the failure of the kidney to respond to typical or increased concentrations of ADH. In the majority of these patients, ADH is incapable of stimulating cyclic adenosine monophosphate (cAMP) formation. There are two major causes of congenital NDI, (1) a X-lined mutation in the v2 receptors, which accounts for 90% of cases and (2) an autosomal recessive mutation of the aquaporin-2 water channels. As an X-chromosome–linked disorder, the ADH receptor mutation form of NDI most commonly affects males. Females are more likely to have the aquaporin-2 water channel gene defect on chromosome 12, q12-13, which produces an autosomal recessive disease. Acquired forms of NDI may be caused by (1) metabolic disorders (hypokalemia, hypercalcemia, and amyloidosis), (2) drugs (lithium, demeclocycline, and barbiturates), and (3) renal diseases (polycystic disease and chronic renal failure). NDI may also be seen in the absence of these factors (idiopathic).

Psychogenic or Primary Polydipsia. A chronic, excessive intake of water suppresses ADH secretion and produces hypotonic polyuria. The polyuria and polydipsia are usually not as sustained as in HDI or NDI. Nocturnal polyuria also is less frequent. Psychogenic factors are most commonly associated with this disorder, but hypothalamic disease affecting the thirst center may be a cause. Drugs also affect the thirst center and result in primary polydipsia.

Diagnosis of Diabetes Inspidus[2,7-10]

In the classical full blown syndrome, the polyuria leads to hypertonic dehydration with hypernatremia and a serum osmolality >295 mOsm/kg. A random urine osmolality that exceeds 750 mOsm/kg excludes DI. The best provocative test to diagnose DI is the water deprivation test. This test should not be performed if (1) hypothyroidism, (2) hypoadrenalism, or (3) osmotic diuresis is present (e.g., uncontrolled diabetes mellitus). Patients are deprived of all fluids, until hourly urine osmolalities are constant and thus vary by <10%. At this point a sample is taken for plasma osmolality and ADH measurement. The test must be terminated if body weight falls by greater than 3%. Thereafter, ADH is administered (Desmopressin 2 μg subcutaneously), and serum and urine osmolality are then measured at 60 and 120 minutes post-ADH injection. In patients with psychogenic polydipsia urine osmolality after dehydration (usually >500 mOsm/kg) is greater than plasma osmolality and does not increase by greater than 10% after ADH. In partial cranial DI, urine osmolality is greater than plasma osmolality post dehydration but increases by >10% with ADH. In more severe cranial DI, urine osmolality increases by at least 50% post ADH. A plasma ADH concentration post dehydration will separate

TABLE 40-5 Causes of the Syndrome of Inappropriate Antidiuretic Hormone

CNS disease	Brain tumor
	Infection (e.g., meningitis, encephalitis, abscess)
	Prolonged seizure
	Psychiatric disease
	Stress (e.g., prolonged nausea)
Non-CNS tumor (e.g., leukemia)	
Pulmonary disease	Hypoxia (e.g., neonatal)
	Infection (e.g., pneumonia, emphysema)
Nonpulmonary infection (e.g., AIDS)	
Drugs	Drugs with CNS effects (anticonvulsants, antiparkinsonian drugs, antipsychotics, antipyretics, antidepressants)
	ACE inhibitors
	Antineoplastic drugs
	First-generation sulfonylureas

ACE, Angiotensin-converting enzyme; AIDS, acquired immunodeficiency syndrome; CNS, central nervous system.

cranial DI (concentrations low) from nephrogenic DI (concentrations high).

Syndrome of Inappropriate Antidiuretic Hormone[2,7-10]

SIADH refers to the autonomous, sustained production of ADH in the absence of known stimuli for its release. In this syndrome, plasma ADH concentrations are "inappropriately" increased relative to a low plasma osmolality and to a healthy or increased plasma volume. Causes of SIADH are shown in Table 40-5.[10] In SIADH a primary excess of ADH, coupled with unrestricted fluid intake, promotes increased reabsorption of free water by the kidney. The result is a decreased urine volume and an increased urine sodium concentration and urine osmolality. As a consequence of water retention, these patients become modestly volume expanded. The increase in intravascular volume causes hemodilution accompanied by dilutional hyponatremia and a low plasma osmolality. Volume expansion also decreases renal sodium reabsorption and thus further increases the urine sodium concentration.

The most common cause of hyponatremia in hospital patients is SIADH. However, other disorders cause dilutional hyponatremia and must be differentiated from SIADH. These conditions include (1) congestive heart failure, (2) renal insufficiency, (3) nephrotic syndrome, (4) liver cirrhosis, and (5) hypothyroidism. Hyponatremia may also occur from renal or extrarenal sodium losses (depletional hyponatremia) as a result of (1) vomiting, (2) diarrhea, (3) excessive sweating, (4) diuretic abuse, (5) salt-losing nephropathy, or (6) mineralocorticoid deficiency.

The clinical manifestations of hyponatremia are nonspecific. Weakness and apathy occur in mild cases, and central nervous system changes (lethargy, coma, and seizures) are present in more severe cases. No signs or symptoms are specific for SIADH. History, physical examination, and routine laboratory test results often suggest that hyponatremia is due to dilution or depletion.

Measurements of sodium and osmolality in blood and urine, combined with a clinical assessment of volume status, usually permit the appropriate differential diagnosis of hyponatremic conditions. The typical patient with SIADH has (1) hyponatremia, (2) hypoosmolar plasma (<280 mOsm/kg), (3) a urine osmolality >100 mOsm/kg, and (4) a urine sodium concentration that is inappropriately elevated (>40 mmol/L). Also both serum uric acid and blood urea nitrogen are decreased from free water retention. To sustain a diagnosis of SIADH, (1) hypothyroidism, (2) hypoadrenalism, (3) renal disease, and (4) diuretic use should be excluded. Patients with dilutional hyponatremia resulting from excess water intake have a hypotonic plasma, an unremarkable urine sodium concentration (<20 mmol/L), and a dilute urine. Patients with depletional hyponatremia caused by extrarenal sodium loss have (1) hypotonic plasma, (2) a low urine sodium concentration (usually <20 mmol/L), and (3) a urine osmolality that is greater than that of plasma. Patients with depletional hyponatremia caused by impaired renal conservation of sodium have similar results except that their urine sodium concentrations are elevated. Measurements of ADH in plasma are not usually needed to make a diagnosis of SIADH.

Analytical Methodology

Numerous immunoassays for measuring ADH in plasma or urine have been described.[10] With most plasma assays, a preliminary extraction procedure is required to concentrate the minute amount of hormone that is present in the specimen and remove nonspecific interfering substances. Given the rare indications for the measurement of plasma ADH, it is best to send the sample to a reference laboratory for a reliable determination.

Oxytocin[8]

Oxytocin is a nonapeptide that promotes uterine contractions and milk ejection and contributes to the second stage of labor in pregnancy.

Biochemistry

Oxytocin is synthesized in the hypothalamus as part of a preprohormone, along with a separate neurophysin-binding protein. These molecular complexes are packaged into secretory granules that migrate down the nerve axons for 12 to 14 hours before reaching the posterior pituitary lobe for storage. Release of oxytocin into the portal circulation occurs via calcium-dependent exocytosis on nerve cell stimulation. Oxytocin exists in plasma mainly in unbound forms.

Secretion

The primary stimulus for oxytocin release is suckling. Stimulation of tactile receptors located around the nipples of the breasts initiates an action potential that propagates along afferent nerve fibers through the spinal cord and midbrain to the hypothalamus. The cell bodies in the paraventricular

nucleus are then stimulated, resulting in the episodic release of oxytocin. Stretch receptors in the uterus and possibly in the vaginal mucosa may also initiate action potentials in afferent nerve fibers that ultimately stimulate the release of oxytocin from the neurohypophysis. Estrogens enhance the response of oxytocin to these stimuli. The influence of other parts of the brain on the release of oxytocin has been reported. For example, emotional stress inhibits lactation.

Physiological Actions

Oxytocin is present in males and females, but its physiological effects are known only for females. Oxytocin stimulates contraction of the uterine myometrium only in the estrogen-primed uterus and activates the smooth muscles associated with milk let-down with nursing. Thus the effects of oxytocin appear limited to events of parturition and lactation. Oxytocin has been used as a therapeutic agent to induce labor, but the physiological mechanism whereby it induces uterine contractions remains obscure. There is some evidence to indicate that oxytocin stimulates prostaglandin production, which may be the vehicle through which myometrial contractility is enhanced.[10] There is evidence indicating that oxytocin may affect the central nervous system and thus modulate human behavior. Progestins are believed to counteract the actions of oxytocin. There are no major syndromes associated with oxytocin excess or deficiency in humans.

Analytical Methodology

Numerous immunoassays for measuring oxytocin in plasma or urine have been described.[10] However, their routine clinical application has been limited because of a lack of physiological relevance to human reproductive disorders.

Assessment of Anterior Pituitary Lobe Reserve

Evaluation of endocrine function is an important part of the management of patients with pituitary tumors.[1,2] Objectives of testing of pituitary function in patients with pituitary tumors are the detection of hormone deficiencies before and after treatment and recognition of hormone-producing tumors.

The assessment of anterior and posterior pituitary lobe function in patients with pituitary tumors has clinical utility for two reasons. The first is to identify clinically significant hormone deficiency states caused by the tumor itself. The second is for the re-evaluation of patients after pituitary surgery or irradiation to detect hormone deficiencies that occur as a result of invasive treatment. Testing of pituitary function is usually performed under basal conditions, but also is performed under provocative conditions to bring out subtle or mild deficiencies that are observed with disorders of the adrenal gland, thyroid, or gonads. Evaluation of pituitary reserve for PRL is usually unnecessary in adult patients because deficiency of this hormone is not believed to be clinically important.

TABLE 40-6 Summary of Pituitary Gland Assessment

Hormone	Deficiency	Excess
GH	GH response to arginine, insulin tolerance tests, exercise, L-dopa, glucagon, GHRH IGF-I levels	IGF-I levels GH response to 75g oral glucose (glucose tolerance test)
PRL	PRL	PRL (serial measurements)
TSH	T_4, TSH	T_4, TSH, α-subunit, TSH response to TRH
Gonadotropins	Menstrual history, testosterone, estradiol, LH, FSH	LH, FSH, α-subunit
ACTH	Cortisol, cosyntropin test, metyrapone test, insulin tolerance test	Urine-free cortisol, overnight or low-dose dexamethasone suppression tests, loss of diurnal rhythm
ADH	Water deprivation test (serum and urine osmol), ADH levels at maximum dehydration	Serum and urine osmol, serum and urine Na^+

ADH, Antidiuretic hormone; ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; IGF-I, insulin-like growth factor I; LH, luteinizing hormone; PRL, prolactin; T_4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

The lowered detection limits of the newer two-site immunoassays for the measurement of pituitary hormones now make it possible to distinguish an abnormally low value from the lower end of the healthy reference interval. Although assessment of a particular aspect of pituitary function should also include clinical signs and symptoms of hormone deficiency and the measurement of hormones secreted by the pertinent endocrine gland (e.g., thyroxine, cortisol, testosterone, and estradiol), the newer, ultrasensitive assays for TSH, FSH, LH, and ACTH may allow for an accurate distinction of a true low result. Because of the importance of diagnosing and treating ACTH deficiency, invariably provocative testing is required as detailed earlier (e.g., cosyntropin, metyrapone, ITT). A summary of the assessment of pituitary function is in Table 40-6.

Hypothalamic-Pituitary-Adrenal Axis

A finding of a healthy value for a normal morning serum cortisol concentration is usually adequate evidence that the hypothalamic-pituitary-adrenal axis is intact and functioning properly. On occasion, however, the cosyntropin (a potent analogue of ACTH) stimulation test is used when the morning cortisol results are low or equivocal or when there is a strong clinical suspicion of adrenal insufficiency. This is provocative test is performed by obtaining a baseline blood specimen for cortisol followed by the intravenous (IV) administration of 250 μg of cosyntropin. Specimens for cortisol are then obtained at 30 and 60 minutes after IV administration of the synthetic ACTH. A peak value for plasma cortisol of 20 μg/dL or greater is considered a healthy

response to ACTH administration. Other useful tests to assess the adrenal reserve include the metyrapone test and the insulin tolerance test.

Hypothalamic-Pituitary-Thyroid Axis

When both the serum-free thyroxine concentration (FT_4) and the ultrasensitive TSH result are within their healthy reference intervals, the hypothalamic-pituitary-thyroid axis is assumed to be intact. In patients with a history of pituitary disease and secondary hypothyroidism, the serum TSH concentration is frequently within a healthy reference interval. Thus in this situation, an FT_4 concentration is the superior test to gauge normality of the hypothalamic-pituitary-thyroid axis. Lowering of the limit of quantification with third-generation TSH tests may allow for the detection of abnormalities of the hypothalamic-pituitary-thyroid axis much earlier in the disease process.

Hypothalamic-Pituitary-Gonadal Axis

History and physical examination are extremely helpful in evaluating the status of the hypothalamic-pituitary-gonadal axis; particularly in women during their reproductive years. The finding of a physiological menstrual cycle is usually indicative of an intact hypothalamic-pituitary-gonadal axis in reproductive-age women. Baseline laboratory assessment for hypothalamic-pituitary-gonadal dysregulation should include measurement of serum (1) LH, (2) FSH and (3) sex steroids (estradiol in females and testosterone in males). Provocative testing of this axis with GnRH and measurements of FSH and LH is useful in selected patients (hypogonadotropic, hypogonadism). These tests, however, are known to be unreliable in differentiating pituitary disorders from hypothalamic dysfunction; thus the physician is usually dependent on an accurate determination of LH, FSH, and sex steroids along with clinical judgment.

Review Questions

1. A function of prolactin (PRL) is to
   a. regulate respiration.
   b. stimulate uterine contraction.
   c. initiate and maintain lactation.
   d. stimulate protein synthesis.
2. A peptide hormone that modifies the body's response to stress by its action on the adrenal gland is
   a. growth hormone (GH).
   b. adrenocorticotropic hormone (ACTH).
   c. antidiuretic hormone (ADH).
   d. follicle-stimulating hormone (FSH).
3. Regulation of electrolytes and water balance is controlled in part by the renal system. Which hormone synthesized by the brain affects water balance and is regulated by the osmolality of blood?
   a. Aldosterone
   b. ACTH
   c. ADH
   d. Oxytocin
4. The anterior pituitary hormone that regulates release of thyroid hormone from the thyroid gland is
   a. TSH.
   b. ACTH.
   c. ADH.
   d. FSH.
5. An example of a hormone synthesized in the adenohypophysis would be
   a. insulin.
   b. ADH.
   c. GH.
   d. erythropoietin.
6. A second function of vasopressin (ADH) other than body water regulation is
   a. sperm growth.
   b. suppression of growth hormone (GH).
   c. inducing estrogen secretion from the ovaries.
   d. elevation of blood pressure.
7. In men, FSH functions to
   a. induce spermatogenesis.
   b. induce production of testosterone.
   c. enhance muscle mass.
   d. induce production of androstenedione.
8. If FSH and LH were decreased in a man, what is the name of the hypothalamic releasing hormone that might be involved?
   a. Thyrotropin-releasing hormone (TRH)
   b. Gonadotropin-releasing hormone (GnRH)
   c. Sheehan hormone
   d. Growth hormone-releasing hormone (GHRH)
9. Oxytocin is synthesized in the
   a. adenohypophysis.
   b. neurohypophysis.
   c. uterus.
   d. hypothalamus.
10. Regarding growth hormone (GH), hypersecretion due to a pituitary tumor would cause which one of the following disorders in an adult?
    a. Gigantism
    b. Dwarfism
    c. Acromegaly
    d. There would be no observable effect.

CHAPTER 41

Disorders of the Adrenal Cortex*

Roger L. Bertholf, Ph.D., Ishwarlal Jialal, M.D., Ph.D., and William E. Winter, M.D.

Objectives

1. Define the following terms:
   - Androgen
   - Angiotensin
   - Glucocorticoid
   - Incidentaloma
   - Mineralocorticoid
   - Renin
   - Steroid hormone
2. State how adrenal cortical steroid hormones are synthesized from cholesterol.
3. Describe the anatomy and physiology of the adrenal cortex.
4. For each of the following hormones, state the function, regulation (including anterior pituitary or hypothalamic hormones involved, if any), site of synthesis, circulatory transport, metabolism, and urinary metabolite:
   - Cortisol
   - Aldosterone
   - Androstenedione
   - Dehydroepiandrosterone (DHEA)
5. Describe the following dynamic test of adrenal function, including reasons for performing, protocol followed, and interpretation of results:
   - Adrenocorticotropic hormone (ACTH) (cosyntropin) stimulation
   - Corticotropin-releasing hormone (CRH) stimulation
   - Insulin-induced hypoglycemia stimulation
   - Metyrapone stimulation
   - Dexamethasone suppression
   - Mineralocorticoid stimulation/suppression
6. Discuss the following adrenocortical disorders including hormone(s) involved, symptoms, primary/secondary/tertiary causes, and screening and suppression/stimulation tests used for assessment:
   - Addison disease
   - Conn syndrome
   - Cushing syndrome/Cushing disease
   - Congenital adrenal hyperplasia (CAH)
7. Summarize the circadian variation of cortisol and aldosterone; list the pre-analytical variables that must be considered when assessing aldosterone.
8. Diagram the renin-angiotensin-aldosterone axis.
9. List and describe the laboratory analyses used to assess adrenocortical function, including methodology, specimen type, collection, and storage requirements for the following analytes:
   - Cortisol (serum and urine)
   - Urinary free cortisol (UFC)
   - Aldosterone
   - Renin
   - Angiotensin
   - 17-hydroxyprogesterone
10. Assess and solve case studies related to disorders of the adrenal cortex and their laboratory assessment.

Key Words and Definitions

Addison disease Deficiency of adrenocortical hormones secondary to disease of the adrenal glands; characterized by hypotension, and a bronzelike hyperpigmentation of the skin. Also called primary hypoadrenalism to distinguish from secondary hypoadrenalism (deficiency of pituitary adrenocorticotropic hormone).

Adrenal androgens A class of sex hormones that produce masculinization.

Adrenocorticotropic hormone (ACTH) A 39–amino-acid anterior pituitary hormone, that acts primarily on the adrenal cortex, stimulating its growth and the secretion of corticosteroids. Also called corticotrophin.

Aldosterone The major mineralocorticoid steroid hormone secreted by the adrenal cortex.

*The authors gratefully acknowledge the contribution of Ronald J. Whitley and Laurence M. Demers to the chapter in the previous edition, on which portions of this chapter are based.

Key Words and Definitions—cont'd

Androstenedione An androgenic steroid produced by the testis, adrenal cortex, and ovary.

Angiotensin II A small (eight-amino-acid) polypeptide hormone; among its functions, it stimulates release of aldosterone and other hormones, constricts blood vessels and controls arterial pressure.

Angiotensin-converting enzyme (ACE) Enzyme that catalyzes the removal of two amino acids from angiotensin I, thus converting it to the active hormone angiotensin II.

Angiotensin-converting enzyme inhibitors Pharmaceuticals that are competitive inhibitors of the angiotensin-converting enzyme. They are used in the treatment of hypertension.

Angiotensinogen A serum globulin formed by the liver that is cleaved by renin to produce angiotensin I.

Conn syndrome A condition of primary aldosteronism arising from oversecretion of aldosterone by an adrenal cortical adenoma.

Congenital adrenal hyperplasia (CAH) A group of inherited disorders in which deficiencies of enzymes that catalyze the biosynthesis of cortisol result in compensatory hypersecretion of corticotropin and subsequent adrenal hyperplasia as well as excessive androgen production.

Cortisol The major adrenal glucocorticoid synthesized in the zone fasciculata (and, to a lesser extent, the zona reticularis) of the adrenal cortex.

Cushing syndrome A condition characterized by an increased concentration of adrenal glucocorticoid hormone in the bloodstream and its effects on the body.

Dehydroepiandrosterone (DHEA) A weak androgenic steroid secreted by the adrenal cortex. It is the major androgen precursor in females.

Glucocorticoids Any of the group of C21 steroids produced by the adrenal cortex that regulate carbohydrate, fat, and protein metabolism.

Hyperaldosteronism A Condition in which the adrenal gland secretes and releases increased quantities of aldosterone.

Hypovolemia A condition characterized by an abnormal decrease in the volume of circulating blood in the body.

Multiple endocrine neoplasia A group of genetic disorders characterized by hyperplasia and hyperfunction of two or more components of the endocrine system.
